Soko-Banja, N.E. of Alexinatz, Servia. 1878, October 13, about 2 P.M. (*Verhandl. der k. geolog. Reichsanstalt*, 1877, 328; *Deut. Chem. Ges. Ber.* 1878, xi. 96).—Two explosions, like salvoes of artillery, were heard, accompanied by a brilliant display of light, such as attends the bursting of shells. This noise lasted some time, and was followed by a sound resembling the firing of musketry. Soon after the explosions a number of meteorites fell to the ground, over an area $1\frac{1}{2}$ mile in length and half a mile in breadth. The total weight of material which fell amounted to 80 kilograms.

All the meteorites are covered with a black rough vitreous crust 0·5 mm. in thickness, and exhibiting numerous depressions; the interior consists of spherules of various sizes, some brown, some yellow, cemented together by an ash-grey material, and presents the appearance of a trachytic lava. The sp. gr. of the stone is 3·502. The meteorite consists of:

	I	II
Nickel-iron	3·8	3·7
Silicates	96·2	96·3
	<hr/> 100·0	<hr/> 100·0

A fragment of nickel-iron was found to consist of:

$$\text{Iron} = 78\cdot13; \text{Nickel} = 21\cdot70; \text{Copper} = 0\cdot17 \quad = 100\cdot00$$

This is a high percentage of nickel; the ratio of the metals is Fe : Ni = 4 : 1. The iron sulphide is monosulphide containing 63·84 per cent. of iron; theory requires 63·64 per cent. The portion acted upon by acid (I) and withstanding that reagent (II) consisted of:

	I	II
Silicic acid	32·24	56·66
Iron protoxide	28·41	23·55
Manganese oxide	0·20	0·003
Magnesia	30·53	20·84
Soda	0·43	—
Potash	0·09	—
Iron	0·70	—
Nickel	0·17	—
Iron monosulphide = 6·78	{ Fe = 4·31 S = 2·47	—
Chromite	—	0·11
Phosphorus	—	trace
	<hr/> 99·55	<hr/> 101·163

Neither alumina nor lime appears to be present, and felspathic and augitic constituents are consequently absent. The oxygen present in the two silicates amounts to—

	I	II
Silicic acid	17·19	30·22
Iron protoxide	6·31	5·23
Magnesia	12·21	9·33
	<hr/> = 18·52	<hr/> = 14·56

The soluble portion is therefore an olivine having approximately the composition

represented by the formula $2(\frac{2}{3}\text{MgO}, \frac{1}{3}\text{FeO}), \text{SiO}_2$; and the insoluble portion a bronzite of the form $(\frac{2}{3}\text{MgO}, \frac{1}{3}\text{FeO}), \text{SiO}_2$; the ratio of iron oxide to magnesia being the same in both silicates.

Meteorite from Tieschitz, Moravia. July 15, 1878; 1.45 P.M. (*Wien. Akad. Denkschriften. Math-naturwissenschaft. Classe xxxix. Nov. 21, 1878*).—A stone fell at this date, with the usual accompanying noise, within 100 paces of some people whose attention was directed to a small dark cloud from which a peculiar and ever increasing noise proceeded. This cloud was suddenly seen to become incandescent, but in no very high degree, and the noise became still louder, when a body was seen to fall from the cloud. The stone was warm when found. The noise was heard in the neighbourhood two miles around. The stone was secured, and was sent on the 19th to the Museum of the Technical High School of Brünn. The meteor appears to have passed over Daubrawic and Sloup, and the path to have been through Azimuth 108° altitude 40° , and the apparent radiant in R A 68° , declination 40° .

This stone only was found, and all search for others was in vain. The stone weighs 27.5 kilog., and has the form of an irregular pyramid with an almost rectangular base. The entire surface is covered in places with a black crust, of about the thickness of that found on the stones which fell at Pultusk; on the large convex side, which is called the 'breast side,' it is much thinner, and exhibits a radiated character. On the back it is thicker and rougher, and without a trace of the radiated structure. The 'breast-side' is free from all great depressions, while the others show them, due probably in part to the original form of the stone, partly to the action of currents of air on the surface when melted. The freshly broken surface of the stone is dull, ash-grey in hue, darker than the Pultusk stone, the texture finer and more sharply marked than in the case of most of the chondrites. It exhibits many small dull grey or dark coloured chondra, and splinters and fragments of the same kind, many larger dull-grey chondra, also white small chondra, and white fragments, the latter much fewer than the former. Between them are an ash-grey earthy matrix and very few yellow metallic lustrous particles. Most of the dark chondra are less than 1 mm. in diameter; those which have a diameter of 1 mm. are fewer, and there are occasional chondra which exceed 1 mm. in size. The largest one had a diameter of 5 mm.

The microscopic examination of the sections of this meteorite displayed many curious features, and appeared to confirm the views already put forth by Tschermak regarding the probable influences which have taken part in the form which the chondra and other enclosures take. Some chondra present an appearance which has not hitherto been observed. They have round depressions, which point to a plasticity of the chondra during contact, as if the spherules had acquired their shape during the act of rubbing which formed the splintered fragments. Others, again, have projections of a rounded form or an almost pointed end. These chondra are the result of volcanic eruption or explosion.

Olivine.—Both in the matrix and in chondra well-developed crystals of olivine are to be met with. They have the same form as the olivine in basalt. Many of the chondra consist of individual crystals. Many crystals have cavities, enclosing black angular grains, or a black impregnation of the crust, or black, slightly translucent spherules or enclosures of 'glass;' some exhibit a most distinct surface of the enclosed material.

Bronzite.—Barred and fibrous individuals of a brown colour are regarded as bronzite. Some of the barred chondra, shown in the plate accompanying the paper by Makowsky and Tschermak, are very perfectly developed and are very curious. Some have a dark border, others a light rim. In these chondra, also, the enclosed material already referred to is met with.

Enstatite.—Many of the chondra of this mineral are distinguished by their marked foliated structure. The enclosed 'glass' is also found in them. Many spherules, and fragments of spherules, of a crystallised mixture of bronzite and olivine, and of enstatite and olivine, were noticed; none, however, of a crystallised mixture of enstatite and bronzite; and it appears, therefore, as if the meteoric tuff originated from two sorts of stony mixtures.

Augite.—A few small chondra, with a compact pale-coloured crust, have a texture and colour which differ from all the foregoing. The entire spherule is shown by polarised light to be an individual; the crust is almost colourless, the interior has a brownish-green hue. Their reaction with light points to their being augite.

Magnetic Pyrites and Nickel-iron.—Magnetic pyrites occurs as grains enclosed in the other chondra and splinters of chondra as well as free in the matrix. The nickel-iron is, for the most part, in the form of irregular particles, with a hackly surface in

the matrix. In some of the spherules, both magnetic pyrites and nickel-iron have a distinct concentric arrangement.

The stone of Tieschitz belongs to that division of the chondritic meteorites which Tschermak some years ago classified as remarkable for 'many brown, finely-fibrous chondra.' The sp. gr. of the stone is 3.59. It contains about 85 per cent. of non-metallic minerals. No trace of any mineral resembling a felspar could be detected. The percentage composition of the stone is as follows :

	Olivine	Bronzite and Enstatite	Augite	Magnetic Pyrites	Nickel iron	Totals (calc.)	Totals (anal.)
SiO ₂ . . .	13.99	18.84	7.90	—	—	40.73	40.23
Al ₂ O ₃ . . .	—	—	2.09	—	—	2.09	1.93
FeO . . .	13.86	5.47	0.73	—	—	20.06	19.89
MgO . . .	10.94	9.53	0.61	—	—	21.08	20.55
CaO . . .	—	—	1.42	—	—	1.42	1.54

100.00

Esterville, Emmet County, Iowa. 1879, May 10, 5 P.M. (*Amer. Jour. Sc.* xviii. 77).—A meteor exploded over this spot, and was seen to fall in full daylight. One fragment, weighing 500 lbs., fell on railroad land, and was dug up from a depth of 14½ feet in a stiff clay soil. Another portion, weighing 170 lbs., fell at a distance of two miles from the first. Many smaller pieces, of a few ounces or pounds weight, were scattered in the vicinity. The smaller mass fell upon a dry knoll, and penetrated the earth vertically to a depth of 4½ feet. The fall was accompanied by a noise described as a continuous roll of thunder accompanied by a crackling sound. The stone has been placed in the hands of Prof. C. W. Hall, of the Minneapolis University, for complete investigation. The preliminary examination points to the metallic portion consisting of an alloy of iron, nickel and tin. Full half the mass consists of stony matter, which appears in dark green crystalline masses imbedded in a light grey matrix. When the whole is powdered a violent reaction ensues on addition of hydrochloric acid, which is increased by boiling. The boiling acid appears to dissolve all but the grey matrix. Some of the crystalline masses are two inches thick, and exhibit distinct monoclinic cleavage. Under the microscope, in thin sections, olivine and a triclinic felspar appear to be imbedded in a matrix of pyroxene. The iron shows the Wiedmannstättian figures very finely.

W. F.

On the Gases occluded in Meteorites (CO, CO₂, CH₄, H, N), see A. W. Wright (*Sill. Am. J.* [3], ix. 459; x. 44; xi. 253; xii. 165; *Jahresb. f. Chem.* 1875, 1312, 1315; 1876, 1312).

METHACRYLIC ACID, C⁴H⁶O² = H²C=C(CH₃).CO²H, or, according to Fittig, =CH—CH(CH₃)—CO²H (*Liebig's Annalen*, clxxxviii. 95). This modification of crotonic acid, which Frankland and Duppa first obtained by acting on ethylic dimethoxalate with phosphorus trichloride, and saponifying the resulting ethylic ether with potash (vi. 825), is also produced by dissolving citraconic acid or anhydride, or mesaconic acid, in fuming hydrobromic acid—or by heating citraconic anhydride or mesaconic acid with strong hydrochloric acid—and boiling the resulting citraconic, bromo-, or chloro-pyrotartaric acid with concentrated soda-ley, e.g.:

This decomposition of citrabromo-pyrotartaric acid affords the means of preparing methacrylic acid in large quantity (vi. 511–587). See also Fittig (*Liebig's Annalen*, clxxxviii. 42).

Methacrylic acid appears to occur in small quantity in the portion of the product of saponification of Roman cumin-oil (consisting chiefly of isobutyric acid) which distils at 160° (Fittig, *Deut. Chem. Ges. Ber.* x. 513).

On the conversion of Methacrylic Acid into Isobutyric Acid by the action of Sodium-amalgam, and into Iodisobutyric Acid by solution in fuming Hydriodic Acid, see p. 587 of this volume.

Methacrylic acid dissolves easily also in fuming *hydrobromic acid*, even at 0° , the solution, after some time, depositing a crystallised addition-product, and almost at the same time a thick oil, which is formed by polymerisation, and solidifies over sulphuric acid and potassium hydrate to an amorphous resinous mass (L. Paul, *Ber.* ix. 122).

METHANE, CH_4 . This hydrocarbon is formed when a mixture of carbon oxide and hydrogen is exposed to the action of electricity in an induction-tube: $\text{CO} + 3\text{H}^2 = \text{H}^2\text{O} + \text{CH}_4$ (Brodie, *Proc. Roy. Soc.* xxi. 245); also by the action of zinc-powder on chloroform dissolved in aqueous alcohol: $2\text{CHCl}^3 + 3\text{H}^2\text{O} + 3\text{Zn} = 3\text{ZnO} + 3\text{ZnCl}^2 + 2\text{CH}_4$ (Sabanejeff, *Ber.* ix. 1810).

When a mixture of methane and *air* is passed over a platinum spiral heated to redness by an electric current, the methane is oxidised to formic acid (Coquillion, *Compt. rend.* lxxvii. 444).

Methane, subjected to the influence of the *silent electric discharge*, yields a small quantity of acetylene, together with free hydrogen and resinous hydrocarbons, an odour of turpentine-oil being also evolved (see *ELECTRICITY*, p. 728). Under the same influence, methane combines with *nitrogen*, forming a solid compound (Berthelot, *Compt. rend.* lxxxiii. 1283).

METHANTHRENE, $\text{C}^{15}\text{H}^{12}$ (A. C. Oudemans, *Junr., Deut. Chem. Ges. Ber.* vi. 1125). A hydrocarbon, metameric with methyl-anthracene (p. 94), obtained together with other products, by distilling *podocarpic acid* (*q.v.*). To separate it, the crude distillate is dissolved in boiling alcohol; the solution is filtered; the mass which separates on cooling is sublimed at 100° – 130° ; and the sublimate is purified by crystallisation from alcohol and resublimation.

Methanthrene crystallises in white laminae, melts at 117° , boils above 300° , and exhibits a violet fluorescence like that of anthracene. It dissolves easily in boiling, less easily in cold alcohol, very easily in carbon sulphide and glacial acetic acid. When heated it exhales a disagreeable peculiar odour, like that of melted asphalt. It forms ill-defined derivatives with bromine and nitric acid; when boiled with potassium dichromate and dilute sulphuric acid, it yields an aromatic acid, probably $\text{C}^{15}\text{H}^{10}\text{O}^2$.

Methanthrene-picric acid, $\text{C}^{15}\text{H}^{12}.\text{C}^6\text{H}^3(\text{NO}^2)^3\text{O}$, is formed by dissolving 4 pts. methanthrene and rather more than 5 pts. picric acid in a small quantity of boiling alcohol, and separates on cooling in very slender orange-coloured needles, which, in the moist state, have the colour of sublimed alizarin, but incline to brown-red when dry. It melts at 117° .

Methanthrene-quinone or *Methanthraquinone*, $\text{C}^{15}\text{H}^{10}\text{O}^2$, is formed on adding chromic acid to a warm solution of methanthrene in glacial acetic acid till the liquid assumes a yellow-green colour, and separates on addition of water in yellow-red flocks. By recrystallisation from alcohol and washing with ether, it is obtained in microscopic rhombic laminae. It melts at 187° , distils without alteration at a higher temperature, is insoluble in water, sparingly soluble in ether, freely in alcohol. By an aqueous solution of sulphurous acid, it is converted into hydromethanthrenequinone or methanthrene-quinol.

METHAZONIC ACID, $\text{C}^2\text{H}^4\text{N}^2\text{O}^3$. The sodium salt of this acid is obtained by acting on nitromethane with alcoholic soda-ley, and heating the resulting crystalline pulp on the water-bath, whereupon it separates into two liquid layers, the upper consisting mainly of alcohol and sodium-compounds soluble therein, the lower of sodium methazonate. The latter may be purified by decanting the upper layer, leaving the remaining liquid to cool, dissolving the crystals which separate in water, and precipitating with alcohol. The sodium salt thus obtained is permanent in the air (unlike sodium-nitromethane), explodes when heated, and forms characteristically coloured precipitates with solutions of the heavy metals, *e.g.* silver, mercury, copper, and lead (P. Fries, *Deut. Chem. Ges. Ber.* ix. 324).

According to Lecco (*ibid.* 705), the sodium salt and the acid are best prepared by dissolving 4 grams of caustic soda in hot alcohol and adding 5 grams of nitromethane drop by drop. The liquid is then boiled for a short time, and after cooling, the salt which has separated is filtered off, dissolved in water, and decomposed by dilute sulphuric acid. On shaking the liquid with ether, the methazonic acid is dissolved; and the solution is dried over anhydrous sodium sulphate and evaporated over sulphuric acid. A yellow syrup is then left behind, which, on standing, is converted into large crystals, mixed with a thick reddish syrup which colours the skin deep red. For purification, the crystals are pressed between paper and recrystallised from warm benzene.

Methazonic acid is isomeric with ethylnitrolic acid, and is an unstable body, which

1302 METHENYLAMIDOPHENOL—METHYL ALCOHOL.

decomposes spontaneously and assumes a red colour. It is readily soluble in water, alcohol, and ether, more sparingly in benzene, and insoluble in petroleum-naphtha. It softens and liquefies at 58° – 60° , and explodes at a higher temperature.

The sodium salt crystallises from dilute alcohol in long prisms, and is more explosive than the acid. The methazonates of the heavy metals are obtained by precipitation. The formation of methazonic acid is explained by the equation:

It is perhaps a kind of anhydride of nitromethane; $\begin{matrix} \text{CH}^2\text{NO} \\ \text{CH}^2\text{NO} \end{matrix} \bigg\} \text{O}.$

Azo-compounds of Methazonic Acid (Kimich, *Deut. Chem. Ges. Ber.* x. 140–144). *Azophenyl-methazonic acid*, $\text{C}^6\text{H}^3\text{N}^4\text{O}^3 = \text{C}^6\text{H}^3\text{N}^2\text{.C}^6\text{H}^3\text{N}^2\text{O}^3$, is precipitated in orange-red flocks on adding a solution of azodibenzene nitrate to an aqueous solution of sodium methazonate. Its formation is expressed by the equation—

It crystallises from alcohol or ether in fine orange-red needles, which melt with decomposition at 164° . It is nearly insoluble in water, but easily soluble in alcohol, ether, and chloroform. Alkalis dissolve it with deep-red, strong sulphuric acid with yellow colour.

The aqueous solution of the sodium salt, $\text{C}^6\text{H}^3\text{N}^4\text{O}^3\text{Na}^2 + 2\text{H}^2\text{O}$, gives coloured precipitates with copper, cadmium, zinc, mercury, and silver salts. The barium salt, $\text{C}^6\text{H}^3\text{N}^4\text{O}^3\text{Ba} + \text{H}^2\text{O}$, is a purple-red powder.

Azoparatolylmethazonic acid, $\text{CH}^3\text{.C}^6\text{H}^4\text{.N}^2\text{.C}^6\text{H}^3\text{N}^2\text{O}^3$, obtained in the same manner as the preceding compound, forms orange-coloured needles, which melt with decomposition at 154° . It dissolves sparingly in water, very easily in alcohol and ether.

METHENYLAMIDOPHENOL, $\text{C}^6\text{H}^4\text{N} \begin{smallmatrix} \diagup \text{O} \diagdown \end{smallmatrix} \text{CH}$, prepared by heating orthamidophenol with formic acid, boils at 182.5° , and after being freed from formic acid by treatment with potassium carbonate, solidifies in transparent shining crystals which melt at 30.5° , and give the vapour-density required by the formula. It is very slowly attacked by air and water. Heated with strong hydrochloric acid, it is decomposed, with formation of orthamidophenol hydrochloride (Ladenburg, *Deut. Chem. Ges. Ber.* x. 1123).

METHENYL-DIPHENYLDIAMINE, $\text{C}^{12}\text{H}^{12}\text{N}^2 = \text{C}^6\text{H}^5\text{N}=\text{CH.NH.C}^6\text{H}^5$. *Formyl-diphenyldiamine* (W. Weith, *Deut. Chem. Ges. Ber.* ix. 1214).—This base, which Hofmann obtained by the action of chloroform on aniline (iv. 459), is also formed by direct combination when aniline is heated with phenyl cyanide (phenyl-carbamine):

Another mode of producing it is to heat aniline with formic acid in a reflux-apparatus.

Methenyl-diphenyldiamine crystallises in long colourless needles (Hofmann obtained it only as a crystalline powder or in small scales), melts at 135° – 136° , and dissolves very easily in alcohol and benzene. The crude product obtained by the action of chloroform on aniline melts at 127° , but when repeatedly crystallised from alcohol and ligroin, it yields needles agreeing exactly with those above described. When methenyl-diphenyldiamine is subjected to prolonged heating in a reflux-apparatus, a small portion of it is resolved into aniline and benzene, but the greater part remains unaltered.

METHIONIC ACID. See METHYLENE-DISULPHONIC ACID, $\text{CH}^2(\text{SO}^3\text{H})^2$ (p. 1313).

METHYL ALCOHOL, $\text{CH}^3\text{.OH}$. *Occurrence.*—This alcohol is almost always found in commercial acetone. Kasantzoff (*Deut. Chem. Ges. Ber.* viii. 435) found it in one sample to the amount of 20 per cent.

Formation.—According to Lieben a. Rossi, and Linnemann a. von Zotta, the distillate obtained by heating calcium formate contains formic aldehyde, which, when treated with sodium-amalgam, yields methyl alcohol (vii. 533). According to Lieben a. Paternò however (*Gazz. chim. ital.* 1873, 290), and Friedel a. Silva (*Compt. rend.* lxxvi. 1545), the distillate in question contains methyl alcohol ready-formed.

Preparation.—Erlenmeyer finds that the pure methyl oxalate required for the preparation of the alcohol may be very easily obtained by dissolving oxalic acid dehydrated at 100° in boiling methyl alcohol, leaving the solution to cool, draining the

resulting crystals on a vacuum filter, and washing them with cold water, till the liquid which runs through no longer exhibits the iodoform reaction. The ether thus purified is decomposed by prolonged boiling with water (a portion remained unaltered even after three hours' boiling), and the methyl alcohol is distilled off (*N. Rep. Pharm.* xxiii. 624).

Reactions.—Methyl alcohol is oxidised by *electrolytic oxygen*, with evolution of carbon monoxide, together with a small quantity of carbon dioxide, and formation of a liquid containing formate and acetate of methyl (A. Renard, *Compt. rend.* lxxx. 236).

Methyl alcohol, distilled with *sulphuric anhydride* and a large quantity of strong sulphuric acid, is converted into oxymethanesulphonic or methyl-isethionic acid, $\text{CH}(\text{OH})(\text{SO}^*\text{H})^2$ (*q. v.*) (Max Müller, *Ber.* vi. 1031).

METHYL CHLORIDE, CH^*Cl (C. Vincent, *J. Pharm.* [4], xxx. 132). This compound is now prepared in France on a large scale by heating trimethylamine hydrochloride to 260° , whereby it is resolved into ammonia, free trimethylamine and methyl chloride:

By bubbling the vapours through hydrochloric acid, the alkaline gases are retained and the gaseous methyl chloride passes on, to be purified by washing with dilute caustic soda and drying with strong sulphuric acid; it is then collected in a gas-holder, from which it is pumped into strong receivers and liquefied. The tension of its vapour not being high and not increasing very rapidly with the temperature (2.48 atm. at 0° , and 7.50 atm. at 35°), the liquefaction is easily effected, and the transport of the liquid can be carried on without danger.

The liquid methyl chloride thus obtained is a most powerful refrigerating agent. When allowed to escape from the receiver into an open vessel, it begins to boil, and in a few moments the temperature of the liquid is lowered by the ebullition below -23° , the boiling-point of the chloride. It then remains for a length of time in a quiescent state, and may be used as a freezing agent. By increasing the rapidity of the evaporation by means of a current of air blown through the liquid, or better by placing the liquid in connection with a good air-pump, its temperature can in a few moments be reduced to -55° , and large masses of mercury easily solidified.

The construction of a small freezing machine employed by M. Vincent is shown in fig. 49. It consists of a double-cased copper vessel, E E, between the two casings of which the methyl chloride A is introduced. The central space M is filled with some liquid such as alcohol, incapable of solidification. The methyl chloride is allowed to enter from the cylindrical reservoir by the screw tap B, and the screw S left open to permit of the escape of the gas. As soon as the whole mass of liquid has been reduced to a temperature of -23° , ebullition ceases, the screw S may be replaced, and if a temperature lower than -23° be required, the tube B placed in connection with a good air-pump. By this simple means a litre of alcohol can be kept for several hours at temperatures either of -23° or -55° , and thus a large number of experiments can be performed, for which hitherto the expensive liquid nitrous oxide or solid carbonic acid was required.

M. Vincent has recently constructed a much larger and more perfect and continuous form of freezing machine, in which by means of an air-pump and a forcing-pump the chloride of methyl is evaporated in the freezing machine and again condensed in the cylinders. This enlarged form of apparatus will probably be found more convenient and economical than the ether and sulphurous acid freezing machines now in use, as it can be simply constructed, the vapour and liquid do not attack metal and are not poisonous, and the frigorific effects produced are extremely energetic.

Another and perhaps more important application of methyl chloride is to the manufacture of the blue, green, and violet dyes produced by replacing part of the

FIG. 49.

hydrogen in rosaniline by methyl. This substitution has hitherto been effected chiefly by the use of the expensive iodide of methyl: the chloride will afford a much more economical method of obtaining them (see ROSANILINE).

The trimethylamine from which the methyl chloride is prepared in the manner above described, is obtained from the spent liquors (*vinasses*) of the stills in which the molasses of beet-juice are distilled for the production of alcohol (see METHYLAMINES).

METHYL OXIDE, $(\text{CH}^3)_2\text{O}$, is formed, together with the chlorides of tri- and tetra-methylammonium, by heating sal-ammoniac with excess of methyl alcohol (Weith, *Deut. Chem. Ges. Ber.* viii. 458).

Preparation.—Erlenmeyer & Kriechhauer (*Ber.* vii. 699) prepare this compound by gradually heating 13 pts. methyl alcohol and 20 pts. sulphuric acid to 140° in a reflux apparatus, washing the evolved gas with soda-ley, and passing it into sulphuric acid, which absorbs 600 vols. of it, forming the compound $\text{SO}(\text{OH})\cdot(\text{OCH}^3)_2$, which may be kept without alteration, and gives off methyl oxide when 1 pt. of it is added by drop to 1 pt. of water.

For preparation on the large scale, a mixture (34°Bm.) of 1 pt. sulphuric acid and rather more than 1 pt. anhydrous wood-spirit is heated to 125° – 128° , as long as methyl oxide continues to be evolved, care being taken that the temperature does not rise above 130° ; it is then left to cool, and to the remaining liquid, marking 45°Bm. , more wood-spirit is added sufficient to lower the density to 34°Bm. ; and by thus alternately heating, cooling, adding fresh wood-spirit, and again heating, &c., as in the preparation of ethyl oxide, large quantities of methyl alcohol may be etherified with only a small quantity of acid. The methyl ether, which is given off as vapour, is freed from carbon dioxide and sulphur dioxide by means of caustic potash, caustic soda, or sugar-lime, and from water by calcium chloride, and finally condensed (Tallier, *Arch. Pharm.* [3], x. 57).

On the Friction-coefficient of Methyl-oxide, see GASES (p. 851 of this volume). On its Imperfect Combustion, p. 436.

METHYL SELENIDE or **SELENMETHYL**, $(\text{CH}^3)_2\text{Se}$ (C. L. Jackson, *Liebig's Annalen*, clxxix. 1). To prepare this compound, phosphorus pentaselenide (obtained by heating an intimate mixture of 5 at. selenium with rather more than 2 at. phosphorus) is coarsely pulverised and drenched in a retort with a mixture of strong soda-ley and a solution of potassium methyl-sulphate. On gently heating the mixture, it froths up, and yields a distillate of water and a yellow liquid, which may be separated from the water by a tap-funnel, and purified by fractional distillation; it then yields, as chief product, methyl monoselenide. If a stronger heat be employed in the preparation, a few drops of a yellow, less volatile liquid pass over, probably consisting of the diselenide, $(\text{CH}^3)_2\text{Se}_2$, and identical with the product which Wöhler & Dean obtained by distilling barium methylsulphate with potassium selenide (iii. 990).

Methyl monoselenide is a colourless, strongly refracting liquid, having a very offensive odour and boiling at 32° . It sinks in water; is decomposed, with separation of selenium, when boiled therewith, and mixes with alcohol and ether. It unites with acid radicles, forming a series of compounds analogous to those of benzyl selenide (p. 316).

Selenmethyl Nitrate, either $(\text{CH}^3)_2\text{Se}(\text{NO}^3)_2$, $(\text{CH}^3)_2\text{SeO}$ or $(\text{CH}^3)_2\text{Se} \begin{smallmatrix} \text{NO}^3 \\ \text{OH} \end{smallmatrix}$, is formed

by adding selenmethyl to strong nitric acid in a vessel which is kept cool, and crystallises, on evaporating the solution over the water-bath, in long colourless prisms. It melts at 90.5° , volatilises below 100° , dissolves easily in water, sparingly in alcohol, and is insoluble in ether. The *dichloride*, $(\text{CH}^3)_2\text{SeCl}_2$, precipitated from a strong solution of the nitrate by hydrochloric acid, forms white nacreous laminae, melting at 59.5° , very soluble in alcohol, less soluble in ether, sparingly in water. The *di-bromide*, $(\text{CH}^3)_2\text{SeBr}_2$ prepared in like manner with hydrobromic acid, and purified by washing the precipitate with cold water, and once crystallising it from alcohol, forms broad sulphur-yellow nacreous laminae having a very unpleasant odour. It melts and decomposes at 82° , and is partially decomposed by boiling with alcohol, in which it is but slightly soluble; it is also sparingly soluble in water, and insoluble in ether. The same compound is formed directly by direct combination of selenmethyl with bromine. The *di-iodide*, precipitated from the nitrate by potassium iodide, is a brick-red, easily decomposable powder, insoluble in water, easily soluble in alcohol and in ether. The *platinochloride*, $[(\text{CH}^3)_2\text{Se}]_2\text{PtCl}_4$, obtained by mixing the monoselenide with solution of platonic chloride, and boiling the resulting pale-red precipitate with water, crystallises in lemon-yellow laminae, nearly insoluble in water, quite insoluble in ether, sparingly soluble in hot alcohol. When heated, it blackens and gives off methyl monoselenide.

METHYL SULPHIDE, $(\text{CH}_3)_2\text{S}$. On the reaction of this compound with benzyl sulphide and methylene sulphide, see SULPHINES. On its reaction with *brom-acetic acid*, see METHYL-THETINE (p. 1317).

METHYLACETANILIDE, $\text{C}_6\text{H}_5\text{N}(\text{CH}_3)(\text{C}^2\text{H}_3\text{O})$. See METHYLANILINES (p. 1306) and BENZENES (METHYLAMIDO-), p. 204 of this volume.

METHYLACETOSUCCINIC ETHERS. See SUCCINIC ETHERS.

METHYLAL, $\text{C}^3\text{H}^3\text{O}^2 = \text{CH}^2(\text{OCH}^3)^2$. This compound is related to form-aldehyde, CH^2O , in the same manner as acetal, $\text{C}^2\text{H}^4(\text{OC}^2\text{H}^5)^2$, to acetaldehyde, $\text{C}^2\text{H}^4\text{O}$. When mixed with anisole, in presence of glacial acetic acid, the vessel being kept cool, it forms dimethoxyphenylmethane (p. 649), and methyl alcohol (ter Meer, *Deut. Chem. Ges. Ber.* vii. 1200):

METHYL-ALIZARIN, $\text{C}^{18}\text{H}^{10}\text{O}^4$. See METHYL-ANTHRAQUINONE.

METHYLAMINES. *Mono-, di-, and tri-methylamine* are found in commercial wood-spirit; and their occurrence, together with aldehyde, may be attributed to the mutual action of ammonia and acetone, which are also constituents of the crude product of the distillation of wood. The reactions may be represented by the following equations:

(C. W. Vincent, *Compt. rend.* lxxvii. 898; *Ann. Chim. Phys.* [5], i. 444). The formation of methylamine and aldehyde by the above reaction has been experimentally demonstrated by Camille.

Methylamine is also formed: *a.* By the reduction of nitromethane with iron filings, acetic acid, and water (Preibisch, *J. pr. Chem.* [2], vii. 480). *β.* Together with triethylamine hydrochloride, tetrethylammonium chloride, and methylic ether, by heating sal-ammoniac (12 grams) with methyl alcohol (12 c.c.) for six hours to 280° – 285° (Weith, *Ber.* viii. 458). *γ.* Together with glycocine, ammonia, and carbon dioxide, by heating methylluric acid to 170° with hydrochloric acid saturated at 0° (H. Hill, *Sill. Am. J.* [3], xii. 828).

The base called mercurialine, from *Mercurialis perennis*, is identical with methylamine (E. Schmidt, *Ber.* x. 2226).

Trimethylamine, $\text{N}(\text{CH}^3)^3$.—This base is now obtained in large quantities from the waste-liquors or spent wash (*vinasses*) of the stills in which the molasses of beet-root sugar is distilled for the production of alcohol. It has long been the custom in France to evaporate these liquors to dryness, and calcine the mass in a reverberatory furnace, with the view of recovering the alkaline salts of the beet root, to be used as manure. By this treatment, the volatile organic products, viz. the ammonia-water, tar, and oils, were of course destroyed; but recently M. Camille Vincent of Paris has succeeded in collecting these products and turning them to profitable account.

The following is an outline of the process, as carried out at the large distillery of Messrs. Tilloy, Delaune, and Co., of Courrières. The spent-wash, having been evaporated until it has attained a sp. gr. of 1.31, is allowed to run into cast-iron retorts, in which it is submitted to dry distillation. This process lasts four hours; the volatile products pass over, whilst a residue of porous charcoal and alkaline salts remains behind in the retort. The gaseous products given off during the distillation are passed through coolers, in order to condense all the portions which are liquid or solid at the ordinary temperature, and the combustible gases pass on uncondensed and serve as fuel for heating the retorts.

The liquid portion of the distillate is a very complex mixture of chemical compounds, resembling in this respect the corresponding product in the manufacture of coal-gas. Like this latter, the liquid distillate from the spent-wash may be divided into ammonia-water and tar. The ammonia-water of the vinasse resembles that of the coal-gas manufacture in so far as it contains carbonate, hydrosulphide, and hydrocyanide of ammonia; but it differs from this (and approximates to the products of the dry distillation of wood) by containing in addition methyl alcohol, methyl sulphide, methyl cyanide, many of the members of the fatty acid series, and large quantities of the salts of trimethylamine. The tar, on re-distillation, yields more ammonia-

water, a large number of oils, the alkaloïds of the pyridine series, solid hydrocarbons, carboïc acid, and, lastly, a pitch of fine quality.

The crude alkaline aqueous distillate is first neutralised by sulphuric acid, and the saline solution evaporated, when crystals of sulphate of ammonia are deposited; and these, after separating and draining off, leave a mother-liquor, which contains the more soluble sulphate of trimethylamine. During the process of concentration, vapours of methyl alcohol, methyl cyanide, and other nitrils are given off, these being condensed, and the cyanide used for the preparation of ammonia and acetic acid by decomposing it with alkali.

Trimethylamine itself has not yet been applied to any industrial use; but its hydrochloride, when heated to 260° , is resolved, as already explained (p. 1303), into trimethylamine, ammonia and methyl chloride, which may be utilised as a refrigerating agent, and, instead of the iodide, for the preparation of methylated aniline dyes (C. Vincent, *Compt. rend.* lxxxiv. 1139; lxxxv. 667; *J. Pharm.* [4], xxx. 132). See also a lecture by Professor Roscoe 'On a New Chemical Industry' (*Chem. News*, xxxix. 107).

A mixture of trimethylamine and aniline hydrochloride yields, when heated, a distillate of methylaniline.

Trimethylamine hydrobromide is resolved between 230° and 300° into trimethylamine, ammonia, and methyl bromide. Trimethylamine hydriodide crystallises in white shining tables, which gradually turn brown on exposure to the air, and at about 210° begin to decompose, with evolution of white vapours, into trimethylamine, ammonia and methyl iodide, tetramethylammonium iodide being also formed by a secondary reaction (Vincent, *loc. cit.*)

Trimethylamine is one of the basic constituents of the aqueous extract of hops (Griessmayer, p. 1040).

Tetramethylammonium Ferrocyanide, $\text{FeCy}_2[(\text{CH}_3)_4\text{NCy}]_4$, is formed by the action of hydroferrocyanic acid on tetramethylammonium hydroxide, the two substances being mixed in aqueous solution, and the product evaporated in a vacuum over sulphuric acid. The compound crystallises in lamino-granular masses containing, when air-dried, 13 mol. H_2O , which, by successive drying over calcium chloride and sulphuric acid, and heating to 100° – 140° , may be reduced to 2 mol., the remainder being given off, with decomposition, at a temperature above 140° . The salt has not yet been obtained pure and anhydrous (L. Barth, *Ber.* viii. 1484).

Tetramethylammonium Iodide is perfectly stable at high temperatures (Hofmann, *Deut. Chem. Ges. Ber.* vii. 526).

METHYL-AMYL, $\text{C}^6\text{H}^{14} = \text{CH}^3.\text{C}^6\text{H}^{11}$, is formed together with diamyl and ethane, by the action of sodium on a mixture of methyl iodide and optically active amyl iodide. It is a liquid boiling at 60° (Le Bel, *Bull. Soc. Chim.* [2], xxv. 516).

METHYLANILINES. *Monomethylaniline*, $\text{C}^7\text{H}^9\text{N} = \text{C}^6\text{H}^5.\text{NH}(\text{CH}_3)$.—The formation of this base, by the action of methyl bromide or iodide on aniline, as discovered by Hofmann in 1850 (iv. 453), has lately been called in question by A. Kern (*Deut. Chem. Ges. Ber.* 1877, 195), who regards the product thus obtained as a mixture of aniline and dimethylaniline. Hofmann, however (*ibid.* 591), by renewed experiments, has confirmed the correctness of his former conclusions, and has shown that monomethylaniline is produced, together with dimethylaniline, by the action of the chloride, as well as of the bromide or iodide of methyl, on aniline. *Chloride of methyl* acts on aniline at the boiling heat, the liquid product on cooling depositing crystals of aniline hydrochloride; on adding anhydrous ether and treating the resulting solution with dilute sulphuric acid, an additional quantity of aniline is separated as sulphate, and the remaining ethereal solution leaves, on evaporation, a basic oil consisting of a mixture of mono- and dimethylaniline, separable by means of acetic anhydride, which converts the monomethylaniline, with great rise of temperature, into methylacetanilide, while the dimethylaniline remains unaltered. The methylacetanilide, distilled with an alkali, yields methylaniline. *Bromide and iodide of methyl* act on aniline dissolved in ether at ordinary temperatures, the solution in the first case depositing aniline hydrobromide in the course of twenty-four hours, and in the second, aniline hydriodide after some days. The remaining ethereal solution contains mono- and dimethylaniline, which may be separated as above by means of acetic anhydride.

In all cases, the largest yield of monomethylaniline is obtained when a considerable excess of aniline is used, the amounts in Hofmann's experiments being, with methyl iodide, 21.2 per cent., with methyl bromide 25.2 per cent., and with methyl chloride 45.7 per cent. of the aniline attacked. The reaction, however, takes place in the same manner with smaller proportions of aniline; thus, 1 mol. methyl iodide and

1 mol. aniline yielded, after prolonged action and repeated distillation, a quantity of monomethylaniline equal to 12·5 per cent. of the aniline attacked, the remainder being converted into dimethylaniline. A mixture of 40 pts. aniline hydrochloride, 60 aniline and 35 methyl alcohol, yielded, on the manufacturing scale, a product consisting of 25 aniline, 30 mono-, and 45 dimethylaniline.

Commercial methylaniline is almost always contaminated with aniline and dimethylaniline. The aniline may be removed by adding dilute sulphuric acid, and separating the resulting crystals of aniline sulphate from time to time by pressing the liquid (undissolved base and sulphate solution) through linen, the addition of sulphuric acid being discontinued when the filtrate after this treatment no longer yields any crystals. The mono- and dimethylated bases (retaining only traces of aniline), after being set free by an alkali, may then be separated by acetyl chloride, which, like the corresponding anhydride, acts only on the monomethylated base. As the action is very violent, it is best to add the chloride through a tap-funnel to the mixture of bases contained in a reflux apparatus. On subsequently shaking out the product into hot water, it dissolves, and the solution on cooling deposits methylacetanilide in large crystals, which may be easily and completely purified by recrystallisation. It melts at 99·5°, and distils, without alteration, at 245°. The separation of methylaniline from this compound is best effected by boiling hydrochloric acid.

Pure monomethylaniline has a density of 0·276 at 15°, and boils at 190°–191° (pure dimethylaniline at 191°–192°). It forms a beautiful platinochloride, and gives no colour reaction with solutions of chloride of lime. Its oxalate, when heated, does not yield aniline (Hofmann, *Deut. Chem. Ges. Ber.* vii. 523; x. 591).

Ch. Girard (*Bull. Soc. Chim.* [2], xxiv. 120) prepares mono- and dimethylaniline by heating methyl alcohol with aniline and hydrochloric acid at 190°–200° under pressure. Noelting a. Boasson (*ibid.* xxviii. 2) have prepared monomethylaniline in large quantity by this process, and by the action of methyl iodide on aniline, and separate it from aniline and dimethylaniline by treatment with nitrous acid, whereby the last two are converted respectively into diazobenzene nitrate and nitroso-dimethylaniline, $\text{C}_6\text{H}_4(\text{NO})\text{N}$, both of which are soluble in water, whilst the monomethylaniline yields methylphenylnitrosamine, $\text{C}_6\text{H}_5\text{N}(\text{CH}_3)\text{NO}$, in the form of a yellow oil

insoluble in water and in acids, and converted by reduction into monomethylaniline. The reaction may be applied to the estimation of monomethylaniline. The substance under examination, having been treated with nitrous acid, is exhausted with ether, which dissolves the methylphenylnitrosamine; the extract is then dried; the ether is evaporated; and the methylphenylnitrosamine, which remains in the form of an oil, is weighed. Dimethylaniline, similarly treated, yields a few yellow crystals but no oil.

Dimethylaniline, $\text{C}_6\text{H}_4\text{N}(\text{CH}_3)_2 = \text{C}_6\text{H}_5\text{N}(\text{CH}_3)_2$. On the formation of this base, see page 1305. *Reactions.* 1. *Decomposition by Heat.*—When the vapour of dimethylaniline is passed through a combustion-tube filled with fragments of glass and heated to low redness, benzonitril is obtained as chief product (25 per cent. of the dimethylaniline decomposed), together with imido-diphenyl, $\text{NH}(\text{C}_6\text{H}_5)_2$ (the so-called carbazol, vii. 253), and a small quantity of benzene, besides ammonia and hydrogen cyanide (Nietzki, *Deut. Chem. Ges. Ber.* x. 474).

2. With *Sulphur Chloride*, S^2Cl_2 , dimethylaniline forms dithiodimethylaniline, $[\text{C}_6\text{H}_4\text{N}(\text{CH}_3)_2]^2\text{S}_2$, an easily crystallisable, nearly indifferent compound (Hannimann, *Ber.* x. 403).

3. With *Sulphuryl Chloride*, SO^2Cl_2 , the product formed is dimethyldichloraniline, $\text{C}_6\text{H}_3\text{Cl}_2\text{N}(\text{CH}_3)_2$, which crystallises slowly from aqueous solution in needles (Wenghöffer, *J. pr. Chem.* [2], xvi. 448). *Ethylsulphuric chloride*, $\text{SO}^2\text{Cl}(\text{OC}_2\text{H}_5)$, acts violently on dimethylaniline, converting it into dimethylparamidobenzene-sulphonie or dimethylsulphanilic acid, $(\text{CH}_3)_2\text{N}.\text{C}_6\text{H}_4.\text{SO}_3\text{H}$ (Wenghöffer).

4. Dimethylaniline is converted by *perchloromethane* at 180° into carbotetradimethylaniline, $[\text{C}_6\text{H}_4\text{N}(\text{CH}_3)_2]^4$, and by *chloroform* at 230° into methenyltridimethylaniline, $\text{CH}[\text{C}_6\text{H}_4\text{N}(\text{CH}_3)_2]^3$. Both these compounds are basic, crystallise in laminae, melt at 81°–83°, and resemble each other in their behaviour with various reagents. Heated with dilute sulphuric acid, the first yields CO, the second CO_2 . The same products are formed, together with methyl chloride and aniline hydrochloride, when these compounds are heated to 220° with strong hydrochloric acid (Hannimann, *Deut. Chem. Ges. Ber.* x. 1689).

5. When dimethylaniline (3 mol.) is heated with *benzyl chloride* (2 mol.) and *bromine* (2 mol.) to 120° in a reflux apparatus for four hours, a sea-green body is obtained, which is insoluble in water, dissolves with blue colour in alcohol, and dyes silk blue-green. With a smaller proportion of benzyl chloride, blue dye-stuffs are produced (Brunner a. Brandenburg, *Ber.* x. 1844).

6. When to a cooled mixture of *benzaldehyde* (20–30 grams), with four or five times that quantity of dimethylaniline—the excess of which acts as a diluent—zinc chloride is gradually added till a thick paste is formed, an equal volume of water added after about an hour, the whole boiled in a reflux apparatus, and the product made alkaline with caustic soda and largely diluted with water, ether will extract from it—together with unaltered materials which may be removed by distillation with steam—a base, $C^{23}H^{22}N^2(=2C^6H^{11}N + C^6H^5O - H^2O)$, which may be purified by repeated crystallisation from a moderate quantity of alcohol, and separates therefrom in white roundish crystals, appearing, when examined by a lens, as groups of small concentrically arranged needles. This base melts at 92° – 93° ; dissolves readily in ether, and with moderate facility in alcohol; retains its pure white aspect when kept in the dry state in closed vessels; but assumes a faint blue-green colour on exposure to the air. The *picrate*, $C^{23}H^{22}N^2 \cdot 2C^6H^2(NO^2)_3OH$, is obtained by adding picric acid to an ethereal solution of the base, as a yellow precipitate, which dissolves with yellow-green colour in alcohol, and crystallises therefrom in small yellow needles. The *platinochloride*, $C^{23}H^{22}N^2 \cdot 2HCl \cdot PtCl_4$, obtained by adding an ethereal or alcoholic solution of the base to an acid solution of platonic chloride, is a white precipitate which assumes a dingy green colour on exposure to the air. The other salts, especially the sulphate, nitrate, and hydrochloride, quickly oxidise, especially in alcoholic solution, to dye-stuffs of fine blue-green colour, and often of complex constitution (O. Fischer, *Ber.* x. 1624).

7. A mixture of dimethylaniline and *furfural*, treated as above with zinc chloride, yields a base which separates from alcoholic solution in fine crystals usually somewhat coloured, but becoming quite white after repeated crystallisation from ligroin. This base melts at about 70° . Its salts exhibit a tendency to oxidise to red dye-stuffs. From the analysis of the platinochloride, it appears to have the composition $C^{23}H^{22}N^2O = 2C^6H^{11}N + C^6H^5O^2 - H^2O$ (Fischer, *ibid.* 1626).

Bromodimethylaniline, $C^6H^4Br.N(CH^3)^2$, is formed on gradually adding bromine to a solution of dimethylaniline in 5 pts. of glacial acetic acid. It is precipitated by soda-ley from the dilute solution as a grey crystalline powder, which is most readily purified by solution in hydrochloric acid and precipitation with caustic soda. It crystallises from alcohol in silvery laminæ, volatilises with vapour of water, melts at 55° , and boils at 247° (bar. 722 mm.) Its salts are very soluble and deliquescent. The *hydrochloride*, obtained by passing hydrogen chloride into a solution of the base in benzene, very easily parts with its acid, and is completely soluble only in acidulated water. The *platinochloride* is granulo-crystalline.

Bromodimethylaniline is not attacked by strong soda-ley or hydrochloric acid at the boiling heat; but at 180° – 200° it is resolved by hydrochloric acid into methyl chloride and monobromaniline, melting at 16° , a small quantity of bromophenol being probably formed at the same time (A. Weber, *Ber.* x. 760).

Brunner a. Brandenburg (*ibid.* 1844), by acting on dimethylaniline with bromine in the manner described by Weber, obtained, instead of the compound just described, a blue-violet colouring matter having the composition of tetramethyl-rosaniline hydrobromide, $C^{26}H^{16}(CH^3)^4N^3 \cdot 4HBr$, which they find is also produced by the action of bromine on dimethylaniline without the intervention of a solvent. Probably bromodimethylaniline was the first product of the reaction, and was subsequently converted into tetramethyl-rosaniline (see ROSANILINE).

Iododimethylaniline, $C^6H^4I.N(CH^3)^2$, is formed : α . By the action of *iodine* on dimethylaniline, both being dissolved in carbon disulphide (Weber, *loc. cit.*) β . By the action of *cyanogen iodide* on dimethylaniline, which takes place in the cold, and is attended with rise of temperature and evolution of hydrogen cyanide.

Iododimethylaniline crystallises in white laminæ, melts at 79° , and dissolves in alcohol and hydrochloric acid. Its *platinochloride* crystallises well. The base is not attacked by caustic soda. It turns bluish at ordinary temperatures, and decomposes when heated above its melting point, with rapid evolution of hydrogen iodide, leaving a dark-coloured mass, which dissolves in alcohol with deep violet colour (Weber).

Nitrodimethylanilines. *Paranitrodimethylaniline*, $C^6H^4(NO^2).N(CH^3)^2$, is formed by gradually adding the calculated quantity of nitric acid to a solution of dimethylaniline in 10 to 12 pts. of glacial acetic acid. A rapid action then takes place, the liquid on cooling, and further on addition of water, depositing yellow needles; and on recrystallising these several times from alcohol, the nitrodimethylaniline is obtained—together with a cinnabar-red substance less soluble in alcohol more soluble in benzene than itself—in yellow needles having a steel-blue lustre and melting at 163° . Nitrodimethylaniline does not form salts, and is not altered by boiling with hydrochloric acid, in which it dissolves, or with soda-ley. By hydro-

chloric acid at 180° – 200° it is decomposed into methyl chloride and other bodies (A. Weber, *Ber.* x. 760). The same nitrodimethylaniline was previously obtained by Schraube (*Ber.* viii. 616), by oxidising nitrosodimethylaniline with potassium ferricyanide, or better with permanganate. Schraube described this product as melting at 167° , and as possessing basic properties; but Wurster (*Ber.* xii. 528) has shown that it is identical with the nitrodimethylaniline obtained by Weber, both products melting at 162° , being destitute of basic properties, and convertible by reduction with tin and hydrochloric acid into dimethyl-paraphenylenediamine.

Paramidodimethylaniline.—The stannosochloride of this base,

produced by treating paranitrodimethylaniline with tin and hydrochloric acid, crystallises from alcohol in cubes. The free base boils almost without decomposition; when exposed to the air it becomes brown and viscid. The *hydrochloride*, treated with weak oxidising agents, very quickly acquires a deep red to violet colour; the same change is produced in it by platonic chloride. At 180° it is resolved by dry hydrogen chloride into methyl chloride and paraphenylenediamine; by oxidation, into quinone (Weber).

Dinitrodimethylaniline is obtained by oxidising nitrosodimethylaniline with dilute nitric acid, and forms large sulphur-yellow crystals melting at 73.5° (Schraube). Weber, by the action of nitric acid on dimethylaniline dissolved in 6 or 7 pts. of glacial acetic acid, obtained it in needles melting at 77° .

Nitrosodimethylaniline, $\text{C}^6\text{H}^4(\text{NO})\text{N}(\text{CH}^3)^2$ (Baeyer a. Caro, *Deut. Chem. Ges. Ber.* vii. 809, 963; Schraube, *ibid.* viii. 61). This base is formed by the action of nitrous acid on dimethylaniline:

Baeyer a. Caro prepare it by adding 100 pts. of amyl nitrite to a mixture of 50 pts. of dimethylaniline, 100 pts. of concentrated hydrochloric acid, and 750 pts. of a mixture of 1 vol. of hydrochloric acid with 2 vol. of alcohol, well cooled with ice. After a short time, yellow needles separate; as soon as these no longer increase in quantity, the mass is thrown on a vacuum-filter and washed with ether-alcohol. An almost quantitative yield of pure nitrosodimethylaniline hydrochloride is thus obtained, in the form of small sulphur-yellow needles. Schraube adds 75 pts. amyl nitrite cooled to 0° to an ice-cold mixture of 50 pts. dimethylaniline, 100 pts. strong hydrochloric acid, and 600 pts. alcoholic hydrochloric acid (1 vol. acid to 2 vol. alcohol).

The crystals of the hydrochloride melt at 177° , but are apparently decomposed at the same time; they dissolve in water, forming a deep yellow solution, and on adding potassium carbonate to this solution, the pure base separates in green flakes; it may be dissolved out by ether, and separates from the solution on evaporation in large green plates which melt at 92° (Baeyer a. Caro), at 85° (Schraube), and are slightly volatile in a current of steam. The salts crystallise well. The *sulphate* and *nitrate* are obtained in slender yellow needles on adding sulphuric or nitric acid to an ethereal solution of the base (Baeyer a. Caro). The *oxalate* crystallises from wood-spirit in brown-red monoclinic crystals containing 2 mol. water (Schraube).

Nitrosodimethylaniline is oxidised by *ferricyanide* or *permanganate of potassium* to nitrodimethylaniline. By boiling with *alkalis*, it is resolved into dimethylaniline and nitrosophenol (Baeyer a. Caro):

By *tin* and *hydrochloric acid*, it is reduced to dimethylphenylenediamine, a very unstable base, the nitrate and sulphate of which crystallise at first in colourless needles, but are very easily decomposed (Schraube).

Nitrosodimethylaniline hydrochloride is converted by *alcoholic potash* into tetramethyldiamidazoxybenzene, which crystallises in brown shining needles, very sparingly soluble in water, wood-spirit, ether, acetic acid, and ligroin, easily in chloroform. This compound is not reduced by alcoholic ammonium sulphide, sulphurous acid, or sodium-amalgam, but by tin and hydrochloric acid it is easily reduced to dimethylphenylenediamine. Its *salts* form brownish-yellow laminæ, which are completely decomposed by water. Its platinochloride is very slightly soluble, and gives a variable amount of platinum (Schraube).

Addition-products, in the form of large splendid dark steel-blue crystals, are obtained by heating a solution of nitrosodimethylaniline in alcohol or benzene with *aniline* or *paratoluidine*. The compound of nitrosodimethylaniline with *dimethylaniline* crystallises from benzene in dark green shining crystals, which quickly effloresce

on exposure to the air. The *phenol-compound*, $2\text{C}^6\text{H}^4(\text{NO})\text{N}(\text{CH}^3)^2 \cdot \text{C}^6\text{H}^5\text{O}$, formed by mixing the components in the required proportions, with addition of water, crystallises in brown slender needles, which give off all their phenol at 70° . Nitrosodimethylaniline also combines with *silver nitrate*, forming a compound which crystallises from water at 25° in small shining crystals, dark blue by reflected, violet by transmitted light (Schraube).

Benzoyl-dimethylaniline, $\text{C}^6\text{H}^5\text{CO} \cdot \text{C}^6\text{H}^4\text{N}(\text{CH}^3)^2$, is formed by heating dimethylaniline with *benzoic acid* and *phosphoric anhydride* to 180° – 200° in a sealed tube for six to eight hours. On exhausting the product with ether, agitating the ethereal solution with potash-ley and hydrochloric acid, and leaving it to evaporate, benzoyl-dimethylaniline remains in the form of an oil which boils at 330° – 335° . It dissolves in petroleum-ether, and crystallises therefrom in rosettes of white needles; dissolves also in the ordinary solvents. With *fuming nitric acid* it forms a dinitro-derivative which dissolves readily in glacial acetic acid, crystallises in nodules, and melts at 142° ; and with *bromine*, a derivative crystallising in needles (O. Fischer, *Ber.* x. 958).

Dimethylaniline-phthalein, $\text{C}^{14}\text{H}^{12}\text{N}_2\text{O}^2 = \text{C}^6\text{H}^4[\text{COC}^6\text{H}^4\text{N}(\text{CH}^3)^2]^2$ (O. Fischer, *Ber.* ix. 753; x. 952). This compound is formed, as a hydrochloride, by the action of phthalic chloride on dimethylaniline:

The two bodies, on mixing, become hot, and the mixture acquires a dark brown colour. On heating it for a short time, the colour changes to yellowish green, a violent frothing takes place, and the thickened mass becomes dark green. The reaction is facilitated by small quantities of zinc-dust. As soon as the frothing is over, water is added to prevent further decomposition, and the excess of dimethylaniline is driven off with the steam. The residue solidifies on cooling to a resin having a reddish surface-shimmer, and may be ground to a deep green powder. The crude product, which dissolves easily and with green colour in alcohol, wood-spirit, chloroform, and acetic acid, sparingly in water, and scarcely at all in ether, is purified by repeatedly boiling it with ether, dissolving it in a small quantity of alcohol, mixing the solution with water, and crystallising the resulting precipitate from chloroform.

Dimethylaniline-phthalein is also formed by the action of dehydrating agents, (ZnCl_2 , P^2O^5), on a mixture of phthalic anhydride and dimethylaniline. It separates from the solution of the hydrochloride, on addition of alkalis, in greenish-white granules which become colourless when freed from the liquid by filtration, but turn green again on drying. It dissolves in alcohol, ether, and wood-spirit, and crystallises from the last in granular masses. It is scarcely attacked by potassium hydroxide at 200° , but is resolved thereby at higher temperatures into phthalic acid and dimethylaniline. Phthalic acid is also formed when a mixture of the phthalein with strong nitric acid is evaporated down on the water-bath.

The *monohydrochloride*, $\text{C}^{14}\text{H}^{12}\text{N}_2\text{O}^2 \cdot \text{HCl}$, prepared as above described, crystallises in small needles having a greenish-yellow lustre. The *dihydrochloride*, $\text{C}^{14}\text{H}^{12}\text{N}_2\text{O}^2 \cdot 2\text{HCl}$, is obtained on adding dry hydrochloric acid to the ethereal solution of the base, previously dried by calcium chloride, as a yellow-red, crystalline, extremely hygroscopic precipitate, which, when heated in the water-bath, gives off hydrogen chloride and is converted into the green salt.

Platinochlorides.—($\text{C}^{14}\text{H}^{12}\text{N}_2\text{O}^2 \cdot \text{HCl}$) $_2\text{PtCl}_4$, is obtained as a blue-green crystalline precipitate on adding an alcoholic solution of platonic chloride to an alcoholic solution of the monohydrochloride; it is very easily soluble in water. Another salt, $\text{C}^{14}\text{H}^{12}\text{N}_2\text{O}^2 \cdot 2\text{HCl} \cdot \text{PtCl}_4$, is obtained by adding a solution of the base in strong hydrochloric acid to alcoholic platonic chloride, as a yellowish-red crystalline precipitate, easily soluble in water, sparingly in alcohol and ether. The *picrate*, $\text{C}^{14}\text{H}^{12}\text{N}_2\text{O}^2 \cdot \text{C}^6\text{H}^2(\text{NO}^2)^3\text{OH}$, prepared by adding an alcoholic solution of picric acid to an alcoholic solution of the monohydrochloride, is a dark green precipitate. A yellow picrate, $\text{C}^{14}\text{H}^{12}\text{N}_2\text{O}^2 \cdot 2\text{C}^6\text{H}^2(\text{NO}^2)^3\text{OH}$, is precipitated on adding a solution of the dihydrochloride to aqueous picric acid. The other salts of dimethylaniline-phthalein crystallise well.

Base obtained by reduction of Dimethylaniline-phthalein.—When an acid solution of the phthalein is reduced with zinc-dust, it becomes decolorised, and soda-ley added to the solution throws down a colourless base, the colourless salts of which easily turn green by oxidation. The *picrate* has a light yellow colour, and the *hydrochloride* gives with *platonic chloride* a nearly colourless precipitate, probably having the composition

Bromodimethylaniline-phthaleïn, $C^{24}H^{22}Br^2N^2O^2$.—The *monohydrochloride* of this base, formed by heating bromodimethylaniline (p. 130) with phthalic chloride, crystallises from alcohol in feathery groups of steel-blue needles, easily soluble in alcohol, wood-spirit, chloroform, and glacial acetic acid, sparingly in water. From its solution in strong hydrochloric acid, water throws down the dingy green *dihydrochloride*, $C^{24}H^{22}Br^2N^2O^2.2HCl$. The alcoholic solution of the monohydrochloride is blue-violet; its solution in wood-spirit has a violet colour more inclining to red; the chloroform solution is almost pure blue. The *platinochloride*, $2(C^{24}H^{22}Br^2N^2O^2.HCl) + PtCl_4$, is a blue crystalline powder. The free base has a blue-violet colour, dissolves in alcohol and ether, and yields a green *picrate* (O. Fischer, *Ber.* x. 1623).

Hexnitrodimethylaniline-phthaleïn, $C^{24}H^{18}N^6O^{14}$, is formed by digesting the hydrochloride of the phthaleïn with fuming nitric acid on the water-bath, and separates, on pouring the resulting liquid into water, in flocks, which are best recrystallised from glacial acetic acid. It dissolves easily in acetone, less easily in alcohol, ether, wood-spirit, and chloroform, not at all in water, easily and with red-brown colour in nitric and sulphuric acids. From glacial acetic acid it separates in small yellow crystals, which melt at 190° – 193° , and detonate when quickly heated (O. Fischer, *Ber.* x. 952).

Dimethylaniline-saliceïn, $C^{30}H^{30}N^2O^4$, is formed, as a hydrochloride, by heating salicyl chloride with dimethylaniline:

The reaction, which is attended with evolution of hydrogen chloride, is facilitated by the addition of very small quantities of zinc-dust.

The *hydrochloride*, $C^{30}H^{30}N^2O^4.HCl.2H^2O$ (after drying at 100°), may be obtained, as a flocculent precipitate, by washing with water, solution in hydrochloric acid, precipitation by large addition of water, and finally solution in chloroform and precipitation with ether. It dyes silk much like methyl-green, and is of much higher tinctorial power than dimethylaniline-phthaleïn. It forms two *platinum-salts*, $C^{30}H^{30}N^2O^4.2HCl.PtCl_4$ and $2(C^{30}H^{30}N^2O^4.HCl).PtCl_4$. The *acetate*, *sulphate*, *nitrate*, and *oxalate* may be prepared by treating the solution of the hydrochloride in dilute potash with the appropriate acids, and purifying the precipitates by solution in chloroform and precipitation with ether. Melting caustic potash resolves the saliceïn into salicylic acid and dimethylaniline; zinc-dust and glacial acetic acid reduce it to a colourless body. Bromine gives a colourless bromo-derivative, acetic anhydride a bright yellow acetyl-derivative, and fuming nitric acid a yellow nitro-compound. Analogous green colouring matters are formed with salicyl chloride and diethyl aniline, and methyl-diphenylamine (Fischer, *ibid.* 934).

METHYL - ANILINE - SULPHONIC ACID, $C^7H^5NSO^3 = (CH^3)HN.C^6H^4.SO^3H$. The modification of this acid obtained by the action of sulphuric acid on methylacetanilide has already been described (p. 234). Another modification is produced by heating the ethylsulphate of methylaniline to 210° , and separates on cooling from a hot aqueous solution in shining laminæ, having the composition $C^7H^5NSO^3 + H^2O$; they are very efflorescent, and insoluble in water and in alcohol. The *barium salt*, $(C^7H^5NSO^3)^2Ba + 3\frac{1}{2}H^2O$, crystallises in small shining prisms which give off their water at 110° ; the *calcium salt*, $(C^7H^5NSO^3)^2Ca + 4H^2O$, in small shining laminæ which become anhydrous at 100° ; the *lead salt*, $(C^7H^5NSO^3)^2Pb + 8H^2O$, in laminæ having a faint yellowish colour. By passing nitrous acid into the alcoholic solution of this acid, a diazo-compound is obtained, as a yellowish-white amorphous powder, which appears to have the composition $(CH^3)N-N-(SO^3)$

Dimethylaniline-sulphonic acid, $(CH^3)^2N.C^6H^4.SO^3H$. See p. 235.

METHYLANTHRACENE, $C^{15}H^{12} = C^{14}H^9(CH^3)$. This hydrocarbon is obtained: 1. By passing dimethylphenylmethane, $CH^2(C^6H^4.CH^3)^2$, or dimethylphenylethane, $CH^2.CH(C^6H^4.CH^3)^2$, through a red-hot tube (pp. 94, 95). 2. From the crude product of the preparation of phenanthrene. The dark-coloured masses formed in this process are freed from the greater portion of the anthracene present by fractional oxidation with potassium dichromate, then distilled in a current of steam, and recrystallised from alcohol, whereby mother-liquors are obtained, yielding, together with phenanthrene, a compound which boils above 360° , and exhibits the composition and properties of methylanthracene. It crystallises from alcohol in laminæ melting at 190° , and exhibiting a green fluorescence; is converted by heating with sodium into

a red body soluble in benzene, ether, and alcohol; and by oxidation into anthraquinone carbonic acid (p. 113) (Japp a. Schultz, *Ber.* x. 1049). 3. By the action of zinc-dust at high temperatures on chrysophanic acid (p. 470); on emodin (trioxymethylantraquinone) (Liebermann, *Ber.* viii. 970); and on aloin, either from Socotrine or from Barbadoes aloes—in small quantity, however, and probably only as a secondary product (E. Schmidt, *ibid.* viii. 1275; *Arch. Pharm.* [3], viii. 496). 4. Vapour of turpentine-oil, passed through a glass tube heated to dull redness, yields a mixture of aromatic hydrocarbons, the portion of which distilling between 320° and 360° appears to contain methylantracene (G. Schultz, *Ber.* x. 84). 5. Wachendorff a. Zincke (*ibid.* 1481) have obtained from aniline-residues—instead of the expected dimethylantracene—a nitrogenous body melting at 187°, and methylantracene, melting at 208°–210°, and convertible by oxidation into methylantraquinone (m. p. 160°–162°).

METHYL-ANTHRAQUINONE, $C^{15}H^{10}O_2$, is prepared by heating methylantracene in a water-bath with alcohol and strong nitric acid. A violent reaction then sets in, and as soon as two-thirds of the alcohol are evaporated, and a little water is added, a yellow precipitate of methylantraquinone separates out on cooling. It melts at 162°–163°, and sublimes in needles or small plates. It is moderately soluble in ether, acetone, chloroform, and boiling alcohol, sparingly in acetic acid and benzene, and crystallises from these solutions in small needles. Heated with zinc-dust and caustic soda, it gives Liebermann's anthraquinone reaction. It yields a crystallised bromo-compound, which, when heated with potash, is converted into methylalizarin, $C^{15}H^{10}O^4$, which, however, is more readily obtained by heating the quinone with fuming sulphuric acid, and fusing the resulting disulphonic acid with potash. It sublimes on heating in tufts of small needles, melting at 250°–252°, and sublimes at 200° in tufts of reddish needles. It dissolves in alkalis with a blue colour, and this solution gives blue precipitates with calcium and barium salts. It dyes mordanted cloth like alizarin, and its alkaline solution gives the same absorption-spectrum as the latter (O. Fischer, *Ber.* viii. 675).

On *Dimethylantracene* and *Dimethylantraquinone*, see vii. 84.

METHYL-BENZGLYCOCYAMINE or *Benzcreatine*, $C^9H^{11}N^2O^2$. See CREATINE (p. 579).

METHYL-BENZHYDROXAMIC ACID, $C^7H^5O.N(CH^3)OH$. See HYDROXAMIC ETHERS (p. 1080).

METHYL-BENZYL OXIDE, $CH^3.O.CH^2(C^6H^5)$, is formed by the action of benzyl chloride on potassium-methyl oxide: $C^7H^7Cl + CH^3.O.K = KCl + CH^3.O.C^7H^7$; also, together with trimethylsulphine bromide, when a mixture of 1 mol. methyl sulphide and 1 mol. benzyl bromide, diluted with methyl alcohol, is heated to 100° in a sealed tube:

It is a very mobile liquid, boiling between 168° and 170° (Cahours, *Compt. rend.* lxxx. 1317).

METHYL-BENZYLTOLYLAMINE, $N(CH^3)(CH^2C^6H^5)(C^7H^4CH^3)$. See TOLYLAMINES.

METHYL-BUTYL CARBINOLS, $CH^3.CHOH.C^4H^9$. See HEXYL ALCOHOLS (p. 1035).

METHYL-BUTYL KETONES. See KETONES (p. 1148).

METHYL-CARBOPYRROLIC ACID. See PYRROL-DERIVATIVES.

METHYL-CHRY SIN, $C^{16}H^{12}O^4$. See CHRY SIN (p. 466).

METHYL-COUMARIC ACID, $C^{16}H^{10}O^3$. Syn. with β -METHYL-ORTHOXY-PHENYLACRYLIC ACID (p. 505).

METHYL-CREOSOL, $C^9H^{12}O^2 = C^6H^2(CH^3)^2(OH)(OCH^3)$. See CREOSOL (p. 580).

METHYL-CRESOLSULPHONIC ACID, $C^6H^2(CH^3)(OCH^3)(SO^3H)$. See vii. 934.

METHYL-CRESOTIC ACID, $C^6H^2(CH^3)(OCH^3)(CO^2H)$. The potassium salt of this acid is formed by the action of potash on methylcresotate, $C^6H^2(CH^3)(OH)CO^2CH^3$ (vii. 394).

METHYL-CROTONIC ACID, $C^4H^5(CH^3)O^2$. See ANGELIC ACID (p. 86). Tiglic acid, a constituent of crotonic oil, is identical with this acid (E. Schmidt, *Ber.* x. 835).

METHYL-CYANAMIDE, $\text{CN.NH}(\text{CH}^3)$. This compound, when heated in aqueous or alcoholic solution, or exposed to the air, especially to moist air, is converted into trimethyl-melamine, $\text{C}^3\text{H}^3(\text{CH}^3)^3\text{N}^3$, identical with that which Hofmann obtained by desulphuration of methyl-thiocarbamide (p. 1271).

METHYL-DIALLYL CARBINOL, $\text{CH}^3\text{CH}(\text{C}^3\text{H}^5)_2\text{COH}$, is formed by the action of zinc on a mixture of allyl iodide and ethyl acetate. It boils at 158.4° (corr.), unites with 4 at. bromine, and forms with acetic anhydride an acetic ether boiling at 177.3° (Sorokin a. A. Saytzeff, *Deut. Chem. Ges. Ber.* ix. 34, 277).

METHYL-DICRESYLAMINE, $\text{N}(\text{CH}^3)(\text{C}^6\text{H}^4.\text{CH}^3)_2$, formed by heating dicresylamine (ditolylamine) with methyl chloride and hydrochloric acid, is an oil boiling under a pressure of 0.02 mm. at 235° – 240° (C. Girard, *Bull. Soc. Chim.* [2], xxiv. 120).

METHYL-DIETHYL-BENZENE, $\text{C}^6\text{H}^3(\text{CH}^3)(\text{C}^2\text{H}^5)_2$. See MESITYLENE, HOMOLOGUES OF (p. 1285).

METHYL-DIETHYLPHOSPHONIUM IODIDE. See PHOSPHINES.

METHYL-DIOXYAZOBENZENE, syn. with PHENYL-AZODIOXYTOLYL (*q.v.*)

METHYL-DIPHENYLAMINE, $\text{N}(\text{CH}^3)(\text{C}^6\text{H}^5)_2$. See PHENYLAMINES.

METHYL-DIPHENYLTHIOSEMICARBAZIDE, $(\text{C}^6\text{H}^5)(\text{CH}^3)\text{N.NH.NH}(\text{C}^6\text{H}^5)$. See HYDRAZINES (p. 1059).

METHYL-DIPROPYL-BENZENE, $\text{C}^{13}\text{H}^{20} = \text{C}^6\text{H}^3(\text{CH}^3)(\text{C}^3\text{H}^7)_2$. See MESITYLENE, HOMOLOGUES OF (p. 1285).

METHYLENE BROMIDE, CH_2Br_2 , heated to 140° – 150° for several hours with 15 to 20 times its bulk of water and excess of lead oxide, yields ethylene-glycol and traces of ethylene oxide, together with lead bromide (A. Jeltkow, *Ber.* vi. 558).

On the *Iodide*, *Acetochloride*, and *Diacetate of Methylene*, see vii. 807.

METHYLENE-DIBENZAMIDE, $\text{CH}_2(\text{NH.CO.C}^6\text{H}^5)_2$, is formed by treating benzonitril (2 mol.), diluted with an equal volume of chloroform, with strong sulphuric acid, and then adding 1 mol. methylal. It crystallises from alcohol in long white felted needles, and dissolves readily in carbon disulphide, ether, and chloroform; melts at 212° , and sublimes at a higher temperature almost without decomposition; burns with a smoky flame. By dilute acids it is converted into benzamide, by alcoholic potash into benzoic acid (Hepp. a. Spiess, *Ber.* ix. 1424).

METHYLENE-DISULPHONIC ACID, $\text{CH}_2(\text{SO}^3\text{H})_2$. *Disulphometholic acid*. *Methionic acid*.—This acid is formed by oxidising methylene thiocyanate with nitric acid. On heating the thiocyanate for a short time with a quantity of strong nitric acid just sufficient to dissolve it, immediately separating the mixture so as to expel the excess of nitric acid, then repeatedly adding water and evaporating, and finally adding barium carbonate, the barium salt, $(\text{CH}_2\text{SO}_3)_2\text{Ba}$, is obtained in crystals having a fine nacreous lustre (Julie Lermontoff, *Ber.* vii. 1282).

Methylene-disulphonic acid is also formed, together with methylamidobenzenesulphonic acid, by heating methyl-acetanilide with sulphuric acid to 140° – 150° (at higher temperatures carbonisation takes place) as long as acetic acid is given off. On diluting the liquid with water, adding barium carbonate, and filtering the liquid while hot, the filtrate deposits the barium salt of methylene-disulphonic acid as a white crystalline powder, while the methylamidobenzenesulphonate remains in the mother-liquor. The formation of the methylene-disulphonic acid is due to the action of the sulphuric acid on the liberated acetic acid (G. A. Smyth, *ibid.* 1237).

METHYLENE-GUANAMINE. See GUANAMINES (p. 901).

METHYLENE-MERCAPTIDE or *Disulphethylmethane*, $\text{CH}_2(\text{S.C}^2\text{H}^5)_2$, formed by the action of methylene iodide on sodium mercaptide, is a colourless, fetid oil, having a density of 0.987 at 20° , and distilling without decomposition at 184° (Niederist, *Liebigs Annalen*, clxxvi. 391).

METHYL-EOSIN. See PHTHALEÏNS.

METHYL-ERYTHRIN or *Monomethyltetra-bromofluoresceïn*. See PHTHALEÏNS.

METHYL-ETHYL-ACETIC ACID, $\text{CH}(\text{CH}^3)(\text{C}^2\text{H}^5).\text{CO}^2\text{H}$. See PENTOIC ACIDS.

METHYL-ETHYL CARBINOL, $\text{CH}^3.\text{CHOH.C}^2\text{H}^5$. See BUTYL ALCOHOLS (p. 359).

METHYL-ETHYL KETONE, $\text{CH}^3\text{CO.C}^2\text{H}^5$. See KETONES (p. 1147).

METHYL-ETHYL SULPHIDE, $\text{CH}^3\text{S.C}^2\text{H}^5$. This compound, prepared by the action of ethyl iodide on sodium mercaptide, $\text{Na.S.C}^2\text{H}^5$, boils, according to Krüger (*J. pr. Chem.* [2], xiv. 193), at $65^\circ\text{--}66^\circ$ (uncorr.), differing therein from the methyl-ethyl sulphide which Carius obtained by heating diethyl sulphophosphate with methyl alcohol, the corrected boiling point of which is given by Carius at $58.8^\circ\text{--}59.5^\circ$ (vi. 598).

METHYL-ETHYL-ACETIC ACID, $\text{CH}(\text{CH}^3)(\text{C}^2\text{H}^5).\text{COOH}$. See PENTOIC ACIDS.

METHYL-ETHYL-OXAMIDE, $\text{CH}^3\text{NH.CO—CO.NH.C}^2\text{H}^5$. See OXAMIDE.

METHYL-ETHYL-PROPYL CARBINOLS, $(\text{CH}^3)(\text{C}^2\text{H}^5)(\text{C}^3\text{H}^7).\text{COH}$. See HEPTYL ALCOHOLS (p. 1026).

METHYL-ETHYL-PROPYL-BUTYL-PHOSPHONIUM IODIDE, $(\text{CH}^3)(\text{C}^2\text{H}^5)(\text{C}^3\text{H}^7)(\text{C}^4\text{H}^9)\text{PI}$. See PHOSPHINES.

METHYL-EUGENOL, $\text{C}^{11}\text{H}^{14}\text{O}^2 = \text{C}^6\text{H}^5(\text{OCH}^3)^2(\text{C}^3\text{H}^3)$. This compound, obtained by distilling eugenol with caustic baryta, boils at $237^\circ\text{--}239^\circ$ (Church, p. 762). The following derivatives of it have lately been obtained by Wassermann (*Compt. rend.* lxxxviii. 1206):

Bromomethyleugenol Dibromide, $\text{C}^6\text{H}^2\text{Br}(\text{OCH}^3)^2.\text{C}^3\text{H}^3\text{Br}^2$, prepared by the action of bromine on a strongly cooled solution of methyl-eugenol in ether, crystallises in long, silky needles, which melt at $77^\circ\text{--}78^\circ$, and are soluble in alcohol and ether.

Bromomethyleugenol, $\text{C}^6\text{H}^2\text{Br}(\text{OCH}^3)^2.\text{C}^3\text{H}^3$, prepared by the action of zinc-dust on a hot alcoholic solution of the preceding compound, is a colourless liquid which boils at 190° , under a pressure of 0.02 mm., and is soluble in alcohol, ether, and acetic acid.

Methyleugenic Acid, $\text{C}^6\text{H}^2(\text{OCH}^3)^2.\text{C}^3\text{H}^3\text{COOH}$, obtained by the action of sodium-amalgam and chlorocarbonic ether on monobromomethyleugenol, crystallises in flat, yellowish needles, which melt at 180° , dissolve in alcohol and ether, and are slightly soluble in water.

Mercurdimethyleugenol, $(\text{C}^{11}\text{H}^{14}\text{O}^2)^2\text{Hg}$, is formed if an excess of sodium-amalgam is used in the preparation of the preceding acid. It crystallises in colourless needles, soluble in alcohol and ether, and fusing at 140° .

By heating an alkaline solution of methyleugenic acid with a solution of potassium permanganate, acidulating, and agitating the concentrated liquid with ether, a substance is obtained having the formula $\text{C}^{12}\text{H}^{12}\text{O}^3$. Its constitution is probably $\text{C}^6\text{H}^2(\text{OCH}^3)^2(\text{CH}=\text{CH}.\text{CHO}).\text{COOH}$. It forms colourless needles, soluble in water, and melting at $162^\circ\text{--}163^\circ$. In no case was any opianic acid formed.

METHYL-FERULIC ACID, $\text{C}^{11}\text{H}^{12}\text{O}^4$. See VANILLIN-DERIVATIVES.

METHYL-GLYCOLLAMIC ACIDS. Methyl-di- and methyltri-glycollamic acids are formed by heating methyl-hydantoic acid with baryta-water (p. 1045).

METHYL-GUANAMINE, $\text{C}^3\text{H}^4(\text{CH}^3)\text{N}^3$. See GUANAMINE (p. 901).

METHYL-GUANIDINE, $\text{CH}^4(\text{CH}^3)\text{N}^3$. See GUANIDINES (p. 904).

METHYL-HEXYL CARBINOL, $\text{CH}^3.\text{CHOH.C}^6\text{H}^{13}$. See OCTYL ALCOHOLS.

METHYL-GLYOXALINE, $\text{C}^3\text{H}^3(\text{CH}^3)\text{N}^2$. See GLYOXALINE (p. 890).

METHYL-HYDANTOÏN, $\text{C}^4\text{H}^6\text{N}^2\text{O}^2$. See HYDANTOÏC ACID (p. 1045).

METHYL-HYDROQUINONE. See QUINOLS.

METHYL-HYDROXYLAMINE, $\text{N}(\text{CH}^3)\text{H}^2\text{O}$. See HYDROXYLAMINE (p. 1081).

METHYL-ISETHIONIC ACID, syn. with OXYMETHANESULPHONIC ACID, $\text{CH}^2(\text{OH}).\text{SO}^3\text{H}$ (q.v.)

METHYL-ISOBUTYL-GLYCERIC ACID,

is formed, together with heptic acid and isobutyl acetone, by the action of alcoholic potash on ethylic bromisobutylacetoacetate (p. 1020). It is a mobile liquid which, when heated, is changed into gummy anhydrides, whilst a small portion distills over with vapour of water. Its barium salt is anhydrous, and crystallises in small needles. The calcium salt is also anhydrous, and crystallises in needles which are more soluble in hot than in cold water.

METHYL-ISOCROTYL OXIDE, $\text{C}^5\text{H}^{10}\text{O} = (\text{CH}^3)^2\text{C}=\text{CH.O.CH}^3$, is formed by heating isocrotyl bromide, $(\text{CH}^3)^2\text{C}=\text{CH.Br}$ (vi. 401), with sodium methylate to

130°–140° for three or four hours. It is a liquid boiling at 70°–74°, and yielding, when heated to 140° for two or three hours with dilute sulphuric acid of 1 per cent., scarcely anything but isobutyl aldehyde and methyl alcohol:

The corresponding ethyl-compound (*loc. cit.*) reacts in a similar manner (Eltékoff, *Deut. Chem. Ges. Ber.* x, 704).

METHYL-ISOPENTYL CARBINOL or **METHYL-AMYL CARBINOL**, $\text{CH}^3.\text{CHOH}.\text{CH}^2.\text{CH}^2.\text{CH}(\text{CH}^3)^2$. The preparation of this secondary alcohol from ethyl-amyI has already been noticed (p. 1025). It is also produced—together with a di-isobutylpinacene, $\text{C}^{11}\text{H}^{20}\text{O}^2$, boiling at 220°–260°—by the reducing action of water and sodium on methyl-isopentyl ketone in ethereal solution, and is obtained, after removal of the ether by distillation, as a colourless liquid of sp. gr. 0.8185 at 17.5°, boiling at 148°–150°, and not solidifying at –26°.

Methyl-is-pentylcarbinyl Acetate, $\text{CH}^3.\text{CH}(\text{OC}^2\text{H}^3\text{O}).\text{C}^5\text{H}^{11}$, obtained by heating the alcohol with acetyl chloride, is a colourless liquid boiling at 166°–168°, smelling like roses and hyacinths, having a sp. gr. of 0.8595 at 23° (water of 17.5° as unity), and boiling at 166°–168°. The *chloride*, obtained by heating the alcohol to 140° with hydrochloric acid, boils at 135°–137°. The *iodide* (which on account of its instability could not be obtained pure) heated in a reflux apparatus with dilute alcoholic potash, yields a heptylene in the form of a light very mobile oil having a pleasant odour of petroleum, and boiling at 75°–80°. This heptylene is probably a mixture of the two isomeric compounds, $(\text{CH}^3)^2\text{CH}.\text{CH}^2.\text{CH}^2.\text{CH}=\text{CH}^2$ and $(\text{CH}^3)^2\text{CH}.\text{CH}^2.\text{CH}=\text{CH}.\text{CH}^3$ (W. Rohn, *Liebigs Annalen*, ex. 305).

METHYL-ISOPROPYL CARBINOL, $\text{C}^5\text{H}^{10}\text{O} = \text{CH}^3.\text{CHOH}.\text{CH}(\text{CH}^3)^2$. See PENTYL ALCOHOLS.

METHYL-ISOPROPYL KETONE, $\text{C}^5\text{H}^{10}\text{O} = \text{CH}^3.\text{CO}.\text{CH}(\text{CH}^3)^2$. This ketone, first prepared by Frankland a. Duppa (*Proc. Roy. Soc.* xiv, 463) by the action of baryta-water on ethylic acetodimethylacetate,—and further examined by R. Münch, who obtained it directly by the dry distillation of a mixture of calcium acetate and isobutyrate (p. 1147) is also produced: *a.* By oxidation of methyl-isopropyl carbinol (*q. v.*) *β.* Together with hydroxylamine and other products, by the reducing action of tin and hydrochloric acid on the so-called dinitroheptylic acid, $\text{C}^8\text{H}^{19}\text{N}^2\text{O}^3$ (one of the products obtained by oxidising camphor with nitric acid), or on mononitroheptylic acid, $\text{C}^8\text{H}^{11}\text{NO}^4$ (formed by the action of sodium-amalgam on the dinitro-acid):

γ. By dehydration of isopropyl-ethyl glycol with ZnCl^2 or P^2O^5 , and of trimethyl-ethyl glycol with P^2O^5 (Flavitzky, *Ber.* x, 2240).

Methyl-isopropyl ketone boils at 94.1° (corr.), gives the iodoform reaction with iodine and potash, and forms a crystalline compound with sodium-hydrogen sulphite (Kachler, *Liebigs Annalen*, ex. 143).

Chlormethyl-isopropyl Ketone, $\text{CH}^2\text{Cl}.\text{CO}.\text{CH}(\text{CH}^3)^2$. See KETONES (p. 1148).

METHYL-NITROLIC ACID, $\text{CH}^2\text{NO}^3 = \text{H}.\text{CO}.\text{NH}.\text{NO}^2$. See NITROPARAFFINS, under PARAFFINS.

METHYL-NONYL KETONE, $\text{C}^{11}\text{H}^{22}\text{O} = \text{CH}^3.\text{CO}.\text{C}^9\text{H}^{19}$ (vii, 808).

METHYL-NORHEMIPINIC ACID,

METHYL-NORMECONIN,

METHYL-NOROPIANIC ACID,

} See NARCOTINE-DERIVATIVES.

METHYL-OKAMETHANE, $\text{CON}(\text{CH}^3).\text{CONH}^2$. See OXAMIC ETHERS.

METHYL-OKETHYLENE-TOLUIDINE. See TOLUIDINES.

METHYL-OXYBENZOIC ACID, $\text{C}^6\text{H}^3(\text{CH}^3)\text{OH}.\text{CO}^2\text{H}$. On the properties of the three isomeric modifications of this acid, derived from the corresponding cresols, see p. 582.

METHYL-OXYBUTYRIC ACID, $\text{C}^4\text{H}^7(\text{CH}^3)\text{O}^3$. See BUTYRIC ACIDS (OXY-) (p. 364).

METHYL-OXYPHENYL-ACRYLIC, -CROTONIC, -ANGELIC and **-PROPIONIC ACIDS**, $\text{C}^8\text{H}^{2n-13}\text{O}^3$, derived from Anisic Aldehyde. See pp 504 and 505.

METHYL-OKYSULPHOBENZIDE. See OXYSULPHOBENZIDE.

METHYL-PARABANIC ACID. See PARABANIC ACID.

METHYL-PARAHOMOSALICYLIC ALDEHYDE. See PARAHOMOSALICYLIC ALDEHYDE.

METHYL-PENTYL CARBINOL, $\text{CH}_3\text{CHOH.C}^5\text{H}_{11}$. See HEPTYL ALCOHOLS (p. 1024).

METHYL-PHENETHENYL KETONE, $\text{CH}_3\text{CO.CH=CH.C}^6\text{H}_5$. See KETONES (p. 1151).

METHYL-PHENYL HYDRAZINE, $(\text{C}^6\text{H}_5)(\text{CH}_3)\text{N.NH}_2$. See HYDRAZINES (p. 1057).

METHYL-PHENYL-NITROSAMINE, or **NITROSO-METHYL-ANILINE**, $\text{C}^6\text{H}_5\text{N}^2\text{O} = \text{C}^6\text{H}_5\text{N}(\text{CH}_3)(\text{NO})$, is formed, like the corresponding ethyl-compound (p. 206), by the action of nitrous acid on methylaniline dissolved in dilute hydrochloric acid, or by mixing the solutions of methylaniline hydrochloride and potassium nitrite; also, with evolution of nitrogen monoxide, by the action of nitrous acid on a salt of methylphenyl-hydrazine:

(E. Fischer, *Liebig's Annalen*, cxc. 158).

METHYL-PHENYL-SEMICARBAZIDE, $(\text{C}^6\text{H}_5)(\text{CH}_3)\text{N.NH.CO.NH}_2$. See HYDRAZINES (p. 1058).

METHYL-PHLORETIC ACID, $\text{C}^6\text{H}_5(\text{OCH}_3).\text{CO}_2\text{H}$. See PHLORETIC ACID.

METHYL-PHLOROL, $\text{C}^6\text{H}_5(\text{CH}_3)\text{O}$. See PHLOROL.

METHYL-PHOSPHENYL CHLORIDE, $\text{C}^6\text{H}_5\text{PClCH}_3$. See PHOSPHINES.

METHYL-PHOSPHINE, $\text{PH}_2(\text{CH}_3)$. See PHOSPHINES.

METHYL-PROPYLACETIC ACID, $\text{C}^6\text{H}_{12}\text{O}_2 = \text{CH}(\text{CH}_3)(\text{C}^5\text{H}_7).\text{COOH}$. This modification of hexoic or caproic acid, obtained from the product of the reaction of potassium cyanide on amylene hydriodide, is a liquid having a density of 0.9279 at 18° and boiling at 193°. Its silver salt separates from a hot saturated solution on cooling in needle-shaped crystals. The barium salt is obtained as a thick syrup, which dries up to a gummy mass. The calcium and zinc salts are less soluble in hot than in cold water; the latter is soluble in alcohol. The solution of the ammonium salt gives with ferric chloride a flesh-coloured precipitate soluble in excess of the iron solution. The ethylic ether is a liquid having a density of 0.867 at 18°, and boiling at 153° (A. Saytzeff, *Deut. Chem. Ges. Ber.* xi. 511).

METHYL-PROPYL CARBINOLS, $\text{CH}_3\text{CHOH.C}^3\text{H}_7$. See PENTYL ALCOHOLS.

METHYL-PROPYL KETONES. See KETONES (p. 1147).

METHYL-PROPYL-CATECHUIC ACID, $(\text{C}^6\text{H}_3)(\text{OCH}_3)(\text{OC}^3\text{H}_7)(\text{COOH})$, is formed from propyl-eugenol, $\text{C}^6\text{H}_3(\text{OCH}_3)(\text{OC}^3\text{H}_7)\text{C}^3\text{H}_5$, by gradual oxidation with a hot dilute solution of potassium permanganate; and its homologues, methyl-butyl- and methyl-amyl-protocatechuic acid, are obtained in like manner from the corresponding homologues of eugenol (p. 763 of this volume).

METHYL-PYRROL, $\text{C}^4\text{H}_5\text{N}(\text{CH}_3)$. See PYRROL.

METHYL-QUININE. See QUININE. On the Sulphato-periodides of this base, see p. 491.

METHYL-QUINIZARIN, $\text{C}^{15}\text{H}^{10}\text{O}^4 = \text{C}^6\text{H}_4.\text{C}^2\text{O}_2.\text{C}^6\text{H}(\text{CH}_3)(\text{OH})^2$ (Nietzki, *Deut. Chem. Ges. Ber.* vii. 2011). This homologue of Quinizarin (p. 102) is produced by heating a mixture of toluquinol (hydrotoluquinone) and phthalic anhydride in equal numbers of molecules with a quantity of sulphuric acid equal to eight or ten times the weight of the toluquinol, the heat being continued for three hours and gradually raised from 130° to 150°. The product, after boiling with water and crystallisation from benzene, is purified by boiling it with solution of sodium carbonate, and decomposing the resulting compound with an acid.

Methyl-quinizarin crystallises from alcohol or glacial acetic acid in tufts of long red needles, from dilute spirit in long capillary felted needles. It melts at 160°, and partly sublimes without decomposition. It dissolves more readily in the greater number of solvents than quinizarin, and its solutions in alkalis and in strong sulphuric acid exhibit the same absorption-bands as those of the latter. With acetic anhydride it forms a diacetyl-derivative, $\text{C}^{15}\text{H}^8(\text{C}^2\text{H}_3\text{O})^2\text{O}^4$, which crystallises in yellow needles melting at 185°.

Methyl-quinizarin distilled over heated zinc-dust yields methyl-anthracene convertible by oxidation with chromic acid into anthraquinone-carbonic acid (p. 113), together with a large quantity of anthraquinone, a circumstance in which it agrees with the only known methyl-anthracene obtained from emodin and chrysophanic acid (p. 1312).

From these results, viewed in connection with the known constitution of anthracene, and the mode of attachment of the two OH-groups and the C^2O^2 -group in quinizarin, as demonstrated by Baeyer (pp. 102, 103), it may be inferred that methyl-anthracene and methyl-quinizarin are constituted in the manner represented by the following formulæ:

METHYL-SUCCINIC ACID, $\text{C}^2\text{H}^3(\text{CH}^3)(\text{CO}^2\text{H})^2$. See PYROTARTARIC ACID.

METHYLSULPHURIC CHLORIDE, $\text{CH}^3\text{O}.\text{SO}^2.\text{Cl}$. See SULPHURYL CHLORIDE.

METHYL-TETRAOXYANTHRAQUINONE, $\text{C}^{14}\text{H}^7(\text{CH}^3)\text{O}^6$. This, according to Tilden (*Chem. News*, xxxv. 273), is the constitution of an orange-yellow compound called *Aloanthin*, which is obtained, together with a small quantity of acetic acid, by oxidising barbaloin and socaloïn with chromic acid. It melts at 260° – 265° , and may be sublimed without decomposition.

METHYL-THETINE, $\text{C}^4\text{H}^8\text{SO}^2 = \begin{array}{c} \text{CH}^2 - \text{S}(\text{CH}^3)^2 \\ | \\ \text{CO} - \text{O} \end{array}$. This compound, which may

be regarded as the sulphur analogue of betaine (p. 323), is obtained, in combination with hydrobromic acid, by mixing bromacetic acid and methyl sulphide in molecular proportions:

The hydrobromide is analogous in composition to betaine hydrobromide, $(\text{CH}^3)^2\text{NBr}.\text{CH}^2.\text{COOH}$. By decomposing this salt with silver oxide, or the sulphate with barium carbonate, free methyl-thetine is obtained in crystals containing 1 mol. H^2O , and exhibiting both acid and basic properties (Crum-Brown. *Deut. Chem. Ges. Ber.* vi. 1384; Crum-Brown a. Letts, *ibid.* vii. 695).

Ethyl-thetine hydrobromide, prepared in like manner, is extremely deliquescent.

METHYL-THIOALDEHYDE or **THIOFORMALDEHYDE**, $\text{C}^3\text{H}^6\text{S}^2 = \text{H}^3(\text{CSH})^2$, is formed by the action of hydrogen sulphide on formaldehyde, HCOH (p. 826).

METHYL-THYMOL. See THYMOL.

METHYL-TRIBROMOGLYOXALINE. See GLYOXALINE (p. 890).

METHYL-TRIBUTYL-PHOSPHONIUM IODIDE, $(\text{CH}^3)(\text{C}^4\text{H}^9)^3\text{PI}$. See PHOSPHINES.

METHYL-TRIMERCAPTIDE, $\text{CH}(\text{S}.\text{C}^2\text{H}^5)^3$, produced by the action of chloroform on sodium-mercaptide, $\text{NaS}(\text{C}^2\text{H}^5)$, is a yellow oil which is partly decomposed by boiling, and is converted by oxidation with nitric acid into ethylenesulphonic acid (Niederist, *J. pr. Chem.* [2], xv. 174).

METHYL-VANILLIN or *Dimethyl-protocatechuic Aldehyde*, $\text{C}^8\text{H}^9(\text{OOH}^3)^2.\text{COH}$. See BENZOIC ALDEHYDE (DIOXY-), (p. 306).

METHYL-KANTHAMIDE. See XANTHAMIDE.

METHYSTICIN, syn. with KAWAIN (p. 1145).

MEYMACITE. A hydrate of tungstic acid from Meymac (Dep. Carrèze), analysed by A. Carnot (*Compt. rend.* lxxix. 638). The analyses lead, after deduction of scheelite and limonite, to the formula $2\text{WO}^3.5\text{H}^2\text{O}$ or $\text{WO}^3.2\text{H}^2\text{O}$. It is evidently a decomposition-product of scheelite, probably under the influence of water containing

free acid, resulting from the decomposition of iron pyrites. The scheelite first assumes a yellow or yellowish-green colour, but retains its directions of cleavage; subsequently, however, it is converted into a soft, pure yellow, or brownish mass.

Analyses.—1 and 2. Soft, yellow to brownish, with sulphur-yellow streak. 3, Harder laminae, with yellowish streak.

WO ³	Ja ² O ⁵	CaO	Fe ² O ³	Mn ² O ³	H ² O	X*	Sp. gr.
71.85	1.00	2.50	6.00	0.75	12.93	4.50 = 99.53	} 3.80
74.25	1.05	4.65	6.10	0.65	11.75	1.85 = 100.30	
75.12	0.70	7.00	6.25	0.32	6.85	2.55 = 98.79	

* Gangue. Also traces of magnesia and sometimes of potash.

MIARGYRITE and KENNGOTTITE. *Miargyrite* is a sulphantimonite of silver, Ag²SbS², from Bräundsdorf in Saxony, containing 21.93 per cent. S, 39.14 Sb, and 36.40 Ag, together with 1.00 Cu and 0.62 Fe. Sp. gr. = 5.2 to 5.4 (iii. 1010). The name *Kenngottite* was given by Haidinger to a mineral, of similar constitution but containing lead as an essential constituent. It occurs at Felsőbánya in Hungary on a quartzose rock, in monoclinic crystals, OP. + P. — P, having the angles $\infty P : \infty P = 42^\circ$ and 138° ; has a black streak, conchoidal fracture; hardness = 2.5; sp. gr. about 6. It is somewhat brittle, melts easily before the blowpipe to a black shining globule, and, when heated for some time in the reducing flame, leaves a butter of silver amounting to 30 per cent. of the whole (Kenngott, *Annales des Mines*, 1856, [5], viii. 495).

More recently (1877) L. Sipőcz (*Liebig's Annalen*, clxxxviii. 343) has analysed *miargyrite* from Felsőbánya, where it occurs implanted on quartz-crystals, and likewise *kenngottite*, with results which show that the two minerals thus named are identical, both being sulphantimonites of silver, AgSbS², in which that metal is partly replaced by lead—or isomorphous mixtures of Ag²SbS² and PbSbS².

Analyses.—1 and 2, *Miargyrite*: 1. Mean of two determinations; 2. The same recalculated after deduction of copper and iron, as unessential, and replacement of the lead by its equivalent in silver (Pb = Ag²); 3 and 4, *Kenngottite*; 3. Analysis. 4. Recalculated with the same corrections as in the case of *miargyrite*. 5. Values calculated from the formula AgSbS².

	S	Sb	Ag	Pb	Cu	Fe	Sp. gr.
1.	21.80	40.68	32.77	4.01	0.51	0.19 = 99.96	} 5.273 to
2.	21.80	40.68	36.95	—	—	— = 99.43	
3.	20.66	39.46	35.28	1.76	0.50	0.25 = 97.91	} 5.2918 to
4.	20.66	39.46	37.12	—	—	— = 97.24	
5.	21.77	41.50	36.73	—	—	— = 100	5.3822

According to A. Weisbach (*Ann. Phys. Chem.* [2], ii. 455) the crystals of *miargyrite* exhibit the axial ratio $a : b : c = 0.9865 : 2850 : 1$. Angle $bc = 48.41'$. Weisbach also infers, from an analysis of *Kenngottite* by Richter, which gave 30.12 per cent. silver with small quantities of arsenic and lead, and a specific gravity = 5.47 at 22°, that this mineral is merely a *miargyrite* comparatively poor in silver. To the same mineral Weisbach also refers Hausmann's dull red silver ore (*fahles Rothgiltigerz*) from Andreasberg, with which also Breithaupt's *Hypargyronblende* (*Hypargyrite*) is very probably identical.

MICA. The following classification of minerals belonging to the mica-group is given by Tschermak (*Jahrb. f. Min.* 1878, 71). Micas are divided into uniaxial and diaxial, and the latter exhibit two kinds of orientation, the uniting line between the optic axes lying, in the first, in a diagonal of the hexagonal lamellae, whilst it is perpendicular to that direction in the second. Uniaxial mica was called *biotite* by Hausmann, whilst certain micas with small angles of the optical axes were called *phlogopite* by Dana. The diaxial micas were all called *muscovite*. Non-ferruginous lithia-mica is called *epidolite*, and is similar to *muscovite* in its properties, but that containing iron (*zinnwaldite*) resembles *phlogopite*.

From the results of former investigations Tschermak arranges the micas in the following manner:—

I.		II.	
Biotite.	Anomite.	Meraxene.	Lepidomelane.
Phlogopite	—	Phlogopite.	Zinnwaldite.
Muscovite.	Lepidolite.	—	—
—	Muscovite.	—	—
—	Paragonite.	—	—
Margarite.	Margarite.	—	—

The micas in Class I. exhibit the same optical orientation, the plane of the optical axes being perpendicular to the plane of symmetry, whilst the plane of the optical axes in the micas of Class II. is parallel to the plane of symmetry. Anomite is a rare mica with peculiar chemical composition. Merroxene is the name given to all Vesuvian micas. Tschermak concludes that *all micas belong to the monosymmetrical (monoclinic) system*, and that their twin-formation leads to the assumption of a system of axes which is characterised by the two axes in the plane of symmetry intersecting each other almost at an angle of 90° . This last peculiarity accounts for the rhombic types at one time and rhombohedral types at another time observed to occur in these micas (iii. 1010). The optical relationships of the micas is given in the following table, the dispersion being stated in the usual manner (ρ denoting red and ν violet light), and in addition $+f$ signifies that the positive optical axis angle is rendered greater by an increased amount of iron in the mineral, and $-f$ that the same angle is diminished by an increase of iron:—

	I.		II.
Anomite . . .	$\rho > \nu + f$.	Merroxene . . .	$\rho < \nu - f$.
Lepidolite . . .	$\rho > \nu$	Phlogopite . . .	$\rho < \nu - f$.
Muscovite . . .	$\rho > \nu + f$.	Zinnwaldite . . .	$\rho < \nu - f$.
Paragonite . . .	$\rho > \nu$		
Margarite . . .	$\rho > \nu$		

From this table it appears that with micas of Class I. the dispersion is generally $\rho > \nu$ up to margarite, and with the micas of Class II. $\rho < \nu$ up to zinnwaldite. In all these cases no relationship can be traced between the chemical and optical properties, a fact which agrees with Tschermak's observations in respect to augite and bronzite.

N. v. Kokscharow, on the other hand (*Jahrb. f. Min.* 1877, 798), regards all micas without exception as belonging to the orthorhombic system, with the angle $\infty P : \infty P\infty$ exactly equal to 120° , their monoclinic character of symmetry being only apparent. The axial ratio $a : b : c$ is $1 : 1.73205 : 2.84953$, or $0.57735 : 1 : 1.64618$. Twins are formed according to the two laws: Twin-plane ∞P or $\infty P3$.

H. Baumhauer (*Münch. Akad. Ber.* 1874, 245; *Jahresb. f. Chem.* 1875, 2) infers from an examination of the corrosion-figures produced on potash-mica and magnesia-mica by the action of a hot mixture of fluorspar and sulphuric acid, that the former belongs to the monoclinic, the latter to the rhombohedral system.

G. vom Rath (*Pogg. Ann.* clviii. 420) describes a six-sided plate of mica with re-entering edges (from Vesuvius) as a twin of the combination $\frac{1}{3}P2 . \infty P2 . 0P$, according to the law: Twin-axis normal to $0P$; angle of rotation 120° . Tschermak (*Min. Mitt.* 1876, 87) describes twins of biotite from Vesuvius as belonging to the monoclinic system.

Potash-mica. Muscovite.—According to M. Bauer (*Berl. Akad. Ber.* 187 684; *Jahrb. f. Min.* 1878, 310), the micas of this variety are monoclinic, the plane of the optic axes being perpendicular to the plane of symmetry, the optic median line forming with the cleavage-face an angle of $88^\circ 18'$ and the angle of the optic axes being equal to $40^\circ 21'$.

No. 4 contains traces of lithia; No. 5 traces of titanio oxide.

Analyses.—1 and 2, from India, analysed by L. Sipöcz. 3. From Bengal, by S. Blau (Ludwig, *Jahrb. f. Min.* 1874, 84). 4 and 5. White, from the granitic gneiss of New York (P. Schweizer, *Amer. Chemist*, iv. 445). 6. Light-brown transparent plates mixed with oligoclase and orthoclase, distinguished by its large amount of sodium and silicon; locality not stated (Löbisch, *Min. Mitt.* 1877, 271). 7. Mica from the eclogite of Saxony (E. v. Gerichten, viii. 703). 8. Mica from the hornblende andesite of Transylvania, analysed by K. John (viii. 1043).

Lithia-mica. 1. *Lepidolite* from Paris, Maine, having a larger grain, and finer lilac colour than the following. 2. *Lepidolite* from Rozena, in Moravia. Bunsen and Kirchoff found in this mineral 0·24 per cent. rubidium, which must be deducted from the amount of potash in the analysis given below: the spectroscope showed also a trace of cesium. 3. *Zinnwaldite*, from Zinnwald, in Bohemia; rubidium and cesium were detected in it spectroscopically; thallium has not been found either in this or in any other lithia-mica (Berwerth, *Jahrb. f. Min.* 1877, 830; 1878, 316). 4. Mica from the neighbourhood of Portland and Middletown, Connecticut, distinguished by its large amount of ferrous oxide and by the presence of lithium, the latter being recognisable by the colour which it gives to the blowpipe flame. This mineral is found in granitic veins in gneiss and mica-slate; it is optically uniaxial (?), and intimately intergrown with muscovite. The numbers under (4) are the mean of two analyses:

Magnesia-micas. 1. *Phlogopite*, occurring, together with apatite, at Oedegarden, in Norway. Colour by reflected light, dark-reddish brown; by transmitted light, rose-red in thick, yellow in thinner laminæ. Optically biaxial (Bröggen a. Reusch, *Jahrb. f. Min.* 1876, 196). 2. Mica from Vesuvius; blackish plates, implanted together with vesuvian or limestone (Berwerth, *ibid.* 1877, 830; 1878, 316). 3. *Barytic Phlogopite*, from Edwards, St. Lawrence County, New York; brown translucent plates. 4. *Barytic Mica*, occurring imbedded in thin white layers in the emerald-bearing mica-slate of the Habach-thal, Salzburg: rhombic, with the faces ∞P and $0P$; cleaving very easily in the direction of the latter (Sandberger, *ibid.* 1876, 624). 5. *Euchlorite* from Chester, Massachusetts (Pisani, *Compt. rend.* lxxiii. 1866).

MICA-PORPHYRY. See PORPHYRY.

MICA-SLATE. On the mica-slate region of the Saxon Erzgebirge, see Kalkowsky (*Zeitschr. geol. Ges.* xxviii. 682; *Jahresb. f. Chem.* xxviii. 682).

MICA-TRAPP. On the mica-trapp of Metzdorf, near Oederan in Saxony, see Kalkowsky (*Jahrb. f. Min.* 1875, 488).

MICROLINE. Triclinic felspar containing from 11 to 16 per cent. potassium and only a small proportion of sodium (see FELSPAR, p. 775).

MICROLITE. See TANTALATES.

MICROSOMMITE. A mineral discovered by Scacchi (*Jahresb. f. Chem.* 1873, 1147) in the pores of blocks ejected from Vesuvius in the eruption of April 1872, and further examined by G. vom Rath (*Jahrb. f. Min.* 1873, 544) and by Rammelsberg (*Berl. Acad. Ber.* 1876, 699). It has probably been formed by the action of volcanic vapours charged with sodium chloride on the leucites and augites of the lavas. It is accompanied by iron-glance. The crystals, which are extremely small (1500 weighing only about 0.1 gm.), belong to the hexagonal system, and exhibit the combination $\infty P.0P$, sometimes with P ; angle of the middle edge = $43^{\circ}40'$, whence the ratio of principal axis to the secondary axes is 1 : 2.88. Hardness = 6. Sp. gr. = 2.6 at 15° . From the results of an analysis (A) made with a very small quantity of substance, vom Rath deduces the formula $(\frac{2}{3}K^2O \cdot \frac{3}{2}CaO).Al^2O^3 \cdot 2SiO^2 + NaCl + \frac{1}{13}(CaO \cdot SO^2)$, which gives the values B, agreeing nearly with the analytical numbers, excepting that the percentage of sodium found is somewhat greater than the calculated value, indicating that the sodium is present only as NaCl.

SiO ^a	Al ^a O ^a	CaO	K ^a O	Na	Cl	SO ^a
33.0	29.0	11.2	11.5	6.5	9.1	1.7 = 102
33.0	28.3	10.5	10.4	6.3	9.8	1.7 = 100

Microsommitte is therefore a member of the sodalite group, nearly related crystallographically to nephelin (vom Rath).

According to Rammelsberg, the crystals of microsommitte are identical in form with nephelin, and consist of a mixture of two substances, one of which contains sulphuric acid, while the other is free from it. The remaining constituents, SiO², Al²O³, CaO, Na²O, K²O, Cl, are the same for both. The silicate of the former is $R^2Al^2Si^2O^8 \cdot 2CaAl^2Si^2O^8$, while that of the latter, which contains chlorine without sulphuric acid, is $R^2Al^2Si^2O^8 \cdot 2Ca^4Al^2Si^2O^8$.

MILARITE. This mineral, from Graubünden, Switzerland, first analysed by Kennogott, who regarded it as a zeolite, and afterwards by Frenzel, who assigned to it the formula $3R^2O \cdot CaO \cdot Al^2O^3 \cdot 18SiO^2$, regarding the water as basic (vii. 809), has been further analysed by Finkener (*Jahrb. f. Min.* 1874, 61), who finds it to contain:

SiO ^a	Al ^a O ^a	CaO	MgO	K ^a O	Na ^a O	H ^a O	Sp. gr.
70.04	11.62	10.05	0.20	2.74	0.65	1.69	99.99 2.5

and by E. Ludwig (*ibid.* 1878, 411), who obtains the numbers given under A, which agree nearly with those found by Finkener, and may be represented by the formula $HKCaAl^2Si^{12}O^{30}$ or $H^2O \cdot K^2O \cdot 2CaO \cdot 2Al^2O^3 \cdot 24SiO^2$, which gives the values B:

	SiO ^a	Al ^a O ^a	CaO	MgO	K ^a O	Na ^a O	H ^a O
(A.)	71.81	10.67	11.65	trace	4.86	trace	1.36 = 100.35
(B.)	72.66	10.39	11.30	—	4.74	—	0.91 = 100

Sp. gr. = 2.5529.

According to Tschermak, the crystals, apparently hexagonal, are really rhombic intersection-twins according to ∞P , and exhibit the faces $\infty P \infty$, $\infty P3$, $3P3$, $0P$.

MILK. Composition. 1. Of Human Milk. The following results have been obtained by Brunner (*Pflüger's Archiv. f. Physiologie*, vii. 445), and Christenn (*Landw. Vers. St.* xx. 439):

	Brunner	Christenn
Total Solids	—	12.75
Water	90.00	87.24
Fat	1.73	4.23
Sugar	6.23	5.96
Proteids	0.63	1.90
Soluble salts	1.41	0.28

For the methods of analysis, see p. 1326.

Analyses of the Milk of women of different ages have been published by H. Gerber (*Bull. Soc. Chim.* [2], xxiii. 342):

Age	33 years	32 years	28 years	27 years	25 years	23 years
Water	88.02	86.22	84.86	86.62	87.57	93.17
Butter	2.90	4.54	5.23	4.64	3.44	2.15
Casein and Albumin	1.60	2.81	2.74	2.03	2.03	1.06
Sugar	7.03	5.96	6.40	6.46	6.27	3.46
Salts	0.31	0.41	0.75	0.22	0.67	0.14
Reaction	slightly acid	neutral	neutral	alkaline	neutral	neutral
Sp gr.	1.0272	1.031	1.029	1.028	1.031	1.0215

H. A. Mott (*Amer. Chemist*, vi. 364) finds that the milk of women of African race is richer in solid constituents than that of women of the Caucasian race.

2. Cows' Milk. The following results have been obtained by Gerber (*loc. cit.*) as the mean of four analyses, and by C. A. Cameron (*Chem. News*, xxxi. 54) as the result of forty analyses, of the milk of cows from Dublin dairies:

	Water	Fat	Proteids	Sugar	Salts	Sp. gr.
Gerber	86.21	4.18	4.43	4.28	0.86 =	99.96 1.0262
Cameron	87.00	4.00	4.10	4.28	0.62 =	100

Stevenson Macadam (*American Chemist*, v. 419; vi. 30) has analysed 66 samples of the milk of 46 cows from dairies in Edinburgh, and 7 samples from a farm where the cows were fed on good pasture, with the following mean results:

	Edinburgh milk	Milk from the farm
Total of Solid Constituents	12.27	12.77 p. c.
Fat	2.58	2.88
Ash	0.71	0.71

From the individual analyses, Macadam concludes that the quality of the milk is affected by that of the fodder and the amount of water contained therein, by the season, the temperature of the cow-house, the race, age, and health of the cow, and the time of calving. Unadulterated milk from town dairies should have a density not less than 1.03, and should contain:

Cream not less than	6	vol. per cent.
Solids	11	"
Fat	2	"
Salts	0.65	"

F. N. Macnamara (*Chem. News*, xxvii. 273) has analysed the milk of small Bengal cows, whose daily food usually consists of about 12 lbs. of rice-straw, $2\frac{1}{2}$ oil-cake, 1 lb. rice-husks, the water in which the rice for the family has been boiled, and 35 lbs. of water. The following are the results:

Milk of Bengal Cows.

	Age of calf	Daily yield of milk	Evaporation-residue of the milk	Casein	Sugar	Fat	Salts
1.	1 month	6½ lb.	15.12	5.50	3.98	4.98	0.76 p. c.
2.	2 "	5 "	12.82	4.30	4.40	3.60	0.70 "
3.	2½ "	5 "	15.28	5.76	4.10	4.10	0.84 "
4.	5 "	4 "	11.90	4.30	4.37	2.52	0.78 "
5.	6 "	10 "	12.04	4.30	4.10	3.20	0.70 "
6.	7 "	5 "	11.65	5.40	3.86	1.90	0.82 "
7.	10 "	4 "	11.92	4.20	4.37	3.00	0.68 "
8.*	2 "	—	15.90	7.76	3.40	4.10	0.90 "

* This cow was milked only every second or third day.

Voelcker (*Chem. News*, xxxii. 26) has analysed the morning and evening milk from the farm of the Royal Agricultural College at Cirencester, for the several months of the year 1863, with the following results:

		Jan.	Feb.	March	April	May	June	July	Sept.	Oct.	Nov.	Dec.
Water	Morning	87.70	87.50	88.60	87.50	88.20	87.30	88.70	89.01	87.60	87.10	86.70
"	Evening	87.40	86.40	88.16	89.00	87.80	87.30	87.80	90.70	90.30	86.20	86.00
Butter	Morning	2.60	2.58	2.71	3.15	2.42	3.05	2.22	1.99	3.90	3.41	3.74
"	Evening	2.28	2.53	2.96	3.47	2.71	2.94	3.61	1.79	2.99	3.78	4.12
Casein and Albumin	Morning	2.94	3.44	2.43	2.94	3.12	3.00	2.94	2.94	2.87	2.94	2.87
"	Evening	2.87	3.37	2.62	2.69	2.87	2.87	2.81	1.81	2.37	3.19	3.62
Milk-sugar	Morning	5.82	5.44	5.35	5.60	5.49	5.89	5.38	4.48	4.84	5.41	5.92
"	Evening	6.56	5.56	5.55	5.08	5.35	6.05	5.10	4.04	3.76	5.68	5.46
Ash	Morning	0.94	1.04	0.91	0.61	0.77	0.76	0.76	0.64	0.79	1.14	0.77
"	Evening	0.89	1.14	0.77	0.76	0.77	0.84	0.68	0.66	0.58	1.15	0.80

E. L. Cleaver (*Pharm. J. Trans.* [3], iv. 973) has examined the changes produced in the amount of the solid constituents of milk by keeping. For this purpose, a quantity of milk drawn from the cow on April 30 was divided into several portions, one of which was analysed immediately, the others at the dates mentioned below:

	Total solids	Fat	Ash
April 30	12.48	3.6	0.7
May 1	12.37	3.6	0.7
" 2	12.18	3.6	0.7
" 4	12.12	3.6	0.7
" 6	12.09	3.6	0.7
" 8	12.07	3.6	0.7
" 12	11.97	3.52	0.7
" 18	11.97	3.4	0.7

A careful examination of the milk of cows both in health and in disease has lately been made by A. Wynter Blyth (*Chem. Soc. J.* 1879, xxxv. 530), whose analyses give for the average composition of healthy cows' milk:

Water	Fat	Sugar	Casein	Albumin	Galactin	Bitter principle	Ash
86.87	3.50	4.00	3.98	0.77	0.17	0.01	0.70

besides a nitrogenous colouring matter called *lactochrome*, the quantity of which was not determined, and traces of creatine and urea.

Galactin is described as a nitrogenous substance (regarded by Blyth as an alkalioid) which is precipitated, together with lactochrome, from the whey by mercury nitrate, after the casein and albumin have been completely removed. On decomposing the mercury precipitate with hydrogen sulphide, and treating the filtrate (freed from excess of H₂S) with lead acetate, a lead-compound of galactin is thrown down; and this, when decomposed by hydrogen sulphide, yields a solution from which, by evaporation, the galactin is obtained in the form of a white, brittle, neutral, tasteless, non-crystalline

mass, soluble in water, insoluble in alcohol, and giving precipitates with sodium phosphomolybdate and metatungstic acid. The composition of galactin appears, from the analysis of its lead compound, to be $C^{84}H^{78}N^4O^{45}$.

The filtrate from the galactin precipitate, freed from excess of lead by hydrogen sulphide and treated with mercury nitrate, yields a precipitate of the mercury-compound of lactochrome, the composition of which is stated to be $HgO.C^6H^{18}NO^6$ (?), and from this precipitate the lactochrome may be separated in the form of bright orange-red, resin-like masses, softening at 100° , very soluble in water and in hot alcohol, but separating partially as the liquid cools. Strong solutions give a simple spectrum, allowing most of the red and yellow rays to pass through.

From analyses of the milk of diseased cows, Blyth infers that a cow suffering even from very acute disease (phthisis, pneumonia, congested liver, &c.) may give milk differing in no essential particular from normal milk, whereas local affections of the udder, characterised by bloody or purulent deposits, may easily be recognised by the presence of such products in the milk. The milk of a cow attacked by cattle-plague was, however, found by Blyth (*Chem. News*, 1875, xxxii, 244) to differ considerably in composition from normal milk, as the following numbers will show:

	Water	Fat	Casein	Sugar	Ash
Average normal milk . .	87.550	3.070	4.160	4.760	0.730 p. c.
Milk 1st day of sickness .	91.239	0.390	2.899	4.809	0.663 „
„ 2nd „ „ .	79.903	5.010	14.380		0.707 „
„ „ „ „ .	86.320	3.838	9.135		0.707 „
„ 3rd „ „ .	87.676	0.891	3.948	7.152	0.333 „
„ 4th „ „ .	83.852	7.798	3.469	4.669	0.212 „
„ 5 „ „ „ .	87.900	1.062	10.376		0.662 „
„ 7 „ „ „ .	86.067	1.587	10.849		0.507 „
„ 14 „ „ „ .	83.882	3.061	11.478		0.679 „

The milk of the diseased cow contained organised structures which were not present in normal milk, and the globules of the butter-fat had a strong tendency to agglutinate.

According to W. Fleischmann (*Dingl. pol. J.* cxxiv. 461), 100 kg. of milk, after being left at rest for twenty-four hours for the cream to separate, and then treated by the ice process, yield the following quantities of the several constituents:

Kilograms		
20.00 Cream		<div style="display: flex; align-items: center;"> <div style="font-size: 3em; margin-right: 10px;">{</div> <div> 3.56 Butter 16.30 Butter-milk 0.14 Loss 7.93 Curd </div> </div>
79.70 Skimmed milk		<div style="display: flex; align-items: center;"> <div style="font-size: 3em; margin-right: 10px;">{</div> <div> 71.45 Whey 0.32 Loss 0.30 Loss </div> </div>
100		100

The percentage composition of fresh cows' milk, and of its products, primary and secondary, was found by Fleischmann to be as follows:

	Water	Fat	Casein	Albumin	Milk-sugar	Ash
Whole Milk	87.60	3.98	3.02	0.40	4.30	0.70
Cream	77.30	15.45	3.20	0.20	3.15	0.70
Skim-milk	90.34	1.00	2.87	0.45	4.63	0.71
Butter	14.89	82.02	1.97	0.28	0.28	0.56
Butter-milk	91.00	0.80	3.50	0.20	3.80	0.70
Curd	59.30	6.43	24.22	3.53	5.01	1.51
Whey.	94.00	0.35	0.40	0.40	4.55	0.60

The division of the individual constituents of the milk between the several products is represented by the following numbers:

Composition of Cows' Milk.

	Water	Fat	Casein	Albumin	Milk-sugar	Ash
Butter . . .	2	73	6	4	1	5
Butter-milk . . .	17	7	20	8	14	17
Curd . . .	5	14	64	70	10	17
Whey . . .	76	6	10	18	75	61

3. *Milk of other Animals.*—The milk of sheep and goats has been analysed by Macadam (*Pharm. J. Trans.* [3], iv. 959); that of mares and sows by Cameron (*Chem. News*, xxxi. 54):

	Water	Fat	Proteids	Sugar	Ash
Mare . . .	90.310	1.055	1.953	6.285	0.397
Sow . . .	81.760	5.830	6.180	5.335	0.895
	Total Solids		Fat	Ash	
Sheep . . .	17.78		5.72	0.94	
Goat . . .	13.43		4.31	0.73	

M. Schrodtt (*Landw. Versuchs.-St.* xxiii. 311) found in the milk of a five-years' old mare, ten weeks after foaling, 8.85 per cent. of dry substance, consisting of 1.27 fat, 1.50 proteids, 5.75 milk-sugar, and 0.37 ash. The fresh milk was perfectly neutral.

J. Duval found in fresh mares' milk an acid different from hippuric acid, which he designates as equinic acid (p. 736).

Reaction of Milk with Litmus, &c.—The most contradictory statements have been made as to the reaction of normal fresh cows' milk with litmus, some observers having found the reaction of milk to be acid, while others describe it as alkaline. Soxhlet considers that milk possesses what he calls an *amphoteric* or *amphigenic* reaction, i.e. that it has the remarkable property of turning simultaneously red litmus blue and blue litmus red; and this arises from the fact that milk contains both acid and neutral phosphates of the alkali-metals. Heintz maintains that a fluid containing both acid and ordinary alkaline phosphates simply imparts a violet colour to red and blue litmus paper.

A. Vogel (*J. pr. Chem.* [2], viii. 137) uses, instead of litmus-paper, a carefully prepared neutral tincture of litmus, and, as the results of his experiments, states that he has never yet found freshly drawn cows' milk with a decided alkaline reaction. When litmus-tincture which has been reddened by milk is left exposed to the air in a watch-glass, it gradually loses the red colour and passes into blue, whereas if it be closely corked up, it retains the red colour, though in some cases it seemed to become slightly blue in the course of an hour or two. In either case it acquires after three or four days a deep red, owing to the formation of lactic acid. Hence it follows that normal fresh cows' milk contains no free lactic acid. Litmus-tincture reddened by milk also becomes blue if shaken up and poured backwards and forwards from one vessel to another, and more especially on heating. Vogel thinks that the restoration of the blue colour in these cases is due to the escape of carbonic acid which fresh milk contains. Soxhlet also found that milk, when subjected to the action of the air-pump, gave up carbonic acid, and became decidedly alkaline. Other tests for alkalinity in liquids were also applied by Vogel to milk, with negative results.

Out of the milk of 30 cows which was examined by Bischoff at Schleisheim, only two specimens showed the double reaction with certainty. In the greater number of cases the reaction was either neutral or transiently acid. Some specimens, however, gave at first a weak alkaline reaction, quickly passing into acid. This effect may have been due to the absorption of ammonia by the milk, as the experiments were made in the stalls.

Fermentation of Milk.—E. Reichardt (*Arch. Pharm.* [3], v. 210) observes that milk-sugar in contact with yeast at 30° passes into alcoholic fermentation. This observation explains the fermentation of mares' milk, which is utilised in the warm climate of Asia for the preparation of alcoholic drinks, such as Koumiss, and likewise points out the means of preventing the spontaneous fermentation of milk, by cooling it rapidly, keeping it in cool places, and protecting it from contact with dough or fermenting liquids, by which yeast-germs might be introduced into it.

E. Tisserand (*Compt. rend.* lxxxii. 266) observes that the nearer milk is brought to the temperature of 0° C., the more quickly does the cream rise to the surface, and the more complete is the separation, so that the yield of butter is thereby increased;

moreover, both the butter and the cheese are improved in quality by exposure to low temperatures during their preparation, probably in consequence of the effect of the cold in arresting the development of organisms which excite fermentation.

According to Soxhlet (*Dingl. pol. J.* cccxiii. 329), milk cooled by ice-water remains sweet and unaltered for fourteen days, but afterwards gradually acquires a rancid taste, and after twenty-eight days becomes coagulable by boiling, in consequence of the presence of acids formed by oxidation of the milk-fat; after thirty-four days it was found to coagulate even in the ice-water.

Observations on the use of *Salicylic acid* as an antiseptic in dairy operations have been published by Manetti a. Musso (*Ber.* ix. 1438; *Pharm. J. Trans.* [3], vii. 175).

On the use of Boric acid for preserving milk, see Hirschberg (*Arch. Pharm.* [5], 520).

Coagulation of Milk.—According to Béchamp (*Compt. rend.* lxxvi. 654, 836), the coagulation of milk is due to the peculiar physiological activity of *microzymes*, which are present in normal milk, and simultaneously excite alcoholic, acetic, and lactic fermentation, whether they have been previously developed into bacteria or not. Recently drawn cows' milk contains alcohol and acetic acid, the quantities of which increase in the curdled milk. Matthieu a. Urbain, on the other hand, attribute the coagulation of milk to a process of oxidation, and the consequent formation of acids.

The observation of Schwalbe (vii. 811), that the curdling of milk is prevented by oil of mustard, has been confirmed by A. Vogel (*N. Rep. Pharm.* xxiii. 505), who finds that this compound greatly retards the formation of lactic acid. *Bitter almond oil* and *cinnamon oil* likewise retard the formation of acids, but in a much lower degree than mustard-oil. Turpentine-oil, clove-oil, benzin (light petroleum), phenol, carbon disulphide, and hydrogen sulphide, added in the proportion of 1 drop to 20 grams of milk, produce scarcely any retarding action. Schwalbe's observation that casein is converted by mustard-oil into albumin has not been confirmed by Vogel.

According to Schreiner (*Landw. Versuchs.-St.* xxii. 60), boiled milk does not coagulate spontaneously so soon as unboiled milk; whilst, on the contrary, boiled milk requires 10 to 12 per cent. more acid to coagulate it than unboiled milk does. The amount of rennet which serves to curdle fresh milk is insufficient to curdle one-tenth the amount of boiled milk, even when applied ten times as long, and at the same temperature (35° C.) The time required for spontaneous coagulation of fresh milk, and the amount of acid required to produce the same effect, depend on the amount of solids in the milk. Unboiled milk treated with rennet curdles the sooner, the less the amount of total solids. The amount of acid required to coagulate milk from the same animal increases in the time from the last calving up to the subsequent dry period, with the increase of the total solids during the lactation period. Milk from Friesland cows gave during this time an increase of solids of from 11 to 13 per cent., whilst that from Simmenthal cows gave an increase from 12 to 16 per cent. Crosses between the two breeds gave milk which sometimes approached the one, and sometimes the other in the amount of increase. Milk, when boiled, evolves hydrogen sulphide which may be easily detected in the usual way.

Dialysis of Milk.—When milk is subjected to dialysis through sized paper, the casein remains on the dialyser in the form of a finely divided precipitate insoluble in soda-ley, acetic acid, and in the concentrated diffusate of the milk, whence it appears to have undergone alteration. If the dialysis be allowed to go on for about thirty hours, and the inner liquid be then filtered, a neutral solution of casein is obtained nearly free from fat, containing only small quantities of the phosphates of magnesium and calcium, and yielding on acidulation a precipitate of casein: the soluble salts, therefore, contribute nothing to the retention of the casein in solution in the milk. If the dialysis be continued for a longer time, the casein becomes insoluble, and the diffusate contains a little albumin, together with a nitrogenous crystalloid substance which Schmidt regards as the solvent of the casein and of the calcium phosphate. Casein, precipitated by acetic acid from diluted milk, washed with water, dissolved in soda-ley, and freed from fat by ether, gave by dialysis a neutral liquid, yielding on acidulation a precipitate of casein which dissolved in the concentrated milk diffusate. Casein is therefore insoluble in water, but is retained in solution in milk through the agency of certain nitrogenous bodies. Casein, precipitated in consequence of spontaneous acidulation, dissolves in the diffusate of milk; casein precipitated by rennet does not.

Milk contains a ferment which converts milk-sugar into lactic acid, and therefore plays an important part in the spontaneous coagulation of milk. The coagulation produced by rennet takes place even in the alkaline liquid, so that the acid plays merely an auxiliary part in the coagulation (*Al. Schmidt, N. Rep. Pharm.* xxiv. 315).

Milk Analysis. The following method is given by Ritthausen (*J. pr. Chem.* [2], xv. 329; xvi. 314). The milk, diluted with 20 pts. of water, is precipitated by a solution of cupric sulphate, and the corresponding quantity of caustic potash or soda-ley; the precipitate, which contains all the proteids and all the fat, is collected on a weighed filter, and the filtrate is used for estimating the milk-sugar by Fehling's process. The fat is extracted from the copper precipitate by ether* and estimated, and the copper precipitate, after final washing with alcohol, is dried, weighed, and ignited, the loss of weight on ignition being reckoned as protein-substance. Ritthausen finds in milk a very small quantity of a carbohydrate different from milk-sugar, and exhibiting some resemblance to dextrin.

G. Christenn (*Landw. Versuchs.-St.* xx. 439) has discussed the several methods which have been proposed for the analysis of milk, and gives the preference to that of Haidlen (iii. 1015), which may be applied to the analysis of the milk of any animal. It consists in mixing the milk with one-fifth of its weight of finely powdered gypsum, evaporating to dryness at 110°, and weighing the residue, the loss giving the amount of water, and the weight of the residue, *minus* the gypsum, giving the weight of solid constituents. The fat is then extracted from this residue by ether, then the milk-sugar and soluble salts by alcohol of 85 per cent. The last residue contains the albuminoids and insoluble salts, the weight of which is equal to that of this residue after deduction of the gypsum. The quantities of the soluble and insoluble salts are determined in the usual manner, and the weight of the latter deducted from that of the last residue gives the amount of the albuminoids.

The alterations in this method, proposed by Christenn, are: 1st, to add powdered glass instead of plaster of Paris* to the milk before evaporating to dryness, in order to avoid errors arising from the hygroscopic nature of the plaster of Paris, and from the solubility of this substance in dilute alcohol. This latter source of error gives too high results for the sugar, at the expense of the albuminoids. 2nd, to dry the residue at 95°-100° instead of 110°.

The following process, devised by Christenn, also gives satisfactory results, closely agreeing with those obtained by Haidlen's method. 10 grams of milk are mixed with 10 c.c. of ether and 20 c.c. of alcohol; the mixture is well stirred; and the precipitated albuminoids are collected on a weighed filter, and washed with a mixture of 1 part of ether and 2 of alcohol, until the filtrate, which is at first turbid, begins to run through clear. The precipitate, dried at 95°-100°, gives the weight of albuminoids and insoluble salts; and the weight of the latter is obtained by ignition. The filtrate evaporated to dryness gives the amount of fat, soluble salts, and milk-sugar; the fat is extracted with ether, the residue weighed, and the fat determined by difference. The mixture of soluble salts and sugar is ignited, and the residue treated with hot water. The weight of soluble salts is obtained by evaporating the aqueous solution to dryness and igniting.

Estimation of Fat.—Macnamara (*Chem. News*, xxvii. 242) encloses 10 c.c. milk and an equal volume of ether and alcohol in a tube holding 50 c.c., heats the liquid for two hours to 80°, then empties the tube, evaporates down to 10 c.c., agitates the residue with ether, and weighs the residue of the ethereal solution after drying it at 100°.

Brunner (for the analysis of woman's milk) adds acetic acid in quantity sufficient to neutralise the alkaline reaction, heats the liquid to boiling, and adds an indifferent salt, such as magnesium or sodium sulphate. The resulting precipitate contains the whole of the proteids and of the fat, which latter may be exhausted from it by ether.

J. Horsley (*Chem. News*, xxix. 224) estimates the fat by introducing 15 c.c. of the milk into a graduated glass tube 11 inches long, then adds an equal volume of ether, and agitates continuously for five minutes. An equal quantity of alcohol is then added, and the liquid, after renewed agitation for five minutes, is left at rest for some time, whereupon the fat collects at the top as an oily layer, and may be directly read off by the graduation, or pipetted off and weighed. The casein separated in this operation may be removed by filtration, and the milk-sugar and salts determined in the filtrate by known methods.

E. L. Cleaver (*Pharm. J. Trans.* [3], v. 703, 718) has compared the several methods proposed for the estimation of fat in milk, and has arrived at the following conclusions:

- (1). Cold ether does not dissolve the whole of the fat from a dry milk-residue.
- (2). Neither does boiling ether take up the whole if the milk-residue is in the state of a coherent mass.
- (3). The residue should be finely pulverised, and treated with boiling ether at least 3 or 4 times.
- (4). During evaporation the boiling of the ether must, as far as possible, be avoided.

* All such additions may, however, be dispensed with, since Wanklyn has shown that milk-residues may be easily and completely dried without the addition of any solid matter (vi. 830).

W. C. Heraeus (*Arch. Pharm.* [3], xii. 443) estimates fat and water in milk by introducing 10 grams of the sample mixed with powdered glass into a small silver boat, placing the boat in an iron tube, one end of which is connected with a Bunsen pump, and the other with a glass tube containing quicklime, and draws air at a temperature of about 35° through the tube for 30 minutes, at the expiration of which time the mixture is found to be perfectly dry. The residue is treated with petroleum ether, and the fat determined from the loss.

Estimation of Nitrogen and Proteids.—Nencki (*Deut. Chem. Ges. Ber.* viii. 1047) finds the direct method of estimating the proteids in woman's milk unsatisfactory, and recommends that the milk be evaporated to dryness with lead chromate, and the nitrogen estimated by Dumas' method. The following are the analytical results:

Days after birth	Albumin directly found	Albumin calculated from the nitrogen found
12	1.6	2.26 per cent.
13	1.26	2.26
15	1.25	2.70
4	2.3	3.19 ⁶
8	1.3	2.40
9	1.12	2.04
10	1.12	1.77
4	1.38	2.75

L. Liebermann (*Wein. Akad. Ber.* [2 Abth.], lxxii, 118) finds that, in the analysis of milk by the methods of Brunner and of Hoppe-Seyler, a considerable portion of the protein-substance escapes precipitation, whereas Haidlen's method precipitates the whole. The proteids of milk may also be completely precipitated by tannin. Milk contains a proteid distinct from albumin and casein, but no nitrogenous body not belonging to the proteid group (comp. Wynter-Blyth, p. 1323).

G. Lachenal (*M. Arch. ph. nat.* lv. 187) has made comparative analyses of the milk of women and of cows, in order to determine whether the whole of the protein-substances can be obtained by precipitation. For cows' milk, he found by precipitation 3.1 per cent., by nitrogen-estimation (Dumas' process) 3.14 per cent. of protein-substance; for woman's milk, 1.41 per cent. by precipitation, 2.53 by nitrogen estimation. For cows' milk, therefore, both methods are applicable, but for woman's milk this is not the case. Cows' milk is richer in proteids than human milk. The serum of cows' milk, after coagulation of the proteids, contains neither casein nor albumin, whereas in woman's milk, after coagulation, nearly the half of these bodies remains in the serum.

To estimate the casein, Manetti a. Musso pour 50 c.c. of very slightly acidulated milk into a basin, and heat it to 39°–40° over a water-bath having a temperature of 50°–60°, then add a few drops of glycerin-solution, and expose the liquid to a temperature of 35°–40°. When the coagulation is complete, the mass is chopped up, washed on a filter, and freed from fat by digestion with alcohol and ether, and the coagulum is dried at 115° and weighed. The phosphates precipitated at the same time are estimated by incinerating the dried mass.

The following method for the estimation of casein and fat in milk is given by J. Lehmann (*Liebig's Annalen*, clxxxix. 358–367). Five grams of milk diluted with an equal weight of distilled water are allowed to flow slowly from a pipette on to a porous earthenware plate standing over sulphuric acid, but covered with a clock-glass to prevent the evaporation of the milk. The pores of the plate must be so small as not to admit the passage of the smallest milk-globule, the diameter of which is 0.001 to 0.025 millimeter. In two hours the serum of the milk will be absorbed by the plate, leaving behind the casein and fat. This residue is removed by the aid of a sharp horn spatula, dried for two hours at 105°, and weighed. The fat is dissolved out in the usual way with ether; and the residue, consisting of casein and mineral matter, is weighed, then ignited, and the weight of ash deducted from the weight of casein and ash. This method gives good results; the fat determinations agree with those made by the ordinary process of evaporating to dryness and extracting with ether; but the amount of casein is higher than that which Hoppe-Seyler obtains by precipitating with acetic acid. The great drawback to the process is the difficulty of obtaining plates possessing the requisite degree of porosity.

MILK-SUGAR. See SUGARS.

MINERALS. *Formation of Metalliferous Veins.*—F. Sandberger (*Deut. Chem. Ges. Ber.* x. 2233), has examined a number of rock-forming minerals, such as olivine, hornblende, augite, and mica, for constituents occurring in the metalliferous veins by which the rocks are traversed, e.g. silver, lead, copper, zinc, cobalt, nickel, bismuth,

arsenic. The result of this examination shows a most intimate relation between the minerals in the veins and these traces of constituents in the adjacent rocks, and thus affords a direct proof of Bischof's suggestion 'that the metals of sulphuretted ores existed previously as silicates in the neighbouring rocks.'

Experiments and observations on the accumulation of copper-ores in veins have been published by C. A. Burghardt (*Chem. News*, xxxvi. 281), leading to the conclusion that crystalline rocks contain metallic copper, which is converted by solutions of sodium chloride and carbonic acid into cuprous oxide, cupric chloride, and malachite. Experiment showed further that iron pyrites and a solution of cupric chloride react at 135°–210°, in such a manner as to form cuprous chloride, ferrous sulphate, cupric sulphate, and cuprous oxide; and that cupric chloride with water at 160°–180° yields a body resembling atacamite, together with free hydrochloric acid. The occurrence of brown hæmatite in association with copper ores is referred to the further decomposition of the ferrous sulphate, and the transference of silica to the veins in the form of opal, to the action of the hydrochloric acid on the adjacent rock.

On the Reduction of Noble Metals by Metallic Sulphides in the Veins, see METALS (p. 1287).

Formation of the Minerals which accompany Metalliferous Veins.—Experiments, old and new, on the formation of these minerals, have been published by Th. Scheerer (*Pogg. Ann. Jubelb.* 1874, 314). *Calc spar* is formed from solutions of calcium carbonate in water containing carbonic acid; in like manner *dolomite*, and probably also *brown spar*, from the corresponding solutions. *Barium sulphate* may be obtained in crystals partly grouped together, by heating a dilute solution of barium chloride to 245° with a slight excess of sulphuric acid. The artificial formation of *fluorspar*, and the simultaneous formation of *fluorspar* and *heavy spar*, have already been described in this volume (p. 798). *Silica* and *fluorspar* were obtained by the mutual action of barium silico-fluoride and calcium chloride at 250°, the latter in octohedrons, the former not as quartz but as a hydrate. All Scheerer's experiments on silica led to the same result, so that the attempts to obtain quartz were not successful. The crystallisation of *fluorspar* in octohedrons at high, and in cubes at ordinary temperatures (p. 798), may throw light on the occurrence of the octohedral form in the older veins, and of the cube in those of more recent formation. All these experiments point to the conclusion that the minerals accompanying metallic ores, and therefore also the veins of ore themselves, have been formed in the wet way, in some instances under high pressure and at high temperatures.

Decomposition.—According to F. W. Clarke (*Sill. Am. J.* [3], xiii. 290), many minerals may be decomposed by mixing them in fine powder with a threefold weight of common salt, covering the mixture with 12 to 15 parts of acid potassium sulphate, and fusing it.

Decomposition by Carbonic Acid.—J. R. Müller (*Jahrb. f. Min.* 1877, 739) has examined the action of water containing carbonic acid, continued for seven weeks under a pressure of 3½ atm. on the following minerals and rocks:

1. *Adularia* from the St. Gotthard. 2. *Oligoclase* from Ytterby. 3. *Hornblende rock* from Altenburg: admixed quartz was as far as possible removed. 4. *Magnetic iron oxide* from the Greiner: crystallised. 5. *Magnetic iron ore* from the Kaschberg in Bohemia: a mixture of augite and magnetic iron oxide, which latter was as far as possible removed by the magnet. 6. *Moraxite* from Hammond, N. America, in crystals of the combination $\infty P.P. \infty P2$. 7. *Apatite* from Katharinenburg. 8. *Asparagus-stone* (a variety of apatite) from Chili. 9. *Olivine rock* from the Uiten-
thal. 10. *Noble Serpentine* from Snarum.

In the following table the first eight columns show the number of parts out of 100 of each constituent of the mineral which passed into solution; the last gives the total amount per cent. of matter produced:

	SiO ²	Al ² O ³	K ² O	Na ² O	MgO	CaO	P ² O ⁵	FeO	Total
1.	0.1552	0.1368	1.3527	—	—	trace	—	trace	0.328
2.	0.237	0.1713	trace	2.367	—	3.213	—	trace	0.533
3.	0.419	trace	—	trace	trace	8.528	—	4.829	1.536
4.	—	—	—	—	—	—	—	0.942	0.307
5.	trace	—	—	—	—	29.015	—	2.428	1.821
6.	—	—	—	—	—	1.696	1.417	—	1.529
7.	—	—	—	—	—	2.168	1.822	—	2.018
8.	—	—	—	—	—	1.946	2.12	trace	1.976
9.	0.873	—	—	—	1.291	trace	—	8.733	2.111
10.	0.354	—	—	—	2.649	—	—	1.527	1.211

Former analyses of the several minerals and rocks were used in the calculations,
Vol. VIII. 4 R

so far as they were available; the following analyses were made specially for this inquiry:

	SiO ²	P ² O ⁵	Al ² O ³	Fe ² O ³	FeO	MgO	CaO	K ² O	Na ² O	H ² O	
1.	65.24	—	18.15	—	trace	—	1.28	14.96	—	—	= 99.63
3.	49.12	—	9.004	14.62	10.305	5.92	8.761	—	2.13	—	= 99.86
5.	1.0655	—	0.4815	61.14	32.2164	—	3.507	—	—	—	= 99.4104
6.	—	44.088	—	1.065	—	—	53.319	—	—	—	= 98.755
9.	40.60	—	0.86	—	12.35	45.81	trace	—	—	—	= 99.62
10.	40.82	—	2.19	—	6.01	36.78	—	—	—	13.48	= 99.28

In 6 also Cl=0.283 per cent.; in 9 traces of copper.

The solutions of the following minerals in aqueous carbonic acid were examined only qualitatively: (1). *Potash mica* from the Ural yielded K²O, CaO, Fe²O³, with trace of SiO². (2). *Cobalt-bloom* from Schneeberg, with admixed quartz yielded Co, Ni, Fe²O³, SiO². (3). *Nickel-bloom*: Ni, Co, Fe²O³. (4). *Wolfram* from the Zinnwald, mixed with quartz, MnO, Fe²O³, SiO².

The final conclusions are as follows: Among the silicates examined, the most easily decomposable is olivine; the bases and acids removed from this rock are to one another in about the same proportion as in serpentine. Hornblende is more easily decomposed than felspar; oligoclase more easily than adularia. The most refractory of all the substances was magnetic iron oxide; apatite is easily attacked, and exhibits after treatment a striking contrast to the appearance of the fresh apatite-crystals of the rock under the microscope.

Action of Organic Acids on Minerals.—H. Carrington Bolton (*Chem. News*, xxxv. 114) finds that, contrary to preconceived ideas based on general notions of the weakness of organic acids, many minerals in fine powder are decomposed by boiling with solutions of citric, tartaric, oxalic, and other organic acids. A large number of carbonates dissolve with effervescence in solutions of the above-mentioned acids, and many sulphides, silicates and other classes of minerals are more or less completely decomposed. The reactions which accompany these decompositions, such as evolution of gases, formation of crystalline precipitates, &c., are characteristic of certain minerals. Moreover, since citric and tartaric acids decompose potassium nitrate, with liberation of nitric acid, a powerful means of attacking sulphides and arsenides which resist organic acids alone is obtained. Metallic copper, lead, tin, and silver also dissolve in the above mixture of reagents. Chlorate of potassium is slower in action than the nitrate. Various silicates yield readily to the action of citric acid in solution, gelatinising as with mineral acids. Besides these acids, Bolton also examined the action of malic, formic, and acetic acids on carbonates, for the sake of comparison, acetic acid giving the least satisfactory result. He recommends the use of these non-volatile acids for mineralogical as well as microscopic work, as the dry acids are readily transported, and can be dissolved when needed.

Observations relating to the same subject have been made by B. J. Grosjean (*ibid.* 190), who finds that a weak solution of tartaric acid acts more readily on calcium carbonate than a strong solution containing the same weight of the acid. When the carbonate, either precipitated or in the form of whiting, was digested in 20 pts. of boiling water containing 4 pts. of tartaric acid, nothing was dissolved in either case, even when the acid was doubled and concentrated to a syrup. When, however, the carbonate is treated with 20 parts of water saturated with tartaric acid, the carbonate dissolves even without dilution of the acid.

On the action of *Iodine*, *Potassium iodide*, and *Citric acid* on certain Minerals, see Bolton (*Chem. News*, xxxviii. 168; *Chem. Soc. J.* xxxiv. 940).

Pyrometric examinations of individual mineral species have been published by W. A. Ross (*Chem. News*, xxxvi. 106, 156).

On *Fluid-cavities in Minerals*, see p. 793.

Minerals formed by the Volcanic Vapours of Vesuvius.—After the eruption of April 26, 1872, numerous minerals were found amongst the sublimation products, including various silicates and fine crystals of apatite, together with iron pyrites in several forms, and large quantities of tenorite. The crystals of the latter mineral, without losing their shape, have been changed by the hydrochloric acid escaping from the fumaroles, into a green body, named, *ateline* which contains 45.59 of cupric oxide, 38.19 of cuprous chloride, and 16.22 of water. Sylvine and sodium chloride were found in large quantities, and generally mixed together. Sal-ammoniac was abundant and in the finest crystalline forms, but not in octohedrons; it was also found in the fumaroles in beautiful yellow crystals, formed after the colourless ones.

The crystals were black at a spot where a charred tree stump lies buried in the lava. Fluorine was found in combination with ammonia and silica, probably as a double salt, $2\text{NH}\cdot\text{F}\cdot\text{SiF}^4$, for which the name *cryptohalite* has been proposed. Calcium chloride occurred in large quantities; it seems to have been formed at the beginning of the eruption; cotunnite was abundant. A new mineral, *erythrosiderite*, consists of red rhombic crystals. Ferric chloride, $(\text{Fe}^2\text{Cl}^6 + x\text{H}^2\text{O})$, occurs in the clefts of the lava, and is often mistaken for sulphur. Sodium-potassium sulphate, *aphthalos*, or *aphthithalite*, was found in white hexagonal laminæ. Anhydrite was not so common. Hydrofluoric acid was found inside the crater in masses of gypsum and sulphur (G vom Rath, *Jahrb. f. Min.* 1877, 844).

Minerals and Rocks of the Island of Vulcano (A. Cossa, *Gazz. chim. ital.* 1878, 235).—This island, belonging to the Lipari group, contains large deposits of potassium-alum, mixed in various proportions with the alums of thallium, cæsium, and rubidium.

The principal deposits of alum are found in the caves of the Faraglione and in the great crater. The Faraglione, also called 'Rocca dell' alume,' is a mass of trachytic rock—decomposed for the most part by sulphuric acid—situated at the southern extremity of the narrow isthmus which joins Vulcanello to Vulcano, and stretching laterally towards the sea. The potassium-alum in its cavities is intimately mixed with aluminium sulphate, gypsum, and sal-ammoniac. In the inner northern wall of the crater of Vulcano there is a rather extensive space called '*la Schicciola*,' formed of a white compact rock to which the potassium-alum adheres in layers of various thickness. From several places in this rock there drips a liquid having a strong acid reaction, and dense enough in some parts to form stalactites with concentric zones. In other parts of the same locality, the liquid which drops from the fissures of the rock contains—in addition to potassium-alum—aluminium sulphate and sodium-alum, which, being much more soluble than the potassium-alum, separate from the latter, and collect at the base of the rock in a crystalline mass of very slender needles, forming the outermost layer of the crystalline matter which adheres to the rock. These more soluble salts exhibit here and there a faint yellow tint due to iron-compounds, or a green tint arising from copper. A specimen examined by the blow-pipe gave the reaction of cobalt, the presence of which was confirmed by testing in the wet way.

The alum of *la Schicciola*, as it comes from the rock, gives a scarcely perceptible indication of the presence of thallium, even when examined with a good spectroscope, the sodium salt with which it is contaminated interfering with the development of the lines which are characteristic of the other metals; but the less soluble salts, when purified by repeated crystallisation, show distinctly, not only the single green line of thallium, but also the lines α and β of cæsium and rubidium.

The alum obtained from different parts of *la Schicciola* contains various quantities of cæsium and rubidium. The exact amounts have not yet been determined, on account of the difficulty of separating these two metals from potassium, and the still greater difficulty of separating them one from the other. Cossa is, however, of opinion that, with the exception of pollux, a mineral found in extremely small quantities on the island of Elba, the alum of Vulcano is the richest known source of cæsium and rubidium.

The separation of cæsium from rubidium is most completely effected by Godeffroy's method of precipitation with antimony trichloride from a solution of the two alums in hydrochloric acid, whereby the cæsium is completely precipitated in the form of the double chloride, $\text{SbCl}^3\cdot 6\text{CsCl}$, while the whole of the rubidium remains in solution (*Deut. Chem. Ges. Ber.* vii. 375; viii. 9; *Chem. Soc. J.* 1876, ii. 272). Stolba's method of precipitation with stannic chloride (*Dingl. pol. J.* cxvii. 336; cxviii. 225) does not give good results, the stannochloride of rubidium, as well as that of cæsium, being insoluble in strong hydrochloric acid.

To determine whether the rock of *la Schicciola* to which the alum adheres has been simply percolated by a solution of cæsiferous alum, or whether the materials of this alum have been furnished by the decomposition of the rock itself, fragments of the rock, after being repeatedly washed with water to remove the alum, were finely pulverised, and the powder was further washed with boiling water, till the washings, when examined by the spectroscope, gave not the slightest indication of potassium. The remaining powder was then decomposed with a mixture of strong sulphuric and hydrofluoric acid, and the mass was washed with boiling water to remove the greater part of the sulphuric acid, whereby a solution was obtained which, when duly concentrated and left at rest, deposited fine crystals of potassium-alum, the solution of which gave by the spectroscope distinct evidence of cæsium and rubidium. Hence it is highly probable that these two metals existed in the rock in the form of silicates.

The mother-liquors separated from the first crystals of the alum obtained as just described, and containing large quantities of the sulphates of aluminium and sodium,

with traces of lithium sulphate, yielded, on addition of sulphuric acid, a precipitate of arsenious sulphide mixed with selenium sulphide. The form in which the arsenic and selenium exist in the rock has not yet been determined.

The rock of *la Schicciola* has a white colour with a slight tinge of yellow, and melts with difficulty, even in thin splinters, producing a white enamel. Its sp. gr. at 12° varies from 1.942 to 2.011. It appears to belong to the liparite group, and contains, in the midst of a microfelsitic paste which does not depolarise light, crystals of orthoclastic felspar, some of which are twinned according to the Carlsbad law. The quartz, which is chiefly in the form of tridymite, does not contain any fluid-cavities, but exhibits polyhedral corpuscles. The rock also contains some very small isometric crystals, the mineral species of which has not yet been determined.

Three unaltered lavas from Vulcano, after treatment with sulphuric acid, also yielded crystals of alum containing cesium and rubidium.

On the edges of a small fumarole at the bottom of the crater of Vulcano, there is found a spongy substance having a crystalline texture, reddish on the surface and dark ash-coloured below. It consists of a mixture of arsenious sulphide, selenium sulphide, boric acid, ammonium chloride, lithium sulphate, thallium- and cesium-alums, and traces of rubidium- and potassium-alums. On treating it with boiling water, the sulphides of arsenic and selenium separate out, and the slightly concentrated solution soon deposits the sparingly soluble alums of thallium and cesium.

Another substance, similar to the preceding, except in the absence of the sulphides of arsenic and selenium, is still richer in the alums of cesium and thallium. In all these porous substances which cover the walls of certain fumaroles, and have the aspect of burnt alum, the quantity of cesium is much greater than that of rubidium.

Aluminium sulphate, mixed with traces of alums, occurs also in the numerous mineral springs which rise up in various parts of the island.

To the south-west of the Faraglione, not far from the works where the boric acid and sulphur are purified, there is a well containing water about a foot and a half deep, from the bottom of which bubbles of gas are continually rising in large quantity, so as to give the water the appearance of boiling. This gas consists chiefly of carbon dioxide, whence the well was called by C. Sainte-Claire Deville, *la Grotta del Cane dell'isola di Vulcano*. The following are analyses of the gas by Deville and Cossa:

	Deville, July 9, 1856.			Cossa, Oct. 17, 1877.	
	Temp. of the gas + 25°.			Temp. of the water + 22°.	
CO ₂ . . .	86.0	83.0	86.0	78.0	80.0

	<hr/> 100.0	<hr/> 100.0	<hr/> 100.0	<hr/> 100.0	<hr/> 100.0

MIRIQUIDITE. This name is given by Frenzel (*Jahrb. f. Min.* 1874, 673) to a blackish or yellowish-brown mineral, accompanying the copper-uranium phosphate (Kupferuranglimmer) of Schneeberg in Saxony. It is a highly basic mineral containing Fe²O₃, As²O₃, P²O₅, and H²O. According to vom Rath, the small hexagonal crystals exhibit the combination R. — $\frac{1}{2}$ R, and have the angle R : R = 66°; whence the ratio of the principal to the secondary axes is 3.363 : 1.

MISTLETOE (*Viscum album*). The ash-constituents of this plant, growing on poplar, acacia, and pine, together with those of the wood of these trees, have been analysed by Grandean and Bouton (*Compt. rend.* lxxxiv. 129, 500). The following table contains the amount of ash per cent. in the dried plants, and the percentage composition of the ash for poplar I, acacia II, and pine III:

These numbers show that the mistletoe assimilates the mineral constituents of the plants on which it lives in very unequal proportions, and that these proportions bear no direct relation to the ash of the plant itself. The amounts of proteids, fat, and woody fibre in the mistletoe likewise vary with those of the plant on which it grows.

Grandean and Bouton have likewise investigated the proximate composition of the branches, leaves, and fruits of the mistletoe from the oak, willow, dog-wood, and pear-tree, with the view of determining the relative nutritive value of the same when employed for feeding cattle. From the numerical results, the following facts may be gathered:

That while the composition of the leaf and branch of the same specimen is nearly identical, their percentage of nitrogenous constituents, when compared with that of the same parts of mistletoes growing on different trees, varies very greatly, as much as 25.66 to 13.02 per cent. for the leaves, and 20.4 to 7.25 per cent. for the branches.

Ash of Mistletoe.

	Wood			Mistletoe on		
	I	II	III	I	II	III

	27·47	31·765	25·878	16·636	20·167	18·99

That the fruits of pear-tree and dog-wood mistletoe are comparatively poor in nitrogenous substances.

That the percentage of non-nitrogenous extractive matter varies greatly in mistletoes growing on different trees (53·20 to 39·94 per cent.), while the proportions of gum and resinous matter are tolerably constant.

That the percentage of ash bears no well-marked relation in any way to the nutritive value of the specimen. Grandea u. Bouton are of opinion that the composition of the green parts of the mistletoe, as shown by their analyses, perfectly justifies the use which is made of it in some districts as an article of fodder. They think that the mistletoe of the oak may rank in nutritive value with ordinary grass and clover; that the leaves of the dog-wood and pear-tree mistletoes are about equal to good hay; and that their branches are about equal in nutritive value to pea-straw, bean-straw, and the chaff of cereals.

MOLYBDENUM. *Atomic Weight.*—Rammelsberg, by reducing the trioxide to metal in hydrogen gas, finds for the atomic weight the number 96·18, agreeing nearly with that which Lothar-Meyer found from the analysis of the chlorides (vii. 816), viz. 95·8. Rammelsberg therefore adopts the number 96 (*Ber. x.* 1776).

Estimation.—Wernicke (*Zeitschr. anal. Chem.* 1875, 1) estimates molybdenum volumetrically by reduction with nascent hydrogen (zinc and sulphuric acid) and re-oxidation with permanganate. De-aërated water must be used for dilution, and the titration performed as quickly as possible, since the air acts rapidly on the reduced product. The method is, however, not very exact, the results differing by 1 to 2 per cent.

Alloy. An alloy of molybdenum and lead occurs in plates measuring 30 mm. in the Empire Mine, Lucin District, Box-Elden County, Utah (B. Silliman, *Sil. Am. J.* [3], vi. 128). Hemimorphous crystals of lead molybdiide from the Upper Schwarzwgrubner vein at Pribram are described by Zerrenner (*Jahrb. f. Min.* 1874, 91).

Chlorides. The *pentachloride*, MoCl⁵, readily parts with two of its chlorine-atoms, and is very useful in the preparation of organic chlorine-compounds as a carrier of chlorine, inasmuch as the molybdenum passes quickly and regularly from one stage of chlorination to another, and is easily removed by ammonia from the product; benzene, for example, is very easily converted by its agency into paradichlorobenzene (p. 172). When carbon disulphide (250 grams) is mixed with the pentachloride (3 or 4 grams), and a strong stream of dry chlorine is passed through the liquid, which must ultimately be warmed, a liquid is formed, which, by fractional distillation and further treatment of the several fractions, may be resolved into carbon tetrachloride and sulphur dichloride, CS² + 3Cl² = CCl⁴ + S²Cl² (Aronheim, *Ber.* ix. 1788).

On the lower Chlorides of Molybdenum, see Liechti a. Kemper (vii. 816).

On the Ferrocyanides of Molybdenum, see CYANIDES (p. 613).

Trioxide, MoO_3 . *Molybdic Acid*.—When this acid, or either of its salts, is heated with strong sulphuric acid, a mass is formed having a splendid blue colour. On evaporating the sulphuric acid, the residue becomes colourless from oxidation; but on adding fresh acid, the blue colour is reproduced, provided that the substance be removed from the flame after heating for a short time, and left to cool completely. This reaction serves for the detection of very small quantities of molybdic acid; with larger quantities the blue coloration is produced in the cold on addition of a little alcohol or sugar to the sulphuric acid (Schönn, *Zeitschr. anal. Chem.* 1869, 379). O. Maschke (*ibid.* 1873, 380) applies this test by placing a small quantity of strong sulphuric acid on a piece of platinum foil bent up into the form of a trough, then adding a small quantity of the finely pounded substance, heating till vapours are quickly evolved, leaving the whole to cool, and breathing on the foil, whereupon, if molybdic acid is present, the liquid will exhibit a bright blue colour.

Maschke also gives a process for the recovery of molybdic acid from the filtrates obtained in phosphoric acid estimations, depending on the formation of an insoluble compound of molybdic acid with lime and ammonia, and the decomposition of this precipitate by nitric acid. The acid liquids containing molybdenum are poured into jars, and lumps of marble are dissolved in them; the solution, mixed with a slight excess of ammonia, is heated to boiling in an iron pot; and the resulting precipitate, after washing and drying, is drenched with 2 pts. water, mixed, with stirring and gently heating, with 3 pts. nitric acid of sp. gr. 1.18; and the clear solution is heated for some minutes to the boiling point. The precipitate of molybdic acid containing lime and ammonia thereby separated is left to settle, the supernatant liquor still containing molybdic acid, is decanted, and the precipitate is washed by decantation till the liquid begins to clarify but slowly. The moist precipitate is then treated with ammonium carbonate, and the resulting solution of ammonium molybdate is filtered from the calcium carbonate and evaporated over the water-bath. The whole of the wash-waters are united, mixed with ammonia, and heated to boiling, and the calcium molybdate which separates is kept for the next operation.

Uelsmann (*ibid.* 1877, 52) precipitates molybdic acid from the residues with sodium phosphate, washes the precipitate, dissolves it in ammonia, precipitates the resulting solution with magnesia mixture, and evaporates the filtrate. The liquid during evaporation deposits crusts of ammonium molybdate.

Ammonium Molybdate.—Champion a. Pellet (*Bull. Soc. Chim.* [2], xxvii. 6) prepare the molybdenum solution used for precipitation of phosphoric and arsenic acids by dissolving 100 grams of molybdenum trioxide in 150 c.c. ordinary aqueous ammonia and 80 c.c. water, and pouring the solution into a mixture of 500 c.c. nitric acid and 300 c.c. water. If a precipitate forms, it must be filtered off.

According to M. Jungk (*Zeitschr. anal. Chem.* 1876, 290), the yellow crystalline precipitate deposited from a solution of ammonium molybdate—which greatly resembles the well-known precipitate of ammonium phosphomolybdate, but does not contain phosphoric acid—is produced by the action of light, the molybdic acid passing into another modification. He therefore recommends that the solution should be kept in the dark. According to S. Kern, on the other hand (*Chem. News*, xxxvii. 98), this precipitate consists of a basic ammonium salt, and is formed in the dark.

A mixture of the aqueous solutions of *ammonium molybdate* and *potassium ferrocyanide* may be used as a test for free mineral acids. Traces of free acids impart to this solution a more or less dark brown colour, which disappears on addition of the slightest excess of alkali (L. Huber, *Zeitschr. anal. Chem.* 1877, 242).

An ammonium molybdate, having the composition $(\text{NH}_4)_2\text{O} \cdot 2(\text{MoO}_3) \cdot \text{H}_2\text{O}$, is formed, as an amorphous precipitate, by heating a solution of sodium molybdate with sal-ammoniac; and the filtrate mixed with a very large quantity of alcohol, deposits a crystalline mass, which, when dried at 100° , contains 78.70 per cent. MoO_3 , 11.10 NH_3 , and 10.20 H_2O (F. Jean, *Compt. rend.* lxxviii. 1436).

Barium Molybdate has a sp. gr. of 4.6589 at 17.5° , and 4.6483 at 19.5° . **Strontium Molybdate**, 4.1554 at 20.5° , and 4.1848 at 21° (F. O. Marsh, *Sill. Am. J.* [3], xiv. 281).

Silver-diamine Molybdate, $[\text{Ag}(\text{NH}_3)_2]_2\text{O} \cdot \text{MoO}_3$. See SILVER.

Arseniomolybdates. Ammonium molybdate forms with arsenic acid a compound similar to that with phosphoric acid, and containing $3(\text{NH}_4)_2\text{O} \cdot \text{As}_2\text{O}_5 \cdot 20\text{MoO}_3$. When it is boiled with aqua regia and the solutions are evaporated, the residue which is left does not, as in the case of the phospho-compound, consist of the pure acid, but contains in addition insoluble molybdic acid and a second arseniomolybdic acid, which is white. By extracting the residue with dilute nitric acid and evaporating in the desiccator, a mixture of the two acids is obtained in crystals large enough to admit of mechanical separation. The yellow acid forms doubly oblique prisms; its probable

formula is $\text{As}^2\text{O}^5.20\text{MoO}^3+27\text{H}^2\text{O}$. It gives with acidified potash-salts a yellow crystalline precipitate of $3\text{K}^2\text{O}.\text{As}^2\text{O}^5.20\text{MoO}^3$. The hydrated acid corresponding with the phosphomolybdic acid, which crystallises from pure water, has not yet been obtained.

The white arseniomolybdic acid is $\text{As}^2\text{O}^5.6\text{MoO}^3+16\text{H}^2\text{O}$. Its ammonium salt may be readily obtained by mixing ammonium molybdate with the theoretical quantity of arsenic acid and crystallising at $50^\circ-60^\circ$. At higher temperatures the yellow salt forms. When the ammonium salt is boiled with aqua regia, a precipitate of yellow arseniomolybdate is at first produced, but subsequently disappears, and the solution on evaporation yields the white acid. It crystallises from syrupy solution in right rhomboidal prisms, and gives white gelatinous precipitates when neutralised with alkalis. The formula of the precipitate with ammonia is $4(\text{NH}^4)^2\text{O}.\text{As}^2\text{O}^5.6\text{MoO}^3+\text{Aq}$ (Debray, *Compt. rend.* lxxviii. 1408).

When a mixture of molybdic acid, arsenic acid, and an ammonium salt is boiled for some time, a crystalline precipitate is obtained, the formula of which is $\text{As}^2\text{Mo}^7\text{O}^{29}\text{H}^4(\text{NH}^2)^2.4\text{H}^2\text{O}$. It is soluble in hot water, gives with silver nitrate a yellow precipitate of $\text{As}^2\text{Mo}^7\text{O}^{29}\text{Ag}^+$, and with lead and barium salts precipitates of similar constitution. The acid itself is obtained by the direct combination of arsenic and molybdic acids; its formula is $\text{As}^2\text{Mo}^7\text{O}^{29}\text{H}^4.11\text{H}^2\text{O}$. It appears also to be formed on treating the ammonium salt with aqua regia (Seyberth, *Ber.* vii. 391).

Phosphomolybdates. The well-known yellow ammonium salt and the corresponding potassium compound have the composition $3\text{R}^2\text{O}.\text{P}^2\text{O}^5.22\text{MoO}^3.12\text{Aq}$. By the action of a small quantity of potash-solution, the yellow potassium salt is converted into a white insoluble modification, $5\text{K}^2\text{O}.\text{P}^2\text{O}^5.15\text{MoO}^3$. On boiling the alkaline filtrate from this salt, a flocculent precipitate of $\text{K}^2\text{Mo}^3\text{O}^{10}$ is obtained. By dissolving this compound in a small quantity of potash-solution and adding phosphoric acid, a salt is obtained in white shining prisms of the composition $5\text{K}^2\text{O}.2\text{P}^2\text{O}^5.10\text{MoO}^3.20\text{Aq}$. By fusing 1 mol. K^2CO^3 with 2MoO^3 , dissolving in water, and adding phosphoric acid to the solution, a compound crystallising in large colourless octohedrons is obtained, the formula of which, $3\text{K}^2\text{O}.\text{P}^2\text{O}^5.5\text{MoO}^3.7\text{Aq}$, exactly corresponds with that assigned by Zenker (*J. pr. Chem.* lviii. 257) to the colourless compound obtained from the solution of the yellow ammonium phosphomolybdate in ammonia (Rammelsberg, *ibid.* x. 1776).

Sulphides. The native disulphide, *molybdenum-glance*, MoS^2 , occurs, with iron pyrites and copper pyrites, imbedded in greasy quartz, at Macchetto, near Quitergo, in the province of Novara, Piedmont. A and B analyses, C values calculated from the formula MoS^2 :

	A	B	C	Sp. gr.
Mo . . .	58.23	59.05	59.0	4.704
S . . .	41.86	41.17	41.0	
	99.59	100.22	100	

(F. A. Genth, *Jahrb. f. Min.* 1877, 949).

Sulphomolybdate of Ammonium, prepared by treating the bimolybdate with strong sulphuric acid, is a very delicate test for many alkaloids, especially for *morphine*, with which it produces a distinct blue colour, even to the millionth degree of dilution. The blue colour appears immediately with 1 pt. *morphine* in 100,000 pts. of solution, and in presence of milk-sugar with 3 pts. in 100,000. The blue colour disappears after some hours. *Quinine* gives, with the same reagent, a light green colour which soon disappears; *strychnine*, *atropine*, and *santonine*, no reaction; *veratrine*, a dirty brown colour, changing to blue and finally to yellow-green; *narcotine*, a yellow-green which soon disappears; *brucine* red, changing to yellow. It must be observed, however, that the reagent, even when left to itself, turns blue after a few hours, especially when exposed to light, on which account it must be prepared fresh for use (Nagelvoort, *Arch. Pharm.* [3], ix. 249).

MONAMINES. The synthesis of aromatic monamines by intramolecular atomic interchange—which Hofmann formerly effected in the methyl-series, converting, for example, trimethylphenylammonium iodide, $\text{C}^6\text{H}^3.\text{N}(\text{CH}^3)^3\text{I}$, by the action of heat, into the hydriodides of the bases $\text{C}^6\text{H}^4(\text{CH}^3).\text{N}(\text{CH}^3)^2$, $\text{C}^6\text{H}^3(\text{CH}^3)^2.\text{N}(\text{CH}^3)\text{H}$, and $\text{C}^6\text{H}^2(\text{CH}^3)^3.\text{NH}^2$ successively (vii. 57)—has, by his later experiments, been extended to aromatic amines containing ethyl and amyl, ethylaniline or ethylamido-benzene, $\text{C}^6\text{H}^5.\text{NH}(\text{C}^2\text{H}^5)$, for example, being converted by similar means into phenethylamine or amidoethylbenzene, $(\text{C}^6\text{H}^4.\text{C}^2\text{H}^5).\text{NH}^2$. See BENZENES, ETHYLAMIDO- and AMYLAMIDO- (pp. 205, 206 of this volume).

MONAS. The spherical Bacterium, called *Monas prodigiosa*, infects eatables, and gives them a red colour. It is conveyed from place to place chiefly by insects, and the spores are also carried through the air. Food placed under a glass shade along with *Monas prodigiosa* turned red in two or three days. When seen under the microscope with a magnifying power of 1000 diameters the monas appears to consist of round bodies, filled with a red substance and swimming in a red fluid.

The colouring matter dyes cotton and linen pink, and wool blood-red; the colour cannot be washed out, but fades on exposure to sunlight. The colouring matter is insoluble in water, and nearly so in ether, but dissolves in alcohol with a blood-red tint; the solution is neutral. There is a marked difference between this dye and the aniline-reds, as shown in the following table:

<i>Aniline-red: a weak solution of Fuchsine.</i>		<i>Colouring-matter of Monas prodigiosa.</i>
Hydrochloric acid	Violet; decolorised by excess.	Pink; unaltered by excess of acid.
Sulphuric acid	Violet; blue with more acid; faint yellow colour with large excess of acid.	Pink; violet with excess of acid.
Nitric acid	No change; with excess first dirty violet, then dull green.	Pink; dirty yellow with large excess of acid.
Potash or ammonia	Colour fades, and is not restored on addition of an acid.	Pure yellow; remains unaltered on heating. On addition of acid the pink colour is restored.
Potassium carbonate	Colour fades.	Yellow.
Ammonium carbonate	No change.	No change.
Stannous chloride	Violet.	No change at first, but gradually bleached.

Lime water, weak solution of chromic acid, and sodium hypochlorite change the yellowish-red colour of the bacterium to yellow; it is destroyed by chloride of lime, or chlorine.

The alcoholic solution of this colouring matter may be kept exposed to light for a long time without change. On evaporation of the alcohol, the colour is obtained in the solid state. It dissolves in petroleum-ether, benzene, and carbon disulphide, in all of which aniline-red is insoluble.

The colour may be obtained tolerably pure by slowly evaporating its alcoholic solution and dissolving the deposit in petroleum-ether, which leaves undissolved a brown tarry residue. On evaporation of the solution in petroleum-ether, the dye is obtained in the same state (O. Helm, *Arch. Pharm.* [3], vi. 19).

MONAZITE. Native Cerium Phosphate. See PHOSPHATES.

MONOTHIODIPRUSSIAMIC ACID. See THIOPRUSSIAMIC ACIDS.

MONTICELLITE, or *Batrachite*. Two analyses of this mineral from Monte Monzoni, leading to the formula $\text{Ca}^2\text{SiO}_4(\text{Mg},\text{Fe})^2\text{SiO}_4$, have been published by G. vom Rath (*Zeitschr. geol. Ges.* xxvii. 379):

SiO^2	FeO	CaO	MgO	Total	Loss by ignition	Sp. gr.
38.35	4.29	34.76	23.15	= 100.55	1.31	3.054
38.15	4.31	34.75	22.94	= 100.15		

MONZONITE. This name, originally applied by v. Kobell to a mineral species from Monte Monzoni (vii. 818), has also been given to a rock from Monte Agnello, South Tyrol, consisting of plagioclase, orthoclase, hornblende, augite, mica, and magnetic iron ore. This rock has a porphyritic structure like that of melaphyre. Its percentage composition is as follows:

SiO^2	Al^2O^3	Fe^2O^3	MnO	CaO	MgO	K^2O	Na^2O	Loss by ignition
52.53	19.48	11.07	trace	6.61	1.53	3.17	2.71	2.34 = 99.44

(Dörlter a. Mattendorf, *Ver. geol. Reichsanst.* 1876, 33). According to C. W. Gümbel, v. Kobell's monzonite is not a homogeneous mineral.

MOONSTONE. This name has been applied to a monoclinic felspar from Ceylon, a variety of adularia (ii. 620); also to a triclinic felspar from Mineral Hill,

Delaware County, Pennsylvania, regarded by Dana (*System of Mineralogy*, 5th Ed. p. 348) as a variety of oligoclase; according to Des Cloizeaux (*Comp. rend.* lxxx. 364), it is a variety of albite.

MORIN, $C^{18}H^{10}O^7$. This compound has hitherto been known in two modifications, viz. *Morin* and *Isonorin* (vi. 837). A third, called *Paramorin*, is obtained, together with resorcin, by the distillation of morin. When morin in portions of 1 to 2 grams is mixed with 4 or 5 parts of sand and distilled, a distillate is obtained, amounting, after expulsion of water, to 25 per cent. of the morin. After recrystallising the product from hot water, the resorcin may be extracted from the mother-liquor by ether, and the paramorin, $C^{12}H^8O^5$, crystallises from the solution on cooling in long, felted, slightly yellow, woolly, anhydrous needles, which may be purified by recrystallisation with addition of blood-charcoal. It is tasteless; melts when heated, and sublimes without decomposition; reduces an alkaline cupric solution; colours ferric chloride but slightly, and dissolves in sulphuric acid without change of colour. Paramorin dissolves very easily in boiling water and in ether (morin is but slightly soluble in these liquids, iii. 1048), and with deep yellow colour in alkalis. From its alcoholic solution, alcoholic *lead acetate* throws down only small quantities of a lead salt (whereby it is distinguished from morin). With *nitrous acid* it forms a yellow nitro-derivative; with *sodium-amalgam*, resorcin or a diresorcin:

The quantity of paramorin obtained in the distillation of morin is but small, the chief product consisting of resorcin. The woolly crystals with which morin becomes covered when heated consist of undecomposed morin (Benedikt, *Ber.* viii. 605).

Respecting Löwe's formulæ for Morin and Morintannic acid, see MACLURIN, (p. 1244).

MORINGIC ACID. This name was given by Walter to an oily acid obtained by saponification of oil of ben (*Moringa aptera*), and regarded by him as a lower homologue ($C^{18}H^{28}O^2$) of oleic acid (iii. 1049). Zaleski, however (*Deut. Chem. Ges. Ber.* vii. 1013), finds, by an examination of a sample of the acid prepared by Walter himself, that it is identical with oleic acid. The identity was shown by conversion of the acid by means of nitrous acid into elaïdic acid (m. p. 49°); by its conversion into the oleic dibromide, $C^{18}H^{32}Br^2O^2$, prepared by Overbeck from oleic acid (vi. 881), and transformation of the latter into stearolic acid [m.p. 48°; formula of barium salt ($C^{18}H^{31}O^2$) 2Ba , vi. 1038], and finally by fusion with potash, whereby, like oleic acid, it yielded palmitic and acetic acids.

MORINTANNIC ACID. See MACLURIN (p. 1244).

MOROXITE. A greenish-blue variety of apatite, originally found at Arendal in Norway, and Pargas in Finland, has lately been found at Hammond, North America, in crystals exhibiting the combination $\infty P.P. \propto P_2$, and containing 44.09 per cent. P_2O^5 , 53.32 CaO, and 1.065 Fe^2O^3 (J. R. Müller, *Jahrb. f. Min.* 1877, 739).

MORPHINE, $C^{17}H^{15}N^2O^6$. *Solubility.*—The solubility of morphine in various solvents saturated with water, and at the boiling heat, has been determined by A. B. Prescott (*Pharm. J. Trans.* [3], vi. 404) with the following results:

Morphine	Ether	Chloroform	Amyl Alcohol	Benzene
Crystallised	6148 parts	4379 parts	91 parts	8930 parts
Amorphous	2112 "	1977 "	—	—
Nascent	1062 "	861 "	91 "	1997 "

According to J. B. Barnes (*ibid.* 201) the solution of morphine in glacial acetic acid forms a perfectly clear mixture with almond-oil and turpentine-oil. The solution remains clear and unaltered for several days if mixed with chloroform or camphor, and may be prepared of any required degree of concentration.

Reactions. Detection.—1. With *ammonium sulphomolybdate*, morphine gives a blue colour, perceptible to the millionth degree of dilution (p. 1334). 2. With *hydrogen sulphide*, see ALKALOIDS (p. 56). 3. With *iodised hydriodic acid*, see p. 55. 4. An *ammoniacal solution of copper* is a delicate test for morphine, losing its splendid colour when boiled therewith, and acquiring a distinct green-blue tint. The copper solution is to be added by drops to a clear and strongly alkaline solution of morphine, till a light blue colour is produced, and the liquid then boiled up once or twice. This test will detect with certainty 1 mg. morphine to the thousandth degree of dilution. The presence of other alkaloids does not interfere with the reaction (G. Nadler, *Zeitschr. anal. Chem.* 1874, 235).

Nadler also describes a base obtained (he does not say how) by treating morphine with an ammoniacal cupric solution. The hydrochloride of this new base is described

as a dazzling white substance insoluble in cold, easily soluble in hot water, insoluble in alcohol and ether. Its aqueous solution, treated with ammonia or potassium carbonate, yields the base as a dense white amorphous precipitate, which dissolves in excess of the precipitant at ordinary temperatures, but may be recovered by boiling the potash-solution, and dries up without alteration on exposure to the air, like aluminium hydrate. The aqueous solution of the hydrochloride gives a pale yellow precipitate with platinic chloride, white amorphous with sulphuric acid, and amethyst-red with ferric chloride. Sulphuric acid with the aid of heat dissolves the base, forming a black-green liquid, which may be heated without alteration till the acid volatilises.

5. Another test for morphine is based upon the reaction of *sulphomorphide with ammonia*, which forms with it a precipitate soon becoming reddish-brown, and dissolving with rose-red colour on agitation with chloroform. Sulphomorphide is easily formed by heating morphine to 150° with a mixture of 2 vols. sulphuric acid and 1 pt. water (Nadler, *loc. cit.*)

6. The presence of morphine may also be detected by adding a few drops of strong sulphuric acid to the substance under examination, and then a small granule of potassium perchlorate, which must be quite free from chlorate; if morphine is present, the liquid will assume a dark-brown colour (Grove, *Zeitschr. anal. Chem.* 1874, 324; Siebold, *ibid.*)

7. For the detection of morphine in chemico-legal investigations, Selmi (*Gazz. chim. ital.* 1875, 255) recommends the use of iodised hydriodic acid followed by tetracetate of lead (comp. p. 55).

On Dragendorff's Method of detecting Morphine in a mixture of Alkaloids, see PLANT-BASES.

On the Action of Organic Acids upon Morphine, see DERIVATIVES (p. 1341).

Certain oxidising agents, viz. nitric acid, iodic acid, potassium ferricyanide, potassium chromate, and the dioxides of manganese and lead, produced in acidulated solutions of morphine, on gentle heating, a deep red colour, even when the quantity of morphine is very small. The best way of applying the test is to add to the substance under examination, first sulphuric acid, then water, and lastly the oxidising agent, if possible in the solid state. The best result is given by iodic acid (D. Lindo, *Chem. News*, xxxvi. 228). D. Datt (*ibid.* 255) observes that this reaction, at least with nitric acid and with potassium dichromate, is produced also by salts of codeine and narcotine, but not by thebaine, papaverine, or narceine. To detect the presence of morphine in quinine salts, H. Hager (*Zeitschr. anal. Chem.* 1873, 220) makes use of Kieffer's reaction (*Liebig's Annalen*, ciii. 271), which consists in adding to the solution a mixture of potassium ferricyanide and ferric chloride acidulated with hydrochloric acid, the ferricyanide being then reduced by the morphine to ferrocyanide, which, with the ferric chloride, produces prussian blue.

Estimation.—For the estimation of morphine in opium, C. Arnoldi (*Russ. Zeitschr. Pharm.* 1873, 641) exhausts the opium completely with water, which should not leave more than two-thirds undissolved; concentrates the aqueous solution on the water-bath; filters it when cold; decolorises it with animal charcoal, and filters again; precipitates the morphine with ammonia, and weighs it. Good opium thus treated should yield from 14 to 19 per cent. of impure morphine, answering to 10 to 13½ per cent. of the pure base.

See also J. Lynn (*Amer. J. Pharm.* [4], vi. 358; *Chem. Centr.* 1878, 158; *Chem. Soc. J.* xxxiv. 612).

SALTS OF MORPHINE. The solution of the *acetate* has a strong tendency to deposit a basic salt or free morphine; the salt decomposes and turns yellow even when kept in carefully closed vessels, and then gives with sulphuric acid no longer a colourless but a yellow solution.

The *hydriodide*, $C^{17}H^{19}NO^3.HI + 2H^2O$, obtained either by saturation or by the action of potassium iodide on morphine acetate, crystallises in long silky needles grouped in rosettes, sparingly soluble in cold water (insoluble according to Bauer, *in/ra*), more freely in hot water. The water of crystallisation is given off at 100° , and reabsorbed on exposure to the air (E. Schmidt, *Ber.* 1877, 194; comp. Winkler, iii. 1054).

The *hydrobromide*, $C^{17}H^{19}NO^3.HBr + 2H^2O$, is very much like the hydriodide (Schmidt).

Periodides. The *sesqui-iodide*, $2C^{17}H^{19}NO^3.I^3$, prepared by triturating 2 pts. morphine with 1 pt. iodine, and crystallising the mixture from alcohol, is a reddish-brown crystalline mass, soluble in alcohol, ether, and chloroform, but insoluble in water. The *triiodide*, $O^{17}H^{19}NO^3.HI^3$, is obtained by precipitating a morphine salt with iodine-solution, as a kermes-brown precipitate, which dissolves in potassium

iodide, and crystallises therefrom in long nearly black prisms, insoluble in ether and in carbon sulphide, soluble in alcohol, benzene, and chloroform. Nitric acid and hydrochloric acid dissolve it with red colour (H. R. Bauer, *Arch. Pharm.* [8], v. 289).

Substitution-derivatives of Morphine.

Acetyl-derivatives. Mono-, di-, and tetracetyl-morphine have been already described (vii. 819, 820). Further observations on the diacetyl-derivatives have been published by Beckett a. Wright (*Chem. Soc. J.* xxviii. 315), who have obtained a third modification (γ) in crystals by dissolving the β -modification in ether, and leaving the solution to evaporate. The mother-liquor then retains a portion of the β -compound unmixed with any other modification. The β -compound appears to give a blue colour with ferric chloride, only when it is decomposed or perhaps contaminated with mono-acetyl-morphine, inasmuch as the production of this colour-reaction, though usual, is not constant.

The following table gives a comparative view of the properties of the three diacetyl-morphines.

	Relative Quantity.	Properties of		
		Free Base.	Hydrochloride.	Ethiodide.
α -Diacetyl-morphine.	2 to 3 per cent.	Crystallises from ether by spontaneous evaporation, sometimes anhydrous, sometimes with 2 mols. water.	Proportionally less soluble in cold water. Crystals contain $6H^2O$.	Crystallises from alcohol of 85 per cent. with 1 mol. water.
β -Diacetyl-morphine.	Forms the chief product.	Quite uncrySTALLISABLE.	Very soluble, amorphous; in aqueous solution much less stable than its isomerides.	Does not crystallise from alcohol of 85 per cent. or from absolute alcohol.
γ -Diacetyl-morphine.	25 per cent.	Crystallises readily, anhydrous, if free from β -compound.	Very soluble in water; crystallises with difficulty.	Crystallises from alcohol of 85 per cent. with 3 mols. water.

Butyryl-morphines (Beckett a. Wright, *Chem. Soc. J.* xxviii. 16). *α -Di-butyryl-morphine*, $C^{34}H^{36}(C^4H^7O)^2N^2O^6$, formed by boiling morphine for five or six hours with twice its weight of butyric acid, crystallises readily from ether, and when pure does not give any colour-reaction with ferric chloride. Its *hydrochloride* is more soluble and crystallisable than that of the corresponding acetyl-base. The ethereal mother-liquor contains β -dibutyryl-morphine, an amorphous base which gives a blue colour with ferric chloride. *Tetra-butyryl-morphine*, formed by heating morphine to 140° for three hours with twice its weight of butyric anhydride, is amorphous, and is very slowly resolved by boiling with water, somewhat more readily with dilute alcohol, into butyric acid and dibutyryl-morphine. Its *hydrochloride*, $C^{34}H^{34}(C^4H^7O)^4N^2O^6 \cdot 2HCl$, is also amorphous, and does not give a blue colour with ferric chloride. *Acetyl-butyryl-morphine* was formed by boiling morphine for several hours with a mixture of acetic and butyric acids, in which the former greatly predominated. Its *hydrochloride*, $C^{34}H^{36}(C^2H^3O)(C^4H^7O)N^2O^6 \cdot 2HCl$, is crystalline, and is very easily resolved, by boiling with water, into the hydrochlorides of diacetyl- and dibutyryl-morphine.

Benzoyl-morphines (Beckett a. Wright, *Chem. Soc. J.* xxviii. 23). *Di-benzoyl-morphine*, $C^{31}H^{26}(C^7H^5O)^2N^2O^6$, is formed by the action of benzoic anhydride on morphine; also, together with benzoic acid, by boiling a solution of tetra-benzoyl-morphine in dilute alcohol. The base thus obtained is amorphous; its hydrochloride is crystallisable, very slightly soluble in water, and is not altered by ferric chloride.

α -Diacetyl-dibenzoyl-morphine, $C^{38}H^{34}(C^2H^3O)(C^7H^5O)^2N^2O^6$, formed by the action of benzoic anhydride on α -diacetyl-morphine, is a crystalline base. Its *hydro-*

chloride is very soluble in water, does not crystallise, and is precipitated in flocks by strong nitric acid.

Tetrabenzoyl-morphine, $C^{24}H^{24}(C^7H^5O^4)^4N^2O^6$, is prepared by heating morphine to about 130° for three or four hours with twice its weight of benzoic anhydride. On dissolving the product in hot dilute hydrochloric acid, precipitating with sodium carbonate, dissolving the precipitate in ether, and leaving the ether to evaporate, the base separates in anhydrous crystals which give no colour-reaction with ferric chloride. Its *hydrochloride*, $C^{24}H^{24}(C^7H^5O^4)^4N^2O^6 \cdot 2HCl$, is amorphous, but in other respects resembles that of dibenzoyl-codeine (p. 1341).

Ethioidides of Substituted Morphines (Beckett a. Wright, *Chem. Soc. J.* xxviii. 318). These compounds are formed by heating the respective bases to 100° for about a quarter of an hour with twice their weight of absolute alcohol and about an equal weight of ethyl iodide. The contents of the tubes usually solidify on cooling, in crystals which may be recrystallised from alcohol of 80–85 per cent.

Tetracetyl-morphine Ethioidide is a somewhat unstable compound, a considerable portion of it being decomposed by a few minutes' boiling with alcohol of 85 per cent. The crystals deposited from this solvent contain $C^8H^8(C^2H^3O)^4N^2O^6 \cdot 2C^2H^3I + H^2O$, and the mother-liquor contains products apparently resulting from removal of acetyl by the alcohol. Silver chloride converts the ethioidide into the corresponding ethylchloride, which is readily soluble, but cannot be obtained in the pure state, as the aqueous solution decomposes partially when heated, or when left over sulphuric acid.

a-Diacetylmorphine Ethioidide, and the isomeric γ -compound, crystallise, the first with 1 mol., the second with 3 mols. H^2O ; the β -compound is amorphous, as are also the ethioidides of dibutyl- and tetrabutyl-morphine, which decompose at 100° . The ethioidides of tetrabenzoyl- and diacetyl-dibenzoylmorphine crystallise with 1 mol. water.

Morphine-derivatives containing Polyatomic Acid Radicles (Beckett a. Wright, *Chem. Soc. J.* xxviii. 689). These compounds are formed by heating morphine with polybasic acids. Morphine, heated to 180° with twice its weight of *succinic acid*, yields the compound $C^8H^{10}N^2O^6(COC^2H^4COOH)^2 + 8H^2O$, which closely resembles the corresponding codeine-compound (p. 1341). Its formation is represented by the equation:

With camphoric acid in like manner, morphine yields a small quantity of the compound, $C^8H^{14}N^2O^4 \cdot O.CO.C^6H^{14}.COOH^2$.

With *oxalic acid*, morphine reacts like codeine (p. 1342), not forming an oxalyl-morphine, but yielding a product consisting chiefly of trimorphine.

Appendix to Morphine.

Alkaloid resembling Morphine (Selmi, *Gazz. chim. ital.* 1875, 398). The detection of small quantities of morphine in the brain and liver is very much interfered with by the presence of another alkaloid very closely resembling it. This base in aqueous solution exhibits an alkaline reaction; it is insoluble in ether, but dissolves in amyl alcohol; reduces iodic acid; is coloured bluish by ferric chloride; does not exert any poisonous action on frogs.

A base very similar to this, and perhaps identical with it, is found in the unripe capsules of the wild poppy. It is distinguished from morphine by the following reactions. Morphine gives with *iodised hydriodic acid* microscopic crystals, which take a considerable time to form, but then remain permanent for 36 hours; the new base, on the other hand, yields crystals which form immediately but quickly disappear. When a drop of dilute morphine solution mixed with a drop of a cold-prepared solution of *minium* in *glacial acetic acid* is evaporated at a gentle heat, there remains a yellow residue, the colour of which changes through orange to violet, and finally becomes dull and indistinct. The new base similarly treated yields an unalterable yellow residue.

Codeine, $C^8H^{12}N^2O^6$. Crystals of codeine, which Flückiger obtained by crystallising the base dried at 100° from carbon sulphide, have been examined by Arzruni (*Zeitschr. Kryst.* i. 302). They are yellowish by transmitted light, strongly refractive, and belong to the orthorhombic system with hemihedro-sphenohedral development, $a : b : c = 0.9298 : 1 : 0.5087$. Plane of optic axes OP.

Acetyl-, Butyl-, and Benzoyl-codeines (Beckett a. Wright, *Chem. Soc. J.* xxviii. 212). *Diacetyl-codeine*, formed by boiling codeine with twice its weight of *glacial acetic acid*, has been already described (vii. 821).

Tetracetyl-dicocodeine, $C^{12}H^{20}(C^2H^3O)^4N^2O^{12}$, obtained by the action of acetic anhydride on dicocodeine (vii. 735), is amorphous, easily soluble in ether, and forms a

crystallisable *hydrochloride*, $C^{72}H^{80}(C^2H^3O)^4N^4O^{12}.4HCl + 10H^2O$, more soluble than the *hydrochloride* of diacetyl-codeine, and an indistinctly crystallised *platinochloride*, $C^{72}H^{80}(C^2H^3O)^4N^4O^{12}.4HCl.2PtCl^4$.

Octacetyl-tetracodeine, $C^{144}H^{160}(C^2H^3O)^8N^8O^{24}$, is obtained by heating tetracodeine with acetic anhydride to 120° for three hours, and evaporating the product to dryness, as a mass insoluble in water and dilute hydrochloric acid, soluble in alcohol and alcoholic hydrochloric acid, and precipitated from these solutions by water in amorphous flocks which become darker when dried over sulphuric acid. The solution in alcoholic hydrochloric acid mixed with alcoholic platinum tetrachloride and then precipitated with water, yields a basic *platinum salt*, the amount of platinum in which agrees approximately with the formula $C^{144}H^{160}(C^2H^3O)^8N^8O^{24}.2HCl.PtCl^4$.

In the conversion of codeine into di- and tetracodeine, the number of hydroxyl-groups in the molecule is not diminished, and the polymerised bases are capable of yielding neutral salts, but their acetyl-derivatives are not.

ETHIODIDES. *Diacetyl-codeine Ethiodide*, $C^{86}H^{40}(C^2H^3O)^2N^2O^6.2C^2H^5I + H^2O$, is obtained by heating codeine with twice its weight of absolute alcohol and about an equal weight of ethyl iodide, to 100° for about a quarter of an hour. It forms snow-white crystals, slightly soluble in cold alcohol either absolute or of 90 per cent., more easily in water and in hot dilute alcohol. It gives off its water at 100° , being at the same time partly decomposed. By the action of recently precipitated silver chloride and water, it is converted into *diacetyl-codeine ethylochloride*, which separates on leaving the solution over sulphuric acid, in crystalline crusts having, when dried at 100° , the composition $C^{86}H^{40}(C^2H^3O)^2N^2O^6.2C^2H^5Cl + H^2O$. The *platinochloride* decomposes in drying.

When *tetracodeine* is heated for twenty minutes in a sealed tube to 120° with an equal weight of ethyl iodide, and the resulting liquid is left to cool, amorphous flocks are deposited which dissolve in boiling alcohol and in hot water, and have the composition $C^{144}H^{160}N^8O^{24}.8C^2H^5I$. *Octacetyl-tetracodeine*, treated in like manner, yields a much more soluble compound, containing 12.72 per cent. iodine, whereas the formula $C^{144}H^{160}(C^2H^3O)^8N^8O^{24}.8C^2H^5I$ would require 25.55 per cent. iodine, and the corresponding formula with $4C^2H^5I$ would require 15.15 per cent. Hence it would appear that the power of a polymeric codeine to take up ethyl iodide is diminished when it is converted into an acetyl-derivative.

Dibutyryl-codeine, $C^{86}H^{40}(C^4H^7O)^2N^2O^6$, is formed by boiling codeine for five or six hours with twice its weight of butyric acid, and by evaporating off the excess of acid, dissolving the residue in water, precipitating with sodium carbonate, dissolving the precipitate in dilute hydrochloric acid, reprecipitating, and finally dissolving the precipitate in ether and leaving the ether to evaporate, it may be obtained as an amorphous perfectly uncrystallisable mass. It is also produced by the action of butyric anhydride on codeine. Its *hydrochloride*, $C^{86}H^{40}(C^4H^7O)^2N^2O^6.2HCl + 6H^2O$, crystallises well, gives off its water of crystallisation at 100° , and yields a *platinochloride* having the composition $C^{86}H^{40}(C^4H^7O)^2N^2O^6.2HCl.PtCl^4$.

Dibenzoyl-codeine, $C^{86}H^{40}(C^7H^5O)^2N^2O^6$, formed by the action of benzoic anhydride on codeine, crystallises anhydrous from ether. It dissolves but very sparingly in water either cold or hot, and is not altered by boiling with water. Its *hydrochloride* forms, with a large quantity of warm water, a clear solution, which on cooling becomes opalescent like starch-paste; and if the solution was concentrated it deposits a soft amorphous mass which may be crystallised, and has the composition $C^{86}H^{40}(C^7H^5O)^2N^2O^6.2HCl + 2H^2O$. The *platinochloride* is anhydrous and more soluble in alcohol than in water.

The *ethiodides* of dibutyryl- and dibenzoyl-codeine crystallise with 1 mol. water.

Codeine-derivatives containing Polyatomic Acid Radicles (Beckett a. Wright, *Chem. Soc. J.* xxviii. 689). *Succino-codeine* or *Codeine-succinic acid*, $C^{86}H^{40}N^2O^6(COC^2H^4COOH)^2$, is formed by heating codeine to 180° with twice its weight of succinic acid, whereupon the whole becomes liquid; and on dissolving the product in water, and freeing it by fractional precipitation with sodium carbonate or ammonia from coloured impurities which separate out first, and then cautiously adding further quantities of the precipitant, the pure compound is thrown down in white flocks, and on dissolving these in boiling alcohol, the acid separates on cooling in small crystals. Its formation is represented by the equation:

The crystals, when air-dried, contain 10 mol. H^2O , which they give off at 100° . The acid is insoluble in water, ether, and benzene, slightly soluble in cold, easily in boiling alcohol, also in acids and in excess of alkali. Its alkali-salts could not be prepared. Its solution in baryta-water is decomposed by carbonic acid; an ammoniacal solution

evaporated over sulphuric acid leaves the acid unaltered, and the addition of silver nitrate is followed by separation of metallic silver.

The compounds with acids, on the other hand, are easily prepared. A solution in hydrochloric acid yields, when evaporated over oil of vitriol, crystals of the compound $C^{14}H^{10}N^2O^{12}.2HCl + 2H^2O$, which gives off its water at 100° , and yields a flocculent precipitate with platinum chloride.

The compound $C^{16}H^{10}N^2O^6(COC^2H^4COOH)^2$ is analogous in constitution to Lourenço's succinethylenic acid, $C^4H^4O^2 \left\{ \begin{smallmatrix} C^2H^4 \\ H^2 \end{smallmatrix} \right\} O^2$ (ii. 582), which, however, more readily

forms metallic salts, but is incapable of uniting with other acids.

Camphoro-codeine, or *Codeine-camphoric acid*, $C^{30}H^{10}N^2O^6(C^{10}H^{15}O^3)^2$.—Camphoric acid and codeine, heated together, form a hard mass, from which may be extracted a crystalline body having the composition above given. It crystallises from dilute alcohol with 8 mol., from alcohol of 80 per cent. with 6 mol. H^2O ; forms a hydrochloride which is slightly soluble in cold water, crystallises from dilute alcohol, has when air-dried the composition $C^{58}H^{70}N^2O^{12}.2ClH + 2H^2O$, and forms an amorphous platinochloride.

Tartaric acid and *Codeine* yield, when heated together, a solid mass, the greater part of which dissolves in water. The residue is insoluble in aqueous but soluble in alcoholic hydrochloric acid, and is reprecipitated by water and alkalis, in the latter case free from chlorine. The hydrochloride and platinochloride contain much less chlorine than might be expected from analogy to the derivatives above described. The product of the reaction may perhaps be regarded as a tartro-derivative of tetra-codeine, which, like acetyl-tetracodeine, has lost some of its binding power.

Oxalic acid and codeine, heated together, melt to a clear liquid, which gives off large quantities of carbon dioxide and monoxide in about equal volumes, and afterwards acid vapours. The oxalyl-derivative could not be isolated, but the product contained di-codeine and probably also tri- and tetra-codeine. Beckett a. Wright are of opinion that these polycodeines are produced from a very easily decomposable codeine-oxalic acid formed in the first instance, and that the formation of the same polymerides by the action of sulphuric and phosphoric acids on codeine (vi. 481; vii. 372) is in like manner preceded by that of intermediate compounds which cannot be isolated.

MOSANDRIUM. See YTTRIUM-METALS.

MOTTRAMITE. See VANADATES.

MUCIC ACID, $C^8H^{10}O^8$. This acid, treated with phosphorus pentachloride, yields a chloride convertible by water into chloromuconic acid, $C^8H^4Cl^2O^4$, which, when treated with water and sodium-amalgam, yields hydromuconic acid, $C^8H^8O^4$; and this latter, dissolved in glacial acetic acid and treated with bromine, yields isodibrom-adipic acid, $C^8H^2Br^2O^4$, which is converted by silver oxide into the silver salt of muconic acid, $C^8H^2O^4$ (vii. 827).

MUCOBROMIC ACID, $C^4H^2Br^2O^4$, is formed by adding bromine in excess to pyromucic acid dissolved in water (vii. 828).

MUCOR. On Alcoholic Fermentation produced by *Mucor Mucedo* and *Mucor racemosus*, see vii. 518; viii. 776. According to Müntz (*Compt. rend.* lxxix. 1182), *Mucor Mucedo* contains trehalose.

MUREX. According to A. and G. de Negri, the purple of *Murex trencuculus* consists of two colouring matters, one of which is identical with indigo-blue. The juice of *Murex trencuculus* becomes coloured on exposure to the air, even in the dark; that of *Murex brandaris* only in the light.

MUREXAN and MUREXID. According to Magnier de la Source (*Bull. Soc. Chim.* [2], xxii. 56), the so-called murexid reaction is to be ascribed partly to the formation of ammonium isalloxanate, $C^4H^2(NH^4)^2N^2O^5$, partly to that of acid ammonium purpurate, $C^6H^4(NH^4)N^2O^6$. The latter compound is formed from alloxantin by the action of ammonium carbonate, while alloxan, treated with the same reagent, yields the former, as will be seen from the following equations:

Consequently, a mixture of alloxan and alloxantin, treated with ammonium carbonate, will produce both these colouring matters. The ammonium isalloxanate may be partly removed from the mixture by washing, and partly remains, perhaps with the purpurate, a circumstance which sufficiently accounts for the great differences among chemists respecting the formula of murexid. See also J. Resch (*Chem. News*, xxxii. 171)

MURRAYIN, $C^{18}H^{22}O^{10}$. A glucoside from the flowers of *Murraya exotica*, m. p. 245° (De Vrij, *Jahresb. f. Chem.* 1876, 850).

MUSA. The colouring matter of *Musa Fehii*, a tree growing on the highlands of Tahiti, is described by Niederstadt (*Dingl. pol. J.* cxxix. 165). The juice separates into a caoutchouc-like mass, and a watery liquid having a raspberry colour in thin, blue-violet in thicker layers. This liquid dyes cotton and linen greyish-violet with alum-mordants, and a splendid violet with tin-mordants.

MUSCARINE, $C^8H^{14}NO^2$. An alkaloid occurring, together with amanitine (choline), in the fly-agaric (*Agaricus muscarius*). The mode of separating the two has been already described (p. 456). Muscarine may be formed artificially by gently heating choline hydrochloride or platinochloride with strong nitric acid; its sparingly soluble platinum salt is easily separated from undecomposed choline platinochloride. The platinochloride of muscarine, decomposed by potassium chloride, yields muscarine hydrochloride, $C^8H^{14}NO^2.HCl$, which is converted by moist silver oxide into the hydrate $C^8H^{14}NO^2.H^2O$, or hydroxide, $C^8H^{14}NO^2.OH$, agreeing in all its properties with the base obtained from the fly-agaric.

Muscarine hydroxide forms irregular deliquescent crystals having an alkaline reaction; it forms an alkaline salt with carbonic acid, neutral salts with the stronger acids. The *aurochloride* has the composition $C^8H^{14}NO^2Cl.AuCl^3$; the *platinochloride* is $(C^8H^{14}NO^2Cl)_2PtCl^4 + 2H^2O$.

Muscarine is related to betaine in the same manner as chloral hydrate to trichloroacetic acid:

Muscarine hydroxide is represented by the formula $(\text{CH}^3)^3\text{N} < \begin{smallmatrix} \text{OH} \\ \text{CH}^2-\text{CH}(\text{OH})^2 \end{smallmatrix}$ (Schmiedeberg a. Harnack, *Chem. Centr.* 1876, 554).

MUSCOVITE. See MICA (p. 1319). A description of the localities of Bengal muscovite is given by O. Feistmantel (*Verh. geol. Reichsanst.* 1875, 301; *Jahresb. f. Chem.* 1875, 1219).

MUST. See WINE.

MUSTARD. *Detection of Adulterations*.—Wheat-flour, &c., may be easily detected by the formation of iodide of starch on addition of iodine-tincture; turmeric by its appearance under the microscope, by the borax reaction, and by the fluorescent properties of its alcoholic solution (see TURMERIC); gamboge by the reddening which it exhibits with alkalis; Cayenne pepper also by the microscope, and by the biting taste which it imparts to the alcoholic extract; mineral substances by incineration. The amount of adulteration may be approximately judged of by determining the quantity of fixed oil obtainable from the mustard, which with pure mustard amounts to 35 or 36 per cent. (A. H. Allen, *Chem. News*, xxx. 116).

In the oil obtained by pressure from the seeds of black mustard, G. Goldschmiedt (*Wien. Akad. Ber.* lxx. 451) has found erucic and benic acids, together with a liquid acid not yet investigated (see ERUCIC ACID, p. 737).

MUSTARD OILS (VOLATILE). See CARBIMIDES (THIO-), (pp. 606–608).

MYCORAPHIN and **MYCOSTERIN**. These names are given by F. A. Hartsen (*Chem. Centr.* 1873, 205) to two substances which he obtained from *Agaricus fasciculatus* and *Lactarius deliciosus*.

MICROCYMES or **MICROZYMES**. See FERMENTS (p. 732).

MYELIN. On the formation of this substance from hæmin, see p. 922.

MYOSIN. See PROTEIDS.

MYRICYL ALCOHOL, $C^{30}H^{62}O = C^{29}H^{59}.CH^2OH$; also called *Melissyl Alcohol*. This alcohol and several of its derivatives have been studied by L. v. Pieverling (*Liebig's Annalen*, clxxxiii. 344). The alcohol was prepared from Carnauba wax by one of the two following processes: (1). The wax is saponified by boiling with alcoholic potash, the alcohol distilled off after filtration, and the soap boiled with a solution of lead acetate. The yellow masses which separate out are washed, dried, and boiled with absolute ether. The wax alcohol crystallises out from the filtered solution in white glittering crystals, and is purified by repeated recrystallisation. (2). The soapy mass

is boiled with dilute hydrochloric acid, and the waxy masses which separate are washed and dried. They are then dissolved in boiling alcohol, the fatty acids removed by ammonium and barium chloride, and the residue, after distilling off the alcohol, is boiled with water and then dried. The myricylic alcohol is then extracted with boiling absolute ether, and purified by repeated recrystallisation. Both these methods yield about 11 per cent.

Myricyl alcohol crystallises from ether in small glittering white needles, which are scarcely soluble in cold alcohol, ether, or benzene, little soluble in cold chloroform, but easily soluble in these media when hot. At 85° it melts to a colourless oil, solidifying at 84° to a white wax. On analysis it gave numbers closely according with those for the formula $C^{30}H^{61}OH$, and not in accord with Maskelyne's formula, $C^{31}H^{63}HO$ (vi. 391).

Myricyl Iodide, $C^{30}H^{61}I$, was prepared by heating the alcohol to 120° , adding phosphorus and iodine by small portions, and at the end of the reaction dissolving the product in alcohol and crystallising from ligroin. It forms small white glistening plates without odour or taste, scarcely soluble in cold alcohol, ether, or benzene, but easily soluble in the same liquids when hot. At 69.5° it melts to a clear, colourless oil.

Myricyl Chloride, $C^{30}H^{61}Cl$, is prepared by acting with phosphorus pentachloride on myricylalcohol, and heating the product first in a water-bath, and then in a current of hydrochloric acid, and purified by repeated solution in hot ether. It forms a pale yellow, waxy mass, melting at 64.5° , and without odour or taste. It is soluble in alcohol, ether, benzene, and ligroin, but does not crystallise from any of these media.

Myricyl Hydrosulphide, $C^{30}H^{61}SH$, formed by the action of an alcoholic solution of myricyl chloride on potassium sulphide, is an amorphous yellow powder, without odour or taste, slightly soluble in boiling ether, ligroin, and alcohol, easily soluble in boiling benzene and chloroform, forming yellow solutions. It melts at 94.5° to a yellow oil, which solidifies at 93° to a yellow amorphous mass.

Myricylamines.—By passing a stream of dry ammonia into melted myricyl iodide for more than twenty-four hours, boiling the whole pulverulent mass with alcohol, and crystallising the residue from benzene, a yellow, crystalline, heavy body is obtained, melting at 78° , nearly insoluble in boiling alcohol and ether, but readily soluble in boiling benzene, toluene, and chloroform. This body appears to be a mixture of the three bases, mono-, di-, and tri-myricylamine, which cannot be separated from one another.

MYRISTIC ACID, $C^{14}H^{28}O^2 = C^{13}H^{27}.CO^2H$. This acid exists in nutmegs, and may be separated therefrom by distillation, whereby an oil is obtained, together with a crystalline substance, which, when washed with cold and repeatedly crystallised from hot alcohol, forms colourless shining laminae, having when fresh the peculiar odour of nutmegs, but losing it by keeping. These crystals are insoluble in alcohol, melt at 54.5° , and give by analysis numbers agreeing with the formula $C^{14}H^{28}O^2$. The alcoholic solution has a faint acid reaction (Flückiger, *N. Rep. Pharm.* xxiv. 213).

Myristic acid is likewise obtained, together with a fragrant oil, by distilling iris root with water (Flückiger, p. 1095).

N.

NAPHTHALENE, $C^{10}H^8$. *Formation*.—This hydrocarbon is formed: 1. On passing the vapour of isobutylbenzene over heated lead oxide at a temperature at which isobutylbenzene alone is not altered (Wreden and Znatovitz, *Ber.* ix. 1606). 2. On passing oil of turpentine through a red-hot tube (Schulz, *ibid.* ix. 548). 3. On distilling colophony and gum-benzoin with zinc-dust (Ciamician, *ibid.* xi. 269). 4. On passing wood-tar through a red-hot tube (Letney, Atherberg, *ibid.* xi. 1210, 1222). 5. On heating dimethylaniline with bromine at 110° – 120° (Brunner and Brandenburg, *ibid.* xi. 697).

Properties.—In connection with his experiments on the simultaneous distillation of water and of bodies not miscible with water, when the latter are heated by the passage of a current of steam, Naumann has determined the vapour-tension of naphthalene to be 2 mm. at 15° , 9 mm. at 78° , and 20.5 mm. at 100° . The amounts of naphthalene and water which distilled over when steam was passed into naphthalene were as follows:

Barometer (corr.)	Temperature		Ratio of naphthalene to water in distillate
	in liquid	in vapour	
795.5	97.8°	99.2°	100 : 520
757	97.7°	99.1°	100 : 570
733		98.2°	100 : 555

(*Ber.* iv. 646; x. 2014, 2100; xi. 33).

The crystallographic characters of a number of allied chlorinated and brominated derivatives of naphthalene have been studied by Hintze (*Pogg. Ann. Sup.* vi. 1873, 177).

Reactions.—Naphthalene combines with α -dinitrochlorobenzene, forming the compound $C^{10}H^8.C^6H^3Cl(NO_2)_2$, which crystallises from alcohol in long white needles melting at 78°. It is decomposed when heated with an alkali or aniline, naphthalene being separated, and a dinitrophenol-salt or dinitrophenylaniline produced (Willgerodt *Ber.* xi. 603).

Thionyl chloride, $SOCl_2$, and naphthalene furnish only a resinous product (Böttinger, *ibid.* xi. 1409). Benzenesulphonic chloride, $C^6H^5.SO_2Cl$, and naphthalene, in presence of aluminium chloride, furnish a similar product (Beckurts a. Otto, *ibid.* xi. 2069).

HYDROCARBONS, &C., RELATED TO NAPHTHALENE.

Naphthalene Hydrides. By heating naphthalene at 280° with twenty times its weight of a solution of hydriodic acid, saturated at 0°, Berthelot obtained a hydrocarbon boiling at 200°–210°, which he regarded as *naphthalene dihydride*, $C^{10}H^{10}$, together with a small quantity of a second hydrocarbon, probably the tetrahydride, $C^{10}H^{12}$. This latter hydrocarbon was subsequently prepared in the pure state by Baeyer, by heating naphthalene with phosphonium iodide; according to Graebe (*Ber.* v. 678), it is much more readily obtained by heating naphthalene with hydriodic acid and amorphous phosphorus (10 grams naphthalene, 3 grams phosphorus and 9 grams of a solution of hydriodic acid boiling at 127° are sealed up in a tube, which is heated for six to eight hours at 220°–250°).

Naphthalene tetrahydride has a density of .981 at 12.5°, and boils at 205°; it readily combines with trinitrophenol. It is dissolved by cold concentrated sulphuric acid, being converted into the sulphonic acid, $C^{10}H^{11}.SO_3H$. When passed through a red-hot tube, it is resolved into naphthalene and hydrogen. It is much more readily oxidised than naphthalene, yielding phthalic acid; the oxidation may be effected either by means of dilute nitric acid (sp. gr. 1.2), or by an acid solution of potassium permanganate. On treatment with concentrated nitric acid, it yields nitro-compounds, and among others trinitrophenol. On adding bromine to its solution in carbon disulphide, hydrobromic acid is evolved in large quantity, and on evaporating off the solvent, an oil is obtained, which decomposes on distillation into brominated compounds, naphthalene, and a hydrocarbon boiling at 210°–212°, which, perhaps, has the composition $C^{10}H^{10}$.

Wreden a. Znatowicz state (*ibid.* ix. 278, 1606; *Liebig's Annalen*, clxxxvii. 164) that the hydrocarbons $C^{10}H^{14}$, $C^{10}H^{16}$, $C^{10}H^{18}$, and $C^{10}H^{20}$ are also formed on heating naphthalene with hydriodic acid and phosphorus, but they have only described the manner in which they prepared one of these, viz. that of the formula $C^{10}H^{20}$, which they term *hexhydrocymene*. This hydrocarbon is said to be a colourless mobile liquid, having a density of .802 at 0° and .788 at 23°; it boils at 153°–158°, and is not attacked by either nitric or sulphuric acid at the ordinary temperature. No reason for terming this hydrocarbon *hexhydrocymene* has been stated. The hex- and oct-hydrides are said to boil respectively at 195°–200° and 185°–190°, and to absorb oxygen on exposure to the air.

Acenaphthylene, $C^{12}H^8$. This hydrocarbon is formed by passing acenaphthene, $C^{12}H^{10}$, over gently heated lead monoxide (Behr a. van Dorp, *Ber.* vi. 753; Blumenthal, *ibid.* vii. 1092). It is very soluble in alcohol, ether, and benzene, and is thus distinguished from acenaphthene, which is difficultly soluble. Acenaphthylene forms large, glistening, golden-yellow plates, melting at 92°–93°; it boils at about 265°–275°, but undergoes partial decomposition. With trinitrophenol it forms the compound $C^{12}H^8.C^6H^3(NO_2)_3OH$, which crystallises in yellow glistening needles, melting at 201°–202°. It is converted into acenaphthene on treatment of its alcoholic solution with sodium amalgam. On oxidation with potassic dichromate and sulphuric acid it yields naphthalic (naphthophthalic) acid, $C^{10}H^6(COOH)_2$. Acenaphthylene combines with bromine, forming a dibromide which yields naphthalic acid on oxidation. This bromide separates from a mixture of benzene and anhydrous alcohol in white needles melting at 121°–123°; by the action of alcoholic potash, it is converted into an oily monobromacenaphthylene, but a second molecule of hydrobromic acid cannot be withdrawn from this compound even by heating with alcoholic potash at 140°. On

treating bromacenaphthylene with bromine, dibromacenaphthylene is produced; this body crystallises in orange-red plates, and apparently yields bromonaphthalic acid on oxidation.

By treating a solution of acenaphthene in carbon disulphide with an excess of bromine, dibromacenaphthene tetrabromide, $C^{12}H^6Br^4$, is produced; but if a single molecular proportion of bromine be added to an ethereal solution of acenaphthene, monobromacenaphthene is formed. The latter yields monobromonaphthalic acid on oxidation.

The relation between acenaphthene, acenaphthylene and naphthalic acid is represented by the following formulae:

Methylnaphthalene, $C^{11}H^{10} = C^{10}H^7.CH^3$. This hydrocarbon appears to be formed on distilling colophonium and gum benzoin with zinc dust (Clamician, *Ber.* xi. 269).

Phenylnaphthalene, $C^{16}H^{12} = C^6H^5.C^{10}H^7$. This hydrocarbon is formed on passing a mixture of naphthalene and bromobenzene through a tube heated to redness. It forms colourless transparent plates, melting at $95^\circ-96^\circ$ (Watson Smith, *Ber.* xii. 1396, 2049). The hydrocarbon produced on distilling chrysoquinone with soda-lime (viii. 472) is probably phenylnaphthalene.

By passing phenylnaphthalene vapour through a red-hot tube, Graebe and Bungener have succeeded in obtaining chrysene (*Ber.* xii. 1078), thus proving that chrysene is analogous in constitution to phenanthrene:

The phenylnaphthalene employed for this purpose was prepared by submitting naphthalene to the combined action of aluminium chloride and phenylacetic chloride, $C^6H^5.CH^2.COCl$, and reducing the naphthylbenzyl-ketone thus obtained by heating it with hydriodic acid and phosphorus at $150^\circ-160^\circ$.

Benzyl-naphthalene, $C^{17}H^{14} = C^{10}H^7.CH^2.C^6H^5$, prepared by digesting a mixture of naphthalene and benzyl chloride with zinc dust, crystallises in monoclinic prisms, melting at $58-6^\circ$. It boils at $320^\circ-330^\circ$. It is only slightly soluble in alcohol, but readily dissolves in ether and carbon disulphide. It yields non-crystalline derivatives with chlorine; monobromobenzyl-naphthalene is a syrup; the higher bromo-derivatives form granular masses. Nitric acid converts it into a trinitro-compound. It forms a crystalline compound with trinitrophenol (Miquel, *Bull. Soc. Chim.* [2], xxvi. 2).

Dinaphthyl, $C^{20}H^{14} = C^{10}H^7.C^{10}H^7$. On treating naphthalene potassium (vi. 844) with ethyl bromide, a yellow hydrocarbon is obtained which, according to Abeljanz (*Ber.* v. 1027), has the composition $C^{20}H^{12}$. Probably this may have been impure dinaphthyl. In addition to the two isomeric dinaphthyls already described (vii. 842), Watson Smith has obtained a third modification, thus completing the series of possible isomeric forms of this hydrocarbon. It would appear that all three are obtainable, though in very different quantities, by passing naphthalene, together with antimony trichloride, through a red-hot tube. By far the largest proportion of the product consists of isodinaphthyl; the next in quantity is the isomeride of lowest melting point; the third modification, identical with that originally obtained by Lossen, is formed by this method in extremely small quantity. The three bodies are separated by a tedious process of fractional crystallisation from low boiling petroleum (*Chem. Soc.* J. 1877, xxxii. 559; 1879, xxxv. 224).

Watson Smith finds that the product prepared by Lossen's method, but using sulphuric acid diluted with rather more than its own bulk of water instead of with twice its weight of water, contains only the one dinaphthyl; this crystallises in perfectly colourless rhomboidal plates, melting at $154^\circ-155^\circ$. This modification is doubtless $\alpha\alpha$ -dinaphthyl, as Lossen also obtained it by the action of sodium-amalgam on α -bromonaphthalene.

So-called *isodinaphthyl* is probably the $\beta\beta$ -modification, as it has the highest melting point of any of the dinaphthyls. It crystallises readily in colourless, very regular rhombic plates, melting at 187° , and is much less soluble in alcohol, ether, benzene, &c. than either of the isomerides.

The third dinaphthyl, which is probably the $\alpha\beta$ -modification, forms small white

six-sided (apparently monoclinic) plates, melting at 76° . It is very soluble in alcohol, ether, and benzene.

All the dinaphthyls boil considerably above 300° , but the most fusible appears to have a lower boiling point than the least fusible. Their vapour-densities, as determined by Meyer's method, agree with the formula $C^{20}H^{14}$. On the supposition that they are constituted as above stated, they are indicated by the following symbols:

A number of experiments have been made by Watson Smith on the action, at a high temperature, of different chlorides on naphthalene. A mixture of naphthalene and antimony trichloride gives a much larger yield of high boiling products (dinaphthyls, &c.) than naphthalene alone; and similar results are obtained with tin tetrachloride. A mixture of naphthalene and tetrachloromethane nearly in the proportion $4C^{10}H^8 : CCl_4$, at a dull red heat, gave a better yield of dinaphthyls—as in other similar cases, chiefly the $\beta\beta$ -modification—than any other mixture at so low a temperature; similar but somewhat less satisfactory results were obtained with trichloromethane. Carbon disulphide does not appear to aid the formation of the dinaphthyls. A mixture of naphthalene and bromonaphthalene in equal molecular proportions yields a considerable quantity of $\beta\beta$ -dinaphthyl. Better results are obtained on passing this mixture over soda-lime; lime alone does not answer so well. Iso- ($\beta\beta$) dinaphthyl yields hexchlorobenzene and hexchloroethane on perchlorination (Watson Smith, *Ber.* xii. 2131).

Dinaphthylethane. A trichlorinated derivative of this hydrocarbon is formed in two isomeric modifications by the action of chloral and sulphuric acid on naphthalene (Grabowski, *Ber.* vi. 224; xi. 298). To a mixture of 3 pts. chloral, 8 pts. naphthalene and 6 pts. chloroform, 6 pts. of ordinary concentrated and afterwards an equal quantity of fuming sulphuric acid are added with constant stirring, the mixture being cooled. As soon as the temperature ceases to rise, 15–20 pts. of water are added, the chloroform is then distilled off, the residue washed with cold water, and afterwards extracted with 10–15 pts. of boiling water. The undissolved portion is then boiled with an equal weight of benzene, and the solution filtered; on cooling, it deposits crystals of β -dinaphthyltrichlorethane, $CCl^2.CH(C^{10}H^7)^2$. The α -compound is contained in the alcoholic solution, but has not yet been obtained free from the β -compound.

β -Dinaphthyltrichlorethane forms triclinic prisms melting at 156° ; it is insoluble in cold alcohol, and sparingly soluble in boiling alcohol and ether, but easily soluble in benzene and chloroform. It is not oxidised by the ordinary chromic acid mixture. It yields a bromo-derivative on treatment with bromine. When submitted to the action of 10 pts. of cold fuming nitric acid, it is converted into a tetranitro-derivative, which is a pale yellow crystalline powder melting at 258° .

β -Dinaphthylidichlorethylene, $CCl^2=C(C^{10}H^7)^2$, is obtained on submitting β -dinaphthyltrichlorethane to dry distillation or to the action of alcoholic potash. It crystallises from benzene, in which it is very easily soluble, in short prisms melting at 219° , difficultly soluble in alcohol; it boils without decomposition above 360° . It combines with bromine. With nitric acid it yields tetranitro- β -dinaphthylidichlorethylene, which melts at 292° .

α -Dinaphthylidichlorethylene is produced on distilling crude α -dinaphthyltrichlorethane with 20 per cent. of its weight of lime. The product is dissolved in the smallest possible quantity of hot benzene, and after the β -compound has crystallised out, the benzene is distilled off, and the residue crystallised from boiling alcohol, from which it separates in long, colourless, silky needles, melting at 150° .

Dinaphthylacetylene, $C^{22}H^{14} = C^{10}H^7.C \equiv C.C^{10}H^7$. This hydrocarbon is formed on heating dinaphthyltrichlorethane with zinc dust, lead oxide, zinc oxide, or

soda-lime. It crystallises from alcohol in long silky needles, melting at 225° , and boils above 360° , but apparently undergoes decomposition.

Dinaphthylanthrylene, $C^{22}H^{12}$. This hydrocarbon is formed under apparently the same conditions as the foregoing. It is best prepared by distilling β -dinaphthyl-trichlorethane with 15 pts. zinc oxide at a red heat. It is difficult to purify. After crystallisation from benzene and sublimation, it forms violet-coloured plates, melting at 270° ; but when separated from its compound with trinitrophenol, it is colourless. Probably it bears the same relation to dinaphthylacetylene that phenanthrene bears to stilbene, thus:

Naphthylphenylcarbinol and **Dinaphthylphenylmethane**. See LEHNE (*Ber.* xiii. 358).

Naphthylphenylcarbazol, $C^{16}H^{11}N$. Graebe a. Knecht have described a compound of the formula $C^{16}H^{11}N$, obtained from coal-tar, and by passing the vapour of β -phenylnaphthylamine through a red-hot tube, which appears to be the analogue of imidodiphenyl (carbazol), $C^{12}H^9N$ (*Ber.* xii. 341, 2242), thus:

This compound was first discovered by Brunck in a sublimate from the residue of the distillation of crude anthracene, and purified by him, in conjunction with Vischer, by crystallising the portion of the sublimate insoluble in boiling glacial acetic acid from hot aniline and then subliming it. Graebe a. Knecht, however, employ benzene instead of aniline. When purified by crystallisation or sublimation, it always possesses an intense greenish-yellow or golden-yellow colour, which, however, does not appear to be characteristic of the pure substance, as it is rendered colourless, if heated with potassium hydrate, without being otherwise altered in properties, and is also obtained colourless when separated from its acetyl-derivative.

It is almost insoluble in cold alcohol and benzene, very slightly soluble in boiling benzene and acetic acid, moderately soluble in hot aniline. Its solutions exhibit an intense blue fluorescence. It melts at 330° , and has a higher boiling point than sulphur; its vapour-density, determined in phosphorus pentasulphide vapour, agrees with the formula $C^{16}H^{11}N$. It dissolves in sulphuric acid, forming a yellow solution; the least trace of nitrous or nitric acid renders the liquid brownish-green.

Heated with acetic anhydride at 220° – 240° , it yields a *monacetyl-derivative*, $C^{16}H^{10}N(C^2H^3O)$, which crystallises from boiling alcohol in colourless prisms melting at 121° . By the action of nitrous acid, it is converted into a *nitroso-derivative*, $C^{16}H^{10}N(NO)$, which crystallises from ether in reddish-yellow needles melting at 240° . This nitroso-derivative dissolves in sulphuric acid, producing a magnificently red-violet coloured liquid, which becomes dark brown on heating.

It is with difficulty oxidised by chromic acid, yielding one or more acids and a quinone, $C^{16}H^8N(O^2)$.

Naphthalene Colours. *Naphthalene* or *Magdala-red* (Hofmann, *Ber.* ii. 374, 412).—This colour has the formula $C^{30}H^{21}N^3$, and is a product of the action of naphthylamine on the so-called azodinaphthylidiamine of Perkin and Church, $C^{30}H^{10}N^3 + C^{10}H^9N = C^{30}H^{21}N^3 + NH^3$. An analogous compound having similar properties is obtained on submitting azodinaphthylidiamine to the action of paratoluidine hydrochloride (Lecco, *Ber.* vii. 1290). Azodinaphthylidiamine, according to Lecco, melts at 174° , and not at 135° , as stated by Perkin a. Church.

A considerable number of azo-derivatives, prepared by the direct action of diazo-compounds on various naphthalene-derivatives, are now in use as dyes. The following compounds of this class have been described by Griess, Hofmann, Typeke and Witt. It will be noticed that they are all derivatives of the azo-compound intermediate in composition between so-called azobenzene and azonaphthalene, thus:

See also Weselsky and Benedikt and Griess (*Ber.* xii. 238, 426).

(a). $C^6H^3.N=N.C^{10}H^4(OH)$.—The compound of this formula is the product of the action of diazobenzene nitrate on α -naphthol. It forms microscopic brown needles, melting at 166° , soluble in alkalis and most of the ordinary solvents; its solutions have a reddish-brown colour and possess considerable tinctorial power. On treatment with sulphuric acid, it is converted into a sulpho-acid, which dyes silk and wool orange-yellow (Typke, *Ber.* x. 1580).

(b). $C^6H^3.N=N.C^{10}H^4(SO^3H).OH$.—The compound of this formula is prepared by adding a solution of sodium α -naphtholsulphonate to a solution of diazobenzene nitrate; it crystallises in hair-fine red needles (Hofmann, *Ber.* x. 1380).

(c). $C^6H^3.N=N.C^{10}H^4(SO^3H).OH$.—This compound is prepared in a similar manner from β -naphtholsulphonate; it forms reddish-brown needles with a golden-green lustre (Griess, *ibid.* 2197).

(d, e). $C^6H^4(SO^3H).N=N.C^{10}H^4(OH)$.—Two modifications of this compound, prepared by the action of paradiazobenzenesulphonate (from paramidobenzenesulphonic or sulphanilic acid) on α - and β -naphthol respectively, are the basis of Poirrier's oranges and of the so-called Tropaeolines 000 1 and 2 (comp. Witt, *Chem. Soc. J.* xxxv. 184).

(f, g). Two other modifications of the same compound may be obtained by the action of metadiazobenzenesulphonate on α - and β -naphthol (Griess, *loc. cit.*)

When submitted to the action of nascent hydrogen (tin and hydrochloric acid) these compounds yield the corresponding amidosulphonic acid and amidonaphthol (Griess).

(h). $C^6H^4(SO^3H).N=N.C^{10}H^4(SO^3H).OH$.—This compound is prepared by adding a solution of paradiazobenzenesulphonate to an alkaline solution of β -naphtholsulphonic acid, &c. It is a yellowish-red crystalline substance. The *barium salt*, $C^{16}H^{10}N^2S^2O^7Ba, 7.5OH^2$, crystallises in dark orange-red microscopic needles, difficultly soluble in hot and very difficultly soluble in cold water.

(i). $C^{10}H^4(SO^3H).N=N.C^{10}H^4.OH$.—This body is a beautiful red colour; it is prepared from diazonaphthalenesulphonic acid and β -naphthol (Griess; comp. *Ber.* xiii. 268).

(j). $C^6H^3(SO^3H)(COOH).N=N.C^{10}H^3(OH)(COOH)$.—This compound is obtained by acting on an alkaline solution of α -hydroxynaphthoic acid with diazosulphobenzoic acid; it crystallises in brown microscopic needles and plates, exhibiting a bronze lustre (Griess).

(k). $C^6H^3Br^2(SO^3H).N=N.C^{10}H^3(OH)^2$.—This compound is prepared from dihydroxynaphthalene and diazodibromobenzenesulphonic acid; it separates from its aqueous solution on the addition of hydrochloric acid in violet-brown microscopic needles (Griess).

DERIVATIVES OF NAPHTHALENE.

Chloronaphthalenes. *Monochloronaphthalenes*, $C^{10}H^7Cl$.—That obtained by the direct action of chlorine on naphthalene—or rather, by the decomposition of naphthalene dichloride—is the α -modification. β -*Monochloronaphthalene* is formed on treatment of β -naphthol or naphthalene- β -sulphonic chloride with phosphoric pentachloride (Rimarenko, *Ber.* ix. 663; Cleve, *Bull. Soc. Chim.* xxv. 257); and by boiling β -diazonaphthalene sulphate with concentrated hydrochloric acid (Liebermann a. Palm, *Liebig's Annalen*, clxxiii. 270). It crystallises from alcohol, in which it is easily soluble, in naphthalene-like plates melting at 61° (L. a. P.); 56° (R.). It boils at about 260° .

Dichloronaphthalenes, $C^{10}H^6Cl^2$.—No fewer than eight of the ten possible modifications of dichloronaphthalene are said to have been obtained.

α -*Dichloronaphthalene*, obtained by acting on naphthalene tetrachloride with alcoholic potash, melts at 35° , and boils at 281° (Faust a. Saame).

β -*Dichloronaphthalene* is formed, together with a small amount of the α -isomeride, when pure naphthalene tetrachloride is decomposed by rapidly heating small quantities to the boiling point, but together with a considerable amount of the same isomeride, when a larger quantity of the tetrachloride is heated and maintained in a state of gentle ebullition until hydrochloric acid is no longer evolved (Krafft a. Becker, *Ber.* ix. 1088). It is also formed on treatment of α -nitro- α -naphthol with phosphoric pentachloride (Atterberg, *ibid.* ix. 1189). It melts at 68° and boils at 281° (Faust a. Saame); on oxidation with nitric acid, it yields dichlorophthalic acid (Atterberg, *ibid.* x. 547).

γ -*Dichloronaphthalene* is best prepared by gradually adding phosphoric pentachloride to so-called α -dinitronaphthalene heated in an oil bath to its melting point, the apparatus being so arranged that the phosphoric oxychloride distils over as it is

produced; it is a product of the action of chlorine on nitronaphthalene (Atterberg, *ibid.* ix. 317, 1188, 1734), and of the action of phosphoric pentachloride on the nitronaphthalenesulphonic acid formed from α -nitronaphthalene and from naphthalene- α -sulphonic acid (Cleve, *Bull. Soc. Chim.* xxiv. 506). γ -Dichloronaphthalene crystallises from alcohol in colourless glistening scales melting at 107°. On oxidation with nitric acid, it yields nitrochlorophthalic acid, $C^6H^2Cl(NO^2)(COOH)$.

δ -Dichloronaphthalene is obtained on distilling the chloride of α -, and ϵ -dichloronaphthalene that of β -naphthalenedisulphonic acid with phosphoric pentachloride. The former crystallises in large brilliant plates melting at 114°; the latter in brilliant prisms melting at 135° (Cleve *Bull. Soc. Chim.* xxvi. 244).

ζ -Dichloronaphthalene is formed in small quantity on distilling β -dinitronaphthalene with phosphoric pentachloride; it crystallises in well-developed prisms, melting at 83° (Atterberg, *Ber.* ix. 1732).

η -Dichloronaphthalene, obtained by distilling nitronaphthalene- β -sulphonic chloride (m.p. 125.5°), with phosphoric pentachloride, melts at 48°. It yields a mixture of chloro- and chloronitrophthalic acid when submitted to the action of nitric acid under pressure at 150° (Cleve, *Bull. Soc. Chim.* xxix. 499).

θ -Dichloronaphthalene is obtained in like manner from the isomeric chloride melting at 169°. It forms small white needles melting at 61.5° (Cleve, *ibid.* xxix. 414, 450).

Trichloronaphthalenes, $C^{10}H^3Cl^3$.—Six of these are now known:

α -Trichloronaphthalene, obtained by boiling α -chloronaphthalene tetrachloride with alcoholic potash, melts at 131.5°; it yields nitrotrichlorophthalic acid when heated with nitric acid at 200° (Widmann, *Bull. Soc. Chim.* xxviii. 511).

β -Trichloronaphthalene is one of the products of the action of chlorine on nitronaphthalene; it forms long pliable needles melting at 90° (Atterberg, *Ber.* ix. 926).

γ -Trichloronaphthalene is also formed by the action of chlorine on nitronaphthalene (Atterberg, *ibid.* ix. 316), and by distilling dichloronaphthalene- α -sulphonic chloride with phosphoric pentachloride (Widmann, *ibid.* xii. 2230). It crystallises in brittle glistening needles melting at 103°.

δ -Trichloronaphthalene may be obtained by distillation of β -dinitronaphthalene, nitro- γ -dichloronaphthalene, α -dinitrochloronaphthalene, β -dinitrochloronaphthalene, and nitro- β -dichloronaphthalene with phosphoric pentachloride (Atterberg, *ibid.* ix. 1187, 1733). It forms very long, flat, pliable needles, melting at 131°; heated with nitric acid, it yields a dichlorophthalic acid.

ϵ -Trichloronaphthalene, prepared by acting upon nitro- η -dichloronaphthalene with phosphoric pentachloride, crystallises in colourless needles melting at 65° (Cleve, *Bull. Soc. Chim.* xxix. 499).

ζ -Trichloronaphthalene, prepared by distilling dichloronaphthalene- β -sulphonic chloride with phosphoric pentachloride, crystallises in fine white pliable needles melting at 76°; it apparently yields nitrodichlorophthalic acid when heated with nitric acid (Widmann, *Ber.* xii. 962).

Tetrachloronaphthalenes, $C^{10}H^2Cl^4$.—Five modifications have been described:

α -Tetrachloronaphthalene, obtained by acting with alcoholic potash on the dichlorotetrachloride formed on chlorinating naphthalene, melts at 130° (Faust a. Saame).

β -Tetrachloronaphthalene is formed on chlorinating nitronaphthalene; it crystallises in needles, very difficultly soluble in alcohol, melting at 194° (Atterberg, *ibid.* ix. 318).

γ -Tetrachloronaphthalene, formed from the isomeric dichlorotetrachloride from naphthalene, melts at 176° (Widmann, *ibid.* x. 1725).

δ -Tetrachloronaphthalene, from γ -dichloronaphthalene tetrachloride, crystallises in fine white needles melting at 141° (Atterberg a. Widmann, *Ber.* x. 1842).

ϵ -Tetrachloronaphthalene, obtained by distilling dinitro- γ -dichloronaphthalene with phosphoric pentachloride, melts at 180° (Atterberg a. Widmann, *loc. cit.*)

Pentachloronaphthalenes, $C^{10}H^1Cl^5$.—In addition to that described by Graebe, a second modification is known, obtained by distilling nitro- δ -tetrachloronaphthalene with phosphoric pentachloride; it melts at 177°, and on oxidation with nitric acid yields trichlorophthalic acid (Atterberg a. Widmann, *loc. cit.*)

Octachloronaphthalene, $C^{10}Cl^8$, according to Ruoff (*ibid.* ix. 1486), melts at 203° and not at 135° as stated by Berthelot and Jungfleisch (vi. 847). When heated with antimonie pentachloride at 280°–300°, it is resolved into hexachlorobenzene, hexachloroethane, and tetrachloromethane.

Naphthalene and Chloronaphthalene Chlorides, *Naphthalene dichloride*, $C^{10}H^8Cl^2$, is obtained, according to E. Fischer (*Ber.* xi. 735, 1411), together with two isomeric tetrachlorides and a monochloronaphthalene dichloride on chlorinating naphthalene according to Depouilly's process, by treatment with potassic chlorate and hydrochloric acid. It has the properties ascribed to it by Laurent. It begins slowly

to decompose at 40°–50°; when heated with sodium or sodium amalgam in sealed tubes at 150°, it is reconverted into naphthalene.

α -Naphthalene tetrachloride, $C^{10}H^6Cl^4$. According to Grimaux (*Ber.* 1872, v. 222; also Schwarzer, *Ber.* x. 379) a saturated solution of chlorine in chloroform at once converts naphthalene into this compound, a pure product being readily obtained. It melts at 182° (vi. 846); and yields almost the theoretical amount of phthalic acid on oxidation with nitric acid (E. Fischer). When decomposed by alcoholic potash, it appears to yield only α -dichloronaphthalene. If, however, it be heated in small quantities (about 1 gram) at a time, as rapidly as possible, to the boiling point, and vigorously boiled for a few minutes, it is almost entirely converted into β -dichloronaphthalene; but if a larger quantity be heated and maintained in gentle ebullition as long as hydrochloric acid is evolved, a considerable amount of α -dichloronaphthalene is also produced (Krafft a. Becker, *Ber.* ix. 1088). If an alcoholic or ethereal solution of naphthalene tetrachloride be digested with zinc, naphthalene is reproduced (Zinin, *ibid.* ix. 288).

β -Naphthalene tetrachloride, according to E. Fischer, melts at 116°–118°; Atterberg doubts the formation of this modification (*ibid.* xi. 1223).

Monochloronaphthalene dichloride, $C^{10}H^7Cl^3$, melts at 176° (E. Fischer).

Monochloronaphthalene tetrachloride, $C^{10}H^7Cl^5$.—That obtained from α -chloronaphthalene melts at 131·5°. The isomeride from β -chloronaphthalene is an oil (Widmann, *ibid.* x. 1724; *Bull. Soc. Chim.* xxviii. 505).

Dichloronaphthalene tetrachloride, $C^{10}H^6Cl^6$.— α -Dichloronaphthalene yields two tetrachlorides, one of which melts at 172°; the other is an oil. β -Dichloronaphthalene tetrachloride, from β -dichloronaphthalene, melts at the same temperature (172°) as, and in other respects closely resembles, crystalline α -dichloronaphthalene tetrachloride. On submitting γ -dichloronaphthalene dissolved in chloroform to the action of chlorine, a tetrachloride is obtained which crystallises in prisms melting at 85° (Atterberg a. Widmann, *ibid.* x. 1842).

Trichloronaphthalene dichloride, $C^{10}H^5Cl^5$, is known in two modifications: one obtained by acting on γ -dichloronaphthalene dissolved in chloroform with chlorine; the other by similarly treating a solution of α -chloronaphthalene in acetic acid. The former crystallises in large glistening prisms melting at 93° (Atterberg a. Widmann); the latter melts at 152° (Widmann).

Bromonaphthalenes. *β -Bromonaphthalene*, obtained by decomposing β -diazonaphthalene perbromide by boiling it with alcohol, crystallises in colourless plates melting at 68°; it is easily soluble in alcohol, ether, benzene, and chloroform (Liebermann a. Palm, *Liebig's Annalen*, clxxxiii. 269).

Dibromonaphthalenes, $C^{10}H^8Br^2$.—The dibromonaphthalene melting at 81°, which is the chief product of the direct action of bromine on naphthalene (vi. 845), probably corresponds in constitution to β -dichloronaphthalene (comp. p. 1378). The isomeric modification which is formed simultaneously, according to Jolin (*Bull. Soc. Chim.* xxviii. 514), melts at 61° and not at 76° as stated by Glaser. By displacing the NH^2 -group in dibromonaphthylamine (m. p. 118°) by hydrogen, Meldola has prepared a dibromonaphthalene which crystallises in white needles melting at 64° (*Ber.* xii. 1961). It is noteworthy that this modification differs totally in appearance from Jolin's dibromonaphthalene, melting at 61°, which is probably analogous in constitution to α -dichloronaphthalene. β -Dibromonaphthalene may also be obtained by distilling α -bromonaphthalenesulphonic bromide or nitro- α -bromonaphthalene with phosphoric pentabromide (Jolin). By distilling nitro- β -dibromonaphthalene with PBr^5 , a tribromonaphthalene (β) is produced, which crystallises in long flexible needles melting at 85° (Jolin).

γ -Dibromonaphthalene is formed by the action of phosphoric pentabromide on α -dintronaphthalene. It crystallises in brilliant scales melting at 129° (Jolin).

δ -Dibromonaphthalene is formed by distilling naphthalene- α -disulphonic acid with phosphoric pentabromide; it crystallises in thin plates, melting at 140·5° (Jolin).

The dibromonaphthalene melting at 126° obtained by Darmstädter and Wichelhaus (vi. 845) was probably the γ -modification.

Tribromonaphthalenes.—In addition to the α -modification (m. p. 75° Glaser) and that described above, a third modification (γ) is known, produced by treating naphthalene- β -sulphonic acid with bromine, and distilling the dibromosulphonic acid with PBr^5 . It crystallises in short brittle needles melting at 86·5° (Jolin).

Hexbromonaphthalene, $C^{10}H^2Br^8$, is obtained by submitting naphthalene to the prolonged action of bromine in presence of iodine, finally at 350°. It closely resembles hexbromobenzene in appearance; it is soluble, although not readily, in hot chloroform,

benzene, toluene, and aniline, but insoluble in alcohol and ether. It sublimes in felt-like masses of needlesh melting at 245° (Gessner, *Ber.* ix. 1510).

Nitrochloronaphthalenes. *a*-Mononitrochloronaphthalene, $C^{10}H^9(NO^2)Cl$, prepared by acting upon *a*-chloronaphthalene with cold nitric acid (sp. gr. 1.4), crystallises from alcohol in concentrically grouped, extremely fine, pale-yellow needles, melting at 85° ; on prolonged digestion with tin and hydrochloric acid, it yields *a*-naphthylamine (Atterberg, *Ber.* ix. 927).

a-Dinitro-*a*-chloronaphthalene, $C^{10}H^8Cl(NO^2)_2$, is obtained, together with the foregoing, on nitration of *a*-chloronaphthalene with warm nitric acid of sp. gr. 1.4, and together with an isomeric modification when the fuming acid is employed. It crystallises in long yellow pliable needles, easily soluble in hot alcohol; it melts at 106° (Faust a. Saame; Atterberg).

β-Dinitro-*a*-chloronaphthalene.—This appears to be formed in relatively larger quantity the higher the temperature of nitration. It is difficultly soluble, even in boiling alcohol; it crystallises from glacial acetic acid in short, pale yellow, brittle needles, melting at 180° (Atterberg, *loc. cit.*).

Nitro-*γ*-dichloronaphthalene, $C^{10}H^6(NO^2)_2Cl_2$, prepared by nitrating *γ*-dichloronaphthalene with cold nitric acid (sp. gr. 1.4), forms short sulphur-yellow prisms, difficultly soluble in alcohol, melting at 142° (Atterberg, *loc. cit.*)

Dinitro-*γ*-dichloronaphthalene, $C^{10}H^4(NO^2)_2Cl_2$, formed by treating the mononitro-derivative with a mixture of nitric and sulphuric acids, crystallises in pale-yellow brittle prismatic needles, very difficultly soluble even in glacial acetic acid. It melts at 246° (Atterberg, *loc. cit.*)

Nitro-*δ*-tetrachloronaphthalene, $C^{10}H^2Cl_4(NO^2)_2$, prepared by the action of concentrated nitric acid on *δ*-tetrachloronaphthalene, crystallises from a mixture of toluene and alcohol in large pale-yellow rhombic plates melting at 154° (Atterberg a. Widmann, *ibid.* x. 1831).

Nitrobromonaphthalenes. Nitro-*a*-bromonaphthalene, $C^{10}H^8Br.NO^2$, formed by nitration of *a*-bromonaphthalene, crystallises from alcohol in yellow needles melting at 85° (Jolin, *Bull. Soc. Chim.* xxviii. 514).

An isomeric bromonitronaphthalene is obtained by displacing the NH^2 -group in bromonitro-*a*-naphthylamine by hydrogen. It crystallises in pale yellow needles, melting at 131° (Liebermann a. Hammerschlag, *Liebig's Annalen*, clxxxiii. 262).

Nitro-*β*-dibromonaphthalene, $C^{10}H^6Br_2.NO^2$, produced by the action of cold nitric acid of sp. gr. 1.4 on *β*-dibromonaphthalene, forms yellow needles melting at 116.5° (Jolin).

Nitronaphthalenes. Nitronaphthalene.—According to Guareschi (*ibid.* x. 294), *a*-nitronaphthalene (m. p. 58° – 59°) is the only mononitro-derivative obtained on nitrating naphthalene under very various conditions.

According to de Koninck and Marquardt (*ibid.* v. 11), nitronaphthalene boils at 304° . It is violently acted upon by phosphoric pentasulphide and pentachloride. If it be mixed with a slight excess of the latter in a retort, and the mixture be very gradually heated, phosphoric oxychloride passes over, the temperature rising gradually to about 120° , or to 150° if an excess of PCl_5 be employed; the residue then consists of monochloronaphthalene and a small amount of unaltered nitronaphthalene.

In a similar manner, nitronaphthalene yields a mixture of mono- and dibromonaphthalene (probably *γ*-di) when heated with an equal volume of a concentrated solution of hydrobromic acid at 195° (Baumhauer, *ibid.* iv. 926).

On oxidation with chromic acid, nitronaphthalene is converted into nitro-naphthalic acid (m. p. 212° ; Beilstein a. Kurbatow, *Ber.* xii. 608).

Dinitronaphthalenes.—In addition to the two modifications (*α* and *β*) formed simultaneously on nitration of naphthalene (vii. 834), which melt respectively at 216° and 170° , a third isomeride is known, obtained by displacing the NH^2 -group in dinitro-*a*-naphthylamine by hydrogen. It crystallises in almost colourless needles, melting at 144° (Liebermann a. Hammerschlag, *Liebig's Annalen*, clxxxiii. 272).

a-Dinitronaphthalene yields nitrophthalic and ordinary dinitrobenzoic acid, *β*-dinitronaphthalene dinitrophthalic and dinitrobenzoic acid, when oxidised with dilute nitric acid (Beilstein a. Kurbatow, *Ber.* xiii. 353).

Trinitronaphthalenes.—Three modifications of this derivative are known. If *a*-dinitronaphthalene be submitted to the prolonged action of fuming nitric acid, it yields *a*-trinitronaphthalene, melting at 122° , together with nitrophthalic acid (Aguiar, *Ber.* iv. 897). If, however, it is boiled for a few minutes with 10 pts. of a mixture of equal weights of fuming nitric and concentrated sulphuric acids, an isomeric *γ*-dinitronaphthalene is obtained (Beilstein a. Kuhlberg, *ibid.* vi. 647), and the same

modification is produced in almost theoretical amount if 150 grams of fuming nitric acid are poured on 9 grams of the dinitronaphthalene and 150 grams of sulphuric acid are then added, the mixture being poured into water as soon as it becomes cool (Aguiar). γ -Trinitronaphthalene crystallises from fuming nitric acid in glistening four-sided plates, and from alcohol in chloride of ammonium-like forms; it melts at 147° (B. a. K.); 154° (A.). β -Dinitronaphthalene yields only β -trinitronaphthalene, whatever the conditions of nitration.

If α -dinitronaphthalene be boiled for several hours with double the quantity of the acid mixture used in converting it into trinitronaphthalene, fuming sulphuric acid also being employed in place of the ordinary acid, it is converted into α -tetranitronaphthalene (Beilstein a. Kuhlberg).

Nitrosonaphthalene, $C^{10}H^7(NO)$. To prepare this compound, a solution of mercury dinaphthyl in carbon bisulphide is mixed with a like solution of nitrosyl bromide—prepared by saturating a solution of bromine in carbon bisulphide at -20° with nitric oxide—in the proportions indicated by the equation: $(C^{10}H^7)^2Hg + NOBr = HgBr.C^{10}H^7 + ^{10}C^{10}H^7(NO)$.

After purification, it forms yellow aggregates, which very rapidly become red on exposure to air; it melts at 84° , and decomposes at about 134° . Nitrosonaphthalene at once combines with aniline, forming a red substance; it dissolves in sulphuric acid, producing a cherry-red liquid; and if it be dissolved in phenol and sulphuric acid be added, a blue colour is produced (A. Baeyer, *Ber.* vii. 1639).

Azonaphthalene, $C^{20}H^{14}N^2 = C^{10}H^7.N=N.C^{10}H^7$. This compound is formed in small quantity on heating nitronaphthalene with zinc-dust (Doer, *Ber.* iii. 291), and on oxidation of naphthylamine with lead oxide (Schichuzky, *ibid.* vii. 1454). The methods by which azobenzene is obtained from nitrobenzene are not applicable to its preparation (Klobukowski, *ibid.* x. 570; comp. 772 and 873). It is identical with Laurent's *naphthase* (Alexejeff, *ibid.* iii. 868; Klobukowski).

Azonaphthalene is very slightly soluble in alcohol, ether, benzene, chloroform, and acetic acid; it crystallises from a hot solution in acetic acid mixed with a couple of drops of fuming nitric acid in yellow needles melting at 275° . It dissolves in concentrated sulphuric acid, forming a dark violet-blue liquid. It appears to combine with bromine, forming an unstable bromide. If heated with bromine at 260° , or only gently warmed with bromine in presence of iodine, it is converted into a pentabromo-derivative.

Naphthalenesulphonic Acids. At present, two monosulphonic acids, two disulphonic acids, and a tetrasulphonic acid are known. The two first mentioned have already been described (vi. 860; vii. 835), but the following derivatives require notice here:

Naphthalene- α -sulphonic chloride, $C^{10}H^7.SO^2Cl$, crystallises from ether in glistening plates melting at 66° , easily soluble in ether, carbon bisulphide, and benzene (Maikopar, *Zeits. Chem.* 1869, 710). By the action of chlorine on its solution in carbon bisulphide, the *tetrachloride*, $C^{10}H^7.Cl^4.SO^2Cl$, is produced. This compound does not appear to crystallise (Widmann, *Ber.* xii. 2228).

Naphthalene- α -sulphonamide, $C^{10}H^7.SO^2(NH^2)$, prepared by warming the chloride with a concentrated aqueous solution of ammonia, and purified by crystallisation from alcohol, melts at 150° ; it is soluble in water, and easily soluble in alcohol (Maikopar). When heated with the equivalent amount of benzoic chloride at 145° – 150° as long as hydrochloric acid is evolved, it is converted into the benzoyl derivative, $C^{10}H^7.SO^2(NH.CO.C^6H^5)$. To purify the product, it is washed with alcohol, dissolved in potassic carbonate solution, precipitated by acid, and crystallised from boiling alcohol. It then crystallises from alcohol, in which it is somewhat difficultly soluble, in four-sided prisms, melting at 194° – 195° . It possesses marked acid properties, decomposing carbonates, and forming metallic derivatives such as $C^{10}H^7.SO^2(NK.CO.C^6H^5)$, &c., and belongs to the class of so-called *aci-amides* (vii. 21; Welkow, *Zeits. Chem.* 1871, 422). If submitted to the action of phosphorus pentachloride, it is converted into the chlorinated compound $C^{10}H^7.SO^2(NC^7H^7Cl)$, this body being doubtless formed in accordance with the following equations:

The new compound crystallises from ether in large four-sided plates, melting at 93° . It is reconverted into the aci-amide by boiling water or alcohol; and on treatment with ammonic carbonate forms the amido-derivative $C^{10}H^7.SO^2(N=C.NH^2.C^6H^5)$ (Wekow, *Ber.* v. 142).

Naphthalene- β -sulphonic chloride, $C^{10}H^7.SO^2Cl$, crystallises in plates; it is less soluble in ether than the α -chloride, and melts at 76° (Maikopar). Like the α -sulphonic

chloride, it is converted into a tetrachloride, $\text{C}^{10}\text{H}^7\text{Cl}^4\text{SO}^2\text{Cl}$, by the action of chlorine. This latter crystallises from chloroform in hard colourless transparent cubes, melting at 131° , easily soluble in chloroform, carbon bisulphide, and boiling acetic acid (Widmann, *Ber.* xii. 960).

Naphthalene- β -sulphonamide, $\text{C}^{10}\text{H}^7\text{SO}^2(\text{NH}^2)$, crystallises from boiling alcohol in small thin plates, difficultly soluble in water and ether (Maikopar); it melts at 217° (corr. Cleve).

Ethyl, phenyl, and naphthyl derivatives of naphthalene α - and β -sulphonamide have been described by Carleson (comp. *Ber.* x. 1725).

Chloronaphthalenesulphonic bromide, $\text{C}^{10}\text{H}^6\text{ClSO}^2\text{Br}$.—This compound is produced on treatment of sodium bromonaphthalenesulphonate with PCl^5 . It crystallises from ether in white needles melting at 115° (Gessner, *ibid.* ix. 1504).

Dichloronaphthalene- α -sulphonic chloride, $\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2\text{Cl}$, is formed on decomposing the tetrachloride obtained from naphthalene- α -sulphonic chloride with alcoholic potash, and treating the resulting potassic salt, when sufficiently purified, with phosphoric pentachloride. It is easily soluble in benzene and boiling acetic acid, crystallising from the former in very large colourless well-formed glistening prisms, and from the latter in glistening scales or needles; it melts at 145° . When distilled with PCl^5 , it is converted into γ -trichloronaphthalene (Widmann).

Dichloronaphthalene- α -sulphonic acid, $\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2(\text{OH})$, prepared by heating the foregoing chloride with water at 140° , crystallises in long colourless glistening flat needles, somewhat soluble in cold water. Its salts are difficultly soluble, and crystallise either in needles or plates; several of them require heating nearly to 200° before they are completely deprived of their water of crystallisation. The *potassium* salt, $\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2\text{K}\cdot 2\text{H}^2\text{O}$, crystallises in groups of fine white pliable needles; it loses 1 mol. of water under the desiccator, and the remaining molecule when heated at 185° ; 1 pt. of the salt dried at 100° dissolves in 115 pts. of water at 15° . The *sodium* salt, $\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2\text{Na}\cdot 3\text{OH}^2$, forms long glistening flat prisms; it loses 1 mol. of water under the desiccator. The *calcium* salt, $(\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2)^2\text{Ca}\cdot 4\text{H}^2\text{O}$, is very difficultly soluble in water, and crystallises from a hot concentrated solution in white glistening quadratic or rectangular plates. The *zinc* salt, $(\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2)^2\text{Zn}\cdot 7\text{H}^2\text{O}$, forms glistening plates difficultly soluble in cold, but more easily in hot water. The *amide*, $\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2(\text{NH}^2)$, crystallises from alcohol in flat feathery groups, melting above 250° (Widmann).

Dichloronaphthalene- β -sulphonic chloride, $\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2\text{Cl}$, prepared in a similar manner to the above from the β -sulphonic tetrachloride, crystallises from benzene in thin white needles, grouped in ball-like forms; it melts at 133° . When distilled with PCl^5 , it yields ζ -trichloronaphthalene (Widmann).

Dichloronaphthalene- β -sulphonic acid, $\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2(\text{OH})$, obtained by decomposing the above chloride with water at 130° , is very soluble in hot, but only moderately in cold water. When a moderately concentrated warm solution is cooled, it solidifies to a jelly-like mass. Its salts also exhibit a great tendency to crystallise in a similar manner in gelatinous masses of extremely fine needles, and are thus sharply distinguished from those of the α -acid. They contain varying amounts of water, according to the conditions under which they are formed, and are all more or less difficultly soluble in water. The *amide*, $\text{C}^{10}\text{H}^5\text{Cl}^2\text{SO}^2(\text{NH}^2)$, crystallises from boiling alcohol in nodular aggregates of extremely fine glistening needles; it melts at about 245° , but, like the α -amide, becomes blackened (Widmann).

α -Nitronaphthalene- α -sulphonic acid, $\text{C}^{10}\text{H}^6(\text{NO}^2)\text{SO}^2\text{H}$.—This acid may be formed by nitration of naphthalene- α -sulphonic acid, and by the action of sulphuric acid on α -nitronaphthalene, but is best prepared by the latter method. It crystallises with 4 mols. of water in long straw-yellow prisms, easily soluble in pure water, but difficultly soluble in presence of sulphuric acid; hence it may be purified by precipitation with sulphuric acid. Its salts crystallise well, the *potassium* salt with half a mol. of water in large plates, the *ammonium* salt with 1.5 mol. of water in needles, and the *silver* salt in anhydrous monoclinic prisms. The *ethyl* salt melts at 101° , the chloride at 113° (Cleve, *Bull. Soc. Chim.* xxiv. 506).

By the action of sodium amalgam on its aqueous solution, α -nitronaphthalene- α -sulphonic acid is converted into sulphuric acid and amidonaphthalene (Claus & Graeff, *ibid.* x. 1303).

The corresponding *amido-acid*, $\text{C}^{10}\text{H}^6(\text{NH}^2)\text{SO}^2\text{H}$, is a crystalline powder; on treatment with nitrous acid, it yields the *diazo*-compound $\text{C}^{10}\text{H}^6(\text{N}^2\text{SO}^2)$, which crystallises in yellow needles, and when heated with water, is converted into a dihydroxynaphthalene, $\text{C}^{10}\text{H}^6(\text{OH})^2$ (Cleve).

Nitronaphthalene- β -sulphonic acid.—Naphthalene- β -sulphonic acid yields, on nitration, several isomeric mononitro-derivatives, which may be partially separated by

means of the barium salts. The acid of the least soluble salt crystallises in yellow needles easily soluble in water. Its salts are mostly difficultly soluble. The *potassium* and *ammonium* salts are anhydrous; the *barium* salt contains 1 mol. of water, and is difficultly soluble, even in boiling water. The *ethyl* salt melts at 114° , the *chloride* at 125.5° .

The corresponding *amido*-acid crystallises in anhydrous rhombic plates or in prisms with 2 mol. of water (Cleve, *Bull. Soc. Chim.* [2], xxvi. 444).

The barium salt remaining after that of the above nitro-acid (Cleve's β -acid) has been separated, appears still to contain two, if not three, nitro-acids. By converting it into the chloride, extracting with hot carbon bisulphide, and crystallising the undissolved portion from carbon bisulphide, the chloride of one of these—the so-called δ -acid of Cleve—may be separated in the pure state. It crystallises in large well-defined prisms, melting at 169° , only sparingly soluble in carbon bisulphide and acetic acid. The acid formed by heating the chloride with water at 130° is easily soluble, and forms easily soluble salts. The *barium* salt, $[\text{C}^{10}\text{H}^6(\text{NO}^2)\cdot\text{SO}^2]_2\text{Ba}\cdot\text{H}^2\text{O}$, forms pale yellow needles. The amide, $\text{C}^{10}\text{H}^6(\text{NO}^2)\cdot\text{SO}^2(\text{NH}^2)$, crystallises in yellow prisms melting at 216° .

The corresponding *amido*-acid crystallises from water in silvery scales (Cleve, *ibid.* xxix. 414).

Amidonaphthalenesulphonic acid. *Naphthionic acid*, $\text{C}^{10}\text{H}^6(\text{NH}^2)\cdot\text{SO}^2\text{H}$.—The acid which Piria obtained, by acting on amidonaphthalene with ammonium sulphite (iv. 17), is identical with that prepared by Schaal a. Schmidt from amidonaphthalene and sulphuric acid (Cleve, *ibid.* xxvi. 241). On displacing the NH^2 -group by Cl and distilling the resulting chloro-acid with PCl^5 , β -dichloronaphthalene is produced.

Naphthalenedisulphonic Acids.—According to Ebert a. Merz (*Ber.* ix. 592), two isomeric *naphthalenedisulphonic acids*, $\text{C}^{10}\text{H}^6(\text{SO}^2\text{H})_2$, are simultaneously produced on heating naphthalene with an excess of sulphuric acid. About equal amounts of the α - and β -acid are formed when a mixture of 1 pt. naphthalene and 5 pts. concentrated acid is heated for four hours at 160° , the product being free from monosulpho-acid; but if the same mixture be heated for about twenty-four hours at 180° , the product consists almost entirely of the β -acid, and the pure α -acid may be converted into the β -acid by prolonged heating with sulphuric acid at 180° .

To separate the two isomerides, the hot aqueous solution is neutralised first with calcium hydrate and finally with calcium carbonate, then filtered, and the filtrate evaporated down. As the liquid becomes concentrated, crystalline crusts of the β -salt separate out, and must be removed from time to time; ultimately the concentrated solution is strained boiling hot, and then evaporated to complete dryness. If the residue thus obtained be added to boiling water, the whole of the α -salt at once dissolves, while but very little of the β -salt goes into solution; the liquid is rapidly filtered, and the filtrate left to cool in covered vessels, when almost pure α -salt is deposited. This is collected, freed from the mother-liquor by pressure, and recrystallised. A considerable amount of β -salt remains with the calcium sulphate; this is extracted by prolonged boiling with a large quantity of water, and the solution evaporated. The residue, together with the crude β -salt previously obtained, is ground up with water, and then carefully washed to remove the adhering α -salt. The calcium salts thus obtained may be converted into sodium or potassium salts in the usual manner.

By heating the dry potassium salts with phosphoric pentachloride at 140° , the corresponding sulphochlorides are obtained in almost theoretical proportions. After distilling off the phosphoric oxychloride, the residue is treated with water, and then once or twice crystallised from boiling benzene.

α -*Naphthalenedisulphonic chloride*, $\text{C}^{10}\text{H}^6(\text{SO}^2\text{Cl})_2$, crystallises from hot benzene in magnificent colourless, transparent four or six-sided plates, which may be obtained of a large size, resembling epidote crystals, by allowing the solution to evaporate spontaneously. From ether it not unfrequently crystallises in sharp needles; it is seldom obtained in well-formed crystals from an acetic acid solution. The crystals deposited from ether or acetic acid remain perfectly colourless and transparent, but those deposited from benzene generally become opaque, this change taking place either immediately or after some time; the change is in no way due to efflorescence. It dissolves in 7.5 pts. of benzene at 14° . It melts at 157° – 158° .

β -*Naphthalenedisulphonic chloride* crystallises from hot saturated solutions in bundles or tufts of small white needles, at most from 3–5 mm. in length. From toluene, on slow evaporation, it is deposited in large thin plates which often exhibit peculiar grotesque outlines. It dissolves in 220.7 pts. of benzene at 14° , but is much more soluble in presence of the α -chloride. It is also very slightly soluble in acetic acid, which very easily dissolves the α -chloride. It melts at 226° . Both

chlorides are decomposed and carbonised with evolution of sulphur dioxide when heated above their melting-points. When triturated with ammonium carbonate and then warmed with concentrated ammonia solution, or directly treated with the latter, they are converted into the corresponding sulphonamides. The naphthalene-disulphonic chlorides are not acted upon by sodium amalgam even at 150° (Gessner, *ibid.* ix. 1503).

α -Naphthalenedisulphonamide, $C^{10}H^8(SO_2.NH_2)_2$, is moderately soluble in hot ammoniacal water or alcohol, whereas the β -amide is very slightly soluble in the first liquid, and almost insoluble in alcohol, ether, benzene, and toluene. The α -amide crystallises in delicate glistening needles, the β -amide in small needles. The former melts at 242° – 243° ; the latter remains unfused at 305° .

By heating with water in sealed tubes at 150° , the naphthalenedisulphonic chlorides are completely converted, within three to four hours, into the corresponding acids; but if the temperature be raised to 200° , they are resolved into naphthalene and sulphuric acid. If the α -sulphonic chloride be heated with only its own volume of water, the α -sulphonic acid crystallises out on cooling in long brilliant white needles. The β -chloride cannot be entirely decomposed by so small a quantity of water at 150° – 160° , and the dilute solution obtained when the necessary amount is taken does not crystallise; but on concentrating the solution in a vacuum, it separates in small glistening white plates. Both acids are sparingly soluble in cold hydrochloric acid solution, but extremely soluble in water.

Acid salts cannot apparently be obtained from either acid. The salts of both are extremely stable; those of the α -acid contain more water than the corresponding β -salts; the water of crystallisation is, in most cases, completely expelled only above 200° . The α -salts crystallise more readily and are more soluble than the β -salts; characteristic of many of the latter is the slowness with which they dissolve.

α -Salts.—The *potassium* salt, $C^{10}H^8(SO_3^K)_2.2H_2O$, crystallises from a hot saturated solution in colourless transparent needles, soluble in 1.4 pts. water at 14° . The *sodium* salt, $C^{10}H^8(SO_3^Na)_2.6H_2O$, forms large glistening needles, soluble in 2.2 pts. water at 18° ; one-half the water of crystallisation is removed by exposure over sulphuric acid. The *calcium* salt, $C^{10}H^8.(SO_3^2)^2Ca$, crystallises with varying amounts of water, separating from a rapidly cooled hot saturated solution with 3 mols., and from a slowly cooled solution with 6 mols.; the latter dissolves in 6.2 pts. water at 18° . It separates from aqueous alcohol in colourless glistening needles. The *barium* salt, $C^{10}H^8.(SO_3^2)^2Ba.2H_2O$, forms long broad needles, soluble in 82.2 pts. water at 19° . The *lead* salt, $C^{10}H^8.(SO_3^2)^2Pb.2H_2O$, is the most beautiful of all the α -salts, crystallising in long glistening needles, easily soluble in water.

β -Salts.—The *potassium* salt, $C^{10}H^8(SO_3^K)_2$, crystallises in bushy groups of white needles, soluble in 19.2 pts. water at 18° . The *sodium* salt, $C^{10}H^8(SO_3^Na)_2.H_2O$, separates in aggregates of well-formed microscopic prisms, soluble in 8.4 pts. water at 19° . The *calcium* salt, $C^{10}H^8.(SO_3^2)^2Ca$, contains, when air-dry, from 1 to 1.5 per cent. of water. It crystallises with difficulty, and although soluble to the extent of 1 pt. in 16.2 pts. water at 18° , it is dissolved with great difficulty by water when it has been once dried. It is no more soluble in hot than in cold water, consequently a saturated solution filtered boiling hot does not deposit crystals on cooling, even after long standing. The *barium* salt, $C^{10}H^8.(SO_3^2)^2Ba.H_2O$, closely resembles the calcium salt, but is more soluble in hot than in cold water. The *lead* salt, $C^{10}H^8.(SO_3^2)^2Pb.OH_2$, like the calcium and barium salts, crystallises badly, and when once separated dissolves with difficulty in water.

On fusion with potassium hydrate, potassium α -naphthalenedisulphonate exchanges both sulpho-groups for hydroxyl, forming a dihydroxynaphthalene, $C^{10}H^8(OH)_2$, but the β -salt exchanges only one; the naphtholsulphonate thus produced is said to be identical with that prepared from β -naphthol and sulphuric acid.

Naphthalenetetrasulphonic Acid, $C^{10}H^8(SO_3^2H)_4$.—According to Senhofer (*Ber.* viii. 1486), this acid is formed on heating a solution of naphthalene in sulphuric acid with phosphoric anhydride in sealed tubes at 260° for three to four hours. Its *barium* salt, $[C^{10}H^8(SO_3^2)^4]Ba^2$, separates partly in ill-defined crystalline masses, and partly in long, solid, pointed prisms.

Naphthalenesulphones. The formation of a compound of the formula $(C^{10}H^7)^2SO_2$, first observed by Berzelius in 1837 (v. 522), by the action of sulphuric acid on naphthalene, has been confirmed by Stenhouse & Groves (*Ber.* ix. 682), and also by Cleve (*ibid.* x. 1723; *Bull. Soc. Chim.*, xxv. 256). A mixture of 8 pts. pure naphthalene and 3 pts. sulphuric acid is heated to 180° in a retort. After two to three hours, water is given off, and in order to maintain the temperature constant, it is necessary to apply more heat; at this stage a reaction appears to take place, lasting one or two hours, and a considerable amount of water passes over. When, after

about another hour, water is no longer given off, the source of heat is removed, and the product allowed to cool down to 100° ; 4 pts. of boiling water are then added, and the whole poured out into a dish. When cool, the product consists of a brownish-yellow cake of the naphthalenesulphonates, mixed with excess of naphthalene, and of a pasty crystalline mass of almost pure naphthalene- β -sulphonic acid. The naphthalene is removed by steam-distillation, and the pulverised residue is then extracted with boiling carbon bisulphide and the undissolved portion washed with this solvent until the liquid runs through colourless. The solution deposits a considerable quantity of hard prismatic crystals of the α -sulphone on cooling, mixed, however, with nodular aggregates of needles, from which they may be separated either mechanically or by repeated crystallisation from alcohol and carbon bisulphide. The α -sulphone is easily purified by alternate crystallisation from these solvents, and when pure melts at 123° . The residue from the treatment of the crude product with carbon bisulphide consists almost entirely of the β -sulphone, which may be purified by recrystallisation from boiling alcohol, in which, however, it is only sparingly soluble; it crystallises in silky needles, melting at 177° (Stenhouse and Groves).

According to Cleve, the β -sulphone yields a mixture of β -chloronaphthalene and of naphthalene- β -sulphonic chloride when distilled with phosphoric pentachloride.

Mixed Sulphonates.—When a mixture of benzenesulphonic chloride, $\text{C}_6\text{H}_5\cdot\text{SO}_2\text{Cl}$, and naphthalene, in equal molecular proportions, is heated with zinc dust, a mixed sulphone of the formula $\text{C}_6\text{H}_5\cdot\text{SO}_2\cdot\text{C}_{10}\text{H}_7$, melting at 121° , is produced (Crustschoff, *Ber.* vii. 1167).

According to Michael A. Adair (*ibid.* x. 585), the same compound is formed, together with an isomeride (α -phenylnaphthylsulphone), on heating a mixture of benzenesulphonic acid and naphthalene with phosphoric anhydride for eight to nine hours at 170° – 190° , and is produced alone on heating a mixture of benzene and naphthalene- β -sulphonic chloride with phosphoric anhydride at 180° – 200° .

α -Naphthylphenylsulphone separates from alcohol in groups of rhombohedral crystals, melting at 100° , easily soluble in hot alcohol, ether, benzene, or acetic acid.

β -Naphthylphenylsulphone crystallises from alcohol or ether in fan-like groups of long needles, melting at 115° – 116° . The crystals are very bulky and glisten, whereas those of the α -compound are lustreless.

Dimethylamido-derivatives of these two sulphonates are obtained on heating dimethylaniline with naphthalene α - and β -sulphonic chlorides (Michler and Salathé, *Ber.* xii. 1789).

Naphthalenesulphinic Acids, $\text{C}_{10}\text{H}_7\cdot\text{SO}_2\text{H}$. The formation of an acid of this formula from naphthalenesulphonic chloride was first indicated by Otto and Mories (vi. 860). The naphthalenesulphinic acids have more recently been studied by Gessner (*Ber.* ix. 1500).

Naphthalene- α -sulphinic acid is prepared by digesting a solution of naphthalene- α -sulphonic chloride in anhydrous ether with sodium amalgam in a flask attached to a reversed condenser. The amalgam is added gradually, finally in excess, and the heating continued until a portion of the solution leaves no residue on evaporation. The ether is then distilled off, the residue dissolved in water, the solution treated with an excess of hydrochloric acid, evaporated to a considerable extent, and then set aside to crystallise. The greater part of the acid separates in crystalline crusts. It is purified by repeated conversion into the barium salt and decomposition by sulphuric acid; finally, its solution is boiled with lead carbonate, the resulting lead salt is decomposed with sulphuretted hydrogen, and the liquid is then evaporated to the crystallising point.

It forms white glistening scales, which melt only at a high temperature, much more soluble in pure water than in water containing hydrochloric acid, moderately soluble in alcohol and sparingly soluble in ether. It is decomposed by dilute hydrochloric acid at 180° into naphthalene and sulphurous acid.

The naphthalene- α -sulphinates crystallise in glistening silky scales or needles, and are, for the most part, easily soluble in water and alcohol. The *potassium* salt, $(\text{C}_{10}\text{H}_7\cdot\text{SO}_2\text{K})_2\cdot\text{H}_2\text{O}$, forms white glistening scales. The *barium* salt, $(\text{C}_{10}\text{H}_7\cdot\text{SO}_2)_2\cdot\text{Ba}\cdot 1\cdot 5\text{H}_2\text{O}$, crystallises in fine needles, and requires 201 pts. of water at 14° and 50 pts. of boiling water to dissolve it. The *lead* salt, $(\text{C}_{10}\text{H}_7\cdot\text{SO}_2)_2\cdot\text{Pb}\cdot\text{H}_2\text{O}$, separates from a concentrated solution in long branched glistening needles. The *silver* salt is anhydrous, crystallising in glistening easily soluble plates which bear heating at 200° and above.

Naphthalene- β -sulphinic Acid.—Naphthalene- β -sulphonic chloride is more readily acted upon by sodium amalgam than the α -sulphonic chloride. If the product—a mixture of sodium chloride and sodium naphthalene- α -sulphinate—be extracted with alcohol, the latter is dissolved, and may readily be isolated. If the aqueous

solution of the sodium salt be treated with hydrochloric acid in excess, the sulphuric acid is precipitated as a white almost lustreless microcrystalline powder. It melts at 105° . It is by no means difficultly soluble in alcohol, ether, and pure water, but almost insoluble in dilute hydrochloric acid. It is more readily decomposed by hydrochloric acid (at 150°) than the α -acid. The barium salt is anhydrous, and forms white glistening needles, soluble in 16 pts. of boiling water. The calcium salt, $(C^{10}H^7.SO_2)^2Ca.3H_2O$, is a white lustreless crystalline powder, easily soluble in water and alcohol. The magnesium salt, $(C^{10}H^7.SO_2)Mg.6H_2O$, forms glistening scales more soluble in alcohol than in water.

Chloronaphthalenesulphonic acid, $C^{10}H^7Cl.SO_2H$, prepared by treating an ethereal solution of chloronaphthalenesulphonic bromide with sodium amalgam, &c., crystallises from alcohol in fine needles. On the addition of barium chloride to its aqueous solution, barium chloronaphthalenesulphinate, $(C^{10}H^7Cl.SO_2)^2Ba.1.5H_2O$, is gradually precipitated; by crystallisation from boiling water, it is obtained in glistening scales.

Naphthalene- α -sulphonic acid apparently yields a bromo-derivative on treatment with bromine. On adding bromine to a solution of barium naphthalene- β -sulphinate, a white precipitate of barium bromonaphthalene- β -sulphinate is at once produced (Gessner).

Naphthalenephosphonic Acids. When mercury dinaphthyl, $Hg(C^{10}H^7)^2$, is heated with phosphorous chloride, PCl_3 , in sealed tubes for several hours at 180° – 200° , two chlorides, $C^{10}H^7.PCl_2$ and $(C^{10}H^7)^2PCl$, are formed. On treatment with water, the former is converted into so-called *naphthylphosphorous acid*, $C^{10}H^7.PO(H)(OH)$, while the latter yields so-called *dinaphthylphosphinic acid*, $(C^{10}H^7)^2PO(OH)_2$, oxygen being absorbed. When the chloride $C^{10}H^7.PCl_2$ is submitted to the action of chlorine, it is converted into the tetrachloride $C^{10}H^7.PCl_4$, and this yields so called *naphthylphosphinic acid*, $C^{10}H^7.PO(OH)_2$, on treatment with water (Kolbe, *Ber.* ix. 1051; xi. 1499). It would be more in accordance with the system adopted in the case of the sulphur acids if the derivatives of phosphoric acid were termed *phosphonic acids*, and the derivatives of phosphorous acid *phosphinic acids*, thus preserving the idea of the relationship of the former to the phosphonium type and of the latter to the phosphine type.

Naphthylphosphonic acid, $C^{10}H^7.PO(OH)_2$, crystallises in long needles, easily soluble in hot, but with difficulty in cold, water. It melts at 190° , and when heated above this temperature is converted into a glassy mass, which, on exposure to moist air, gradually regains the crystalline structure. When strongly heated, it decomposes, with separation of carbon, into metaphosphoric acid and naphthalene. The silver salt, $C^{10}H^7.PO(OAg)_2$, falls as a white precipitate on the addition of silver nitrate to a solution of the ammonium salt.

Dinaphthylphosphonic acid, $(C^{10}H^7)^2PO(OH)_2$, crystallises in needles melting at 203° ; it is insoluble in water, but easily soluble in alcohol. It decomposes carbonates.

Naphthylphosphinic acid, $C^{10}H^7.PO(H)(OH)$, crystallises in aggregates of small white needles, difficultly soluble in cold but more soluble in hot water, almost insoluble in hydrochloric acid. When dry, it melts at 125° , but when boiled with water, it melts before dissolving.

Naphthylarsonic acid, $C^{10}H^7.AsO(OH)_2$. *Naphthylarsinic acid* (Kolbe).—This acid is prepared in the same way as the corresponding phosphonic acid, using arsenious chloride, $AsCl_3$, instead of phosphorous chloride. The former acts much more readily on mercury dinaphthyl than the latter, however. The acid crystallises from water in colourless needles, melting at 197° (Kolbe, *Ber.* xi. 1503).

Cyanonaphthalenes. *α -Cyanonaphthalene* is formed in by no means inconsiderable quantity when a mixture of cyanogen gas and naphthalene vapour is passed through a tube heated to dull redness. It is also formed on passing naphthalene vapour over a mixture of potassium ferrocyanide and quartz sand heated somewhat above dull redness (Scheibner; Merz a. Weith, *Ber.* x. 746). Another method of producing it consists in heating sulphocarbonaphthalide with copper powder (Weith, *ibid.* vi. 967).

If a solution of 2 pts. β -cyanonaphthalene in 1 pt. of alcohol be saturated with hydrochloric acid gas, it begins, after a few hours, to deposit crystals, and after twenty-four hours is converted into a solid crystalline cake of the hydrochloride of so-called *β -naphthimidoethylate*, $C^{10}H^7.C(NH^2Cl).OC^2H^5$ (Lohmann a. Pinner, *Ber.* xi. 1485). This compound decomposes when heated into ethyl chloride and β -naphthoic amide, $C^{10}H^7.CONH^2$. If it be agitated with an excess of ammonia solution, the free base, $C^{10}H^7.C(NH).OC^2H^5$, separates as an oil, which crystallises only after months, insoluble in water but easily soluble in alcohol, benzene, and ether. If the hydrochloride is digested with an alcoholic solution of ammonia at 50° – 60° , it is converted into the hydrochloride of the imidoamide $C^{10}H^7.N(NH)(NH^2Cl)$; this crystallises in

star-like groups of needles, easily soluble in water and alcohol, melting at 224° – 226° . The corresponding base, $C^{10}H^7.C(NH)(NH^2)$, separates as an oil on treatment of the hydrochloride with sodium hydrate solution; on exposure *in vacuo*, it solidifies to a white granular mass.

By employing isobutyl alcohol in place of ethyl alcohol, the corresponding *isobutyl* compound, $C^{10}H^7.C(NH^2Cl).OC^4H^9$, is obtained. The free base crystallises from ether in long needles melting at 38° ; on digestion with acetic anhydride, it is converted into the acetyl-derivative, $C^{10}H^7.C(NH).OC^2H^3O$, which crystallises from boiling alcohol in glistening white needles melting at 150° – 152° .

Bromo- α -cyanonaphthalene, $C^{10}H^6Br.CN$, prepared by the action of bromine on a solution of α -cyanonaphthalene in carbon bisulphide, sublimes in fine white needles melting at 147° . It is easily soluble in chloroform, benzene, boiling alcohol, ether, and glacial acetic acid (Hausmann, *ibid.* ix. 1516).

Bromo- β -cyanonaphthalene sublimes in broad white needles melting at 148° – 149° . It is easily soluble in benzene and chloroform (Hausmann).

Dicyanonaphthalenes. By distilling the pure potassium or sodium salts of the isomeric α - and β -naphthalenedisulphonic acids with potassium cyanide, Ebert a. Merz (*Ber.* ix. 604) have obtained the corresponding dicyanonaphthalenes, $C^{10}H^6(CN)^2$, in a state of purity. Externally they very closely resemble each other, subliming easily and almost entirely in long white glistening needles, and crystallising in a similar manner from solvents, especially acetic acid. The α -dicyanide, however, melts at 267° – 268° , the β -dicyanide at 296° – 297° . The β -compound is almost insoluble in boiling ether, alcohol, and benzene; the α -compound is in a not inconsiderable degree soluble in boiling alcohol. By heating under pressure with hydrochloric acid at 200° – 213° , or by boiling with a solution of potassium hydrate in amyl alcohol, both are completely converted into corresponding dicarboxylic acids, but the β -compound is much the more slowly acted upon.

It is doubtful whether the dicyanonaphthalenes prepared by Darmstädter and Wichelhaus from the bromonaphthalenesulphonic acids were obtained in a state of purity.

Naphthalenecarboxylic Acids. *Naphthoic Acids*, $C^{10}H^7.COOH$. In preparing the naphthoic acids according to Merz's method, potassium ferrocyanide may with advantage be employed in place of potassium cyanide in converting the sulpho-salts into cyanides (Witt, *Ber.* vi. 488; Hausmann, *ibid.* ix. 1514).

A number of metallic salts of β -naphthoic acid have been described by Vieth (*ibid.* viii. 1278; comp. viii. 1505; ix. 1513; *Liebig's Annalen*, clxxx. 314). Both α - and β -naphthoic acid yield phthalic acid when boiled with a solution of chromic anhydride in glacial acetic acid (Vieth).

Methyl- β -naphthoate, $C^{10}H^7.COOCH^3$, produced by heating β -naphthoic chloride with methyl alcohol, forms glistening crystalline scales melting at 77° , and boiling at about 290° . The corresponding *ethyl* salt, $C^{10}H^7.COOC^2H^5$, is a very easily fusible substance; it boils at 308° – 309° (Vieth).

β -Naphthoic chloride, $C^{10}H^7.COCl$, prepared by treating β -naphthoic acid with phosphoric pentachloride, is a crystalline substance melting at 43° ; it boils at 305° (Grucaevic a. Merz, *Ber.* vi. 1242; Vieth, *loc. cit.*)

β -Naphthoic amide, $C^{10}H^7.CO(NH^2)$, produced by warming the chloride with pulverised ammonium carbonate, crystallises in colourless plates, melting at 192° ; it is difficultly soluble in cold, more soluble in hot alcohol, ether, chloroform and benzene.

β -Naphthoic phenylamide, $C^{10}H^7.CO.NH(C^6H^5)$, prepared by adding the chloride in equivalent quantity to a solution of aniline in benzene, or by heating a mixture of β -naphthoic acid with an excess of aniline for several hours at 120° , forms glistening plates, easily soluble in alcohol and warm benzene and chloroform; it melts at 170° . *β -Naphthoic-tolylamide*, $C^{10}H^7.CONHC^7H^7$, obtained in a similar manner, forms silky glistening needles, easily soluble in alcohol and chloroform; it melts at 191° . *β -Naphthoic naphthylamide*, $C^{10}H^7.CONHC^{10}H^7$, crystallises in very small needles, difficultly soluble in ether, but moderately soluble in alcohol, chloroform, and benzene; it melts at 157° . *β -Naphthoylurea*, $C^{10}H^7.CO.N^2H^3CO$, produced by warming the chloride with urea, crystallises from hot alcohol in microscopic needles, melting at 215° (Vieth).

$\alpha\beta$ -Naphthoic anhydride, $(C^{10}H^7.CO)^2O$, is produced by heating a mixture of α -naphthoic chloride and dry potassium β -naphthoate at 150° – 160° , until the odour of the chloride has disappeared. It crystallises in fine needles melting at 126° (Hausmann, *Ber.* ix. 1515).

β^2 -Naphthoic anhydride, $(C^{10}H^7.CO)^2O$, prepared in a similar manner from β -naphthoic chloride and potassium β -naphthoate, crystallises from ether in needles united in the form of glistening plates; it melts at 134° (Hausmann).

Naphthoylbenzoic acid, $C^{10}H^7.CO.C^6H^4.COOH$. See Ador and Crafts (*Ber.* xii. 2086).

Bromonaphthoic acids.—*Bromo- α -naphthoic acid*, $C^{10}H^6Br.COOH$, may be produced either from the corresponding cyanide (p. 1359), or by the action of bromine on silver α -naphthoate, by heating α -naphthoic acid with bromine and water at 150° – 160° , or by the action of bromine in presence of iodine on a warm acetic acid solution of α -naphthoic acid, being best prepared by the last-mentioned process. It sublimes in small white needles melting at 242° ; it is almost insoluble in boiling water, sparingly soluble in cold ether, alcohol, and acetic acid, easily soluble in benzene; from hot alcohol or acetic acid, it crystallises in granules.

In the formation of this acid from bromo- α -cyanonaphthalene, *bromo- α -naphthoic amide*, $C^{10}H^6Br.CONH^2$, is obtained as an intermediate product; it crystallises from hot alcohol in broad white needles melting at 241° .

Bromo- β -naphthoic acid is prepared in the same manner as the α -acid; the corresponding amide is also obtained as an intermediate product in its formation from bromo- β -cyanonaphthalene. The acid crystallises from alcohol or acetic acid in white granules, and sublimes in fine needles melting at 256° . It is less soluble than the α -acid.

The salts of the two acids differ considerably in solubility, the α -barium salt requiring 59 pts. and the β -salt 4300 pts. of water at 21° , while the α -calcium salt dissolves in 66.5, the β -salt in 5000 pts. of water at 20° . Both α - and β -naphthoic acid yield tetrabromo-derivatives when heated with 4–5 mols. of bromine containing some iodine, finally at a temperature of about 350° ; a portion of the acid, however, is decomposed into bromonaphthalene and carbon dioxide. By heating the β -acid with slightly more than 3 mols. of bromine containing iodine, a tribromo-derivative is produced. *Tetrabromo- α -naphthoic acid*, $C^{10}H^2Br^4.COOH$, separates from its solution in boiling alcohol or acetic acid in small granular crystals melting at 239° . The β -acid forms similar crystals melting at 260° . Both sublime with partial decomposition in needles. *Tribromo- β -naphthoic acid*, $C^{10}H^3Br^3.COOH$, melts at 270° ; it also sublimes with partial decomposition in needles (Hausmann).

Nitronaphthoic Acids.—The mononitronaphthoic acids have recently been further examined by Ekstrand (*Ber.* xii. 1393). According to this chemist; both α - and β -naphthoic acid yield two isomeric mononitro-derivatives if an excess of fuming nitric acid is added to a hot concentrated glacial acetic acid solution of either of the two, and the liquid is heated for some hours on the water bath. As the solution cools, the greater part of the less soluble modification then separates out, the more soluble modification remaining for the most part in the mother-liquor, from which it may be precipitated by the addition of water; it is most difficult, however, to separate the two modifications completely, and it is doubtful whether they have yet been obtained pure.

The less soluble *nitro- α -naphthoic acid*, after repeated recrystallisation from alcohol, forms bundles of fine pliable yellowish needles, melting at 233° , easily soluble, especially in warm alcohol, ether, acetic acid, and benzene, a hot concentrated alcoholic solution becoming almost solid on cooling. The *ethyl* salt of this acid crystallises in almost colourless long hair-fine needles melting at 92° . The *calcium* salt crystallises in hard prisms, soluble in 160 pts. of cold water.

The more soluble *nitro- α -naphthoic acid* crystallises in hard colourless prisms melting at 196° . Its *ethyl* salt forms thick hard crystals melting at 63° . The *calcium* salt forms needles or prisms soluble in 47 pts. of cold water.

To obtain the less soluble *nitro- β -naphthoic acid*, the mixture of the two acids, which could not be further separated by recrystallisation from alcohol, was digested with ether and the residue converted into calcium salt, the latter recrystallised, and then decomposed by hydrochloric acid. In this way a small quantity of an acid was obtained, difficultly soluble even in warm alcohol and acetic acid, from which it crystallised in small concentrically grouped needles, melting at about 280° . The *ethyl* salt of this modification crystallises in long glistening needles, often grouped in stars, melting at 107° . The *calcium* salt forms small plates, soluble in 930 pts. of cold water. The more soluble *nitro- β -naphthoic acid* crystallises in small needles melting at about 220° , easily soluble in warm alcohol. Its *ethyl* salt crystallises from alcohol in small needles melting at 82° . The *calcium* salt forms small needles, soluble in 388 pts. of cold water.

Sulphonaphthoic acids, $C^{10}H^6(SO^3H)(COOH)$, (Stumpf, *Liebig's Annalen*, clxxxviii. 1).— α -Naphthoic acid yields three isomeric monosulpho-acids on treatment with weak fuming sulphuric acid, that already described by Battershall being the chief product. On fusion with potassic hydrate, these furnish three corresponding *hydroxynaphthoic acids*, $C^{10}H^6(OH).COOH$, all different from the carbonaphthoic acid

of Eller and Schaeffer (vi. 852); that obtained from Battershall's sulpho-acid yields α -naphthol when distilled with lime, β -naphthol being formed when the two isomeric acids are thus treated. β -Naphthoic acid yields at most traces of an isomeric sulpho-acid, besides that described by Battershall. The corresponding hydroxy-acid furnishes α -naphthol when distilled with lime.

Naphthalenedicarboxylic Acids.—No less than four of these acids are known, viz. *naphthalic* (naphthophthalic) acid, *naphthoterephthalic* acid, and the two isomerides corresponding to the two isomeric (α - and β -) naphthalenedisulphonic acids.

Naphthalic or *Naphthophthalic* acid, $C^{10}H^6(COOH)^2$, is obtained by oxidation of acenaphthene and acenaphthylene (*ante*, p. 1345). According to Blumenthal, it is completely converted into the anhydride $C^{10}H^6O^3$ by mere exposure over sulphuric acid *in vacuo* (Ber. vii. 1092); the broad serrated plates, melting at 266° , obtained on subliming the acid (Behr, Dorp, vi. 852), appear to consist of the anhydride.

Bromonaphthophthalic acid, $C^{10}H^5Br(COOH)^2$, obtained by oxidation of bromacenaphthene, crystallises from benzene in white needles melting at 210° ; it is less readily converted into the corresponding anhydride than naphthophthalic acid on exposure over sulphuric acid. When boiled with ammonia, it yields the imide, $C^{10}H^5Br \begin{Bmatrix} CO \\ CO \end{Bmatrix} NH$, which crystallises in yellow prisms melting above 265° (Blumenthal, *loc. cit.*)

Naphthoterephthalic acid, $C^{10}H^6(COOH)^2$, obtained by boiling the dicyanophthalene prepared from bromonaphthalenesulphonic acid with potassic hydrate solution, crystallises in microscopic needles, which remain unfused at 240° (Wichelhaus a. Darmstädter, *Liebigs Annalen*, clii. 309).

Naphthalene- α and β -dicarboxylic acids, $C^{10}H^6(COOH)^2$, prepared from the dicyanophthalenes from naphthalene- α - and β -disulphonic acids by digestion with hydrochloric acid at 200° – 210° , or by boiling with a solution of potassic hydrate in amyl alcohol, are too difficultly soluble to be purified by recrystallisation; if dissolved in an alkali, boiled with animal charcoal, precipitated by an acid, and then well washed and dried, they are obtained as white coherent apparently amorphous masses. As prepared by decomposing the dicyanides with hydrochloric acid, the α -acid crystallises in long needles, the β -acid in short needles. The α -acid is very slightly soluble, and the β -acid almost insoluble, in boiling benzene, toluene, and acetic acid; they are somewhat more soluble in boiling alcohol. They melt far above 300° , but are decomposed. Their salts are with difficulty rendered anhydrous, some being completely dehydrated only when heated at 300° . The α -potassium salt does not crystallise; the β -salt forms large tufts of needles, very easily soluble in water, of the composition $C^{10}H^6(COOK)^2 \cdot 7\frac{1}{2}H^2O$. The α -calcium salt, $C^{10}H^6(CO^2)^2 \cdot 4OH^2$, is precipitated on the addition of calcium chloride to a neutral solution of the ammonium salt in small, often microscopic needles, but slightly soluble in water. The β -salt, $C^{10}H^6(CO^2)^2Ca \cdot 3\frac{1}{2}H^2O$, forms microscopic needles almost insoluble in water. The α - and β -silver salts are anhydrous amorphous powders which do not alter on exposure to light. Barium and zinc salts furnish white gelatinous precipitates with soluble α - and β -dicarboxylates. *Ethyl naphthalene- α -dicarboxylate*, $C^{10}H^6(COOC^2H^5)^2$, obtained by double decomposition from the silver salt and ethyl iodide, crystallises from ether in colourless needles, but is easily decomposed (Ebert a. Merz, Ber. ix. 606).

Hydroxynaphthalenes or Naphthols. *Dibromo- α -naphthol*, $C^{10}H^5Br^2.OH$.—To prepare this compound, bromine is added to a solution of α -naphthol in 3 pts. glacial acetic acid; it is formed even when only a single molecular proportion of bromine is employed. Crystallised from alcohol, in which it is easily soluble, it forms long glistening pliable needles, melting at 111° . It is readily and completely decomposed by an alcoholic solution of potassium hydrate, forming an easily oxidisable trihydroxynaphthalene (Biedermann, Ber. vi. 1119).

Bromo- β -naphthol, $C^{10}H^5Br.OH$, is obtained on adding the equivalent amount of bromine dissolved in an equal volume of glacial acetic acid to a tolerably concentrated acetic acid solution of β -naphthol. It separates in colourless needles of adamantine lustre, melting at 84° , soluble in alcohol, ether, benzene, and petroleum. It yields phthalic acid when oxidised by an alkaline solution of potassium permanganate (Smith, Chem. Soc. J. xxxv. 789).

Tetrabromo- β -naphthol, $C^{10}H^3Br^4.OH$.—This compound is formed by adding bromine in excess to an acetic acid solution of β -naphthol. It is less soluble than the monobromo-derivative, separating in white needles melting at 156° . When oxidised by an alkaline solution of potassium permanganate, it is converted into a monobromophthalic acid, the anhydride of which melts at 125° (Smith).

Nitronaphthols.— α -Naphthol, or the acetate formed from it, does not furnish

nitro-derivatives on nitration, but are both converted into resinous masses (Biedermann, *loc. cit.*) The nitro- α -acetamidonaphthalene, $C^{10}H^6(NO^2).NHC^2H^3O$, obtained by nitrating α -acetamidonaphthalene, however, readily exchanges the acetamido-group for hydroxyl when boiled with a concentrated aqueous solution of sodium hydrate (Andreoni a. Biedermann, *ibid.* vi. 342). The product thus obtained is a mixture of two isomeric mononitro- α -naphthols, which may be separated by extracting the mixture with cold spirit, when that of higher melting point dissolves, or better by boiling with water, as that of higher melting point is readily soluble therein, and the isomeride only slightly soluble (Liebermann a. Dittler, *Liebig's Annalen*, clxxxiii. 245).

α -Nitro- α -naphthol, $C^{10}H^6(NO^2).OH$, crystallises in very fine needles, melting at 164° , extremely soluble in alcohol and acetic acid; it is almost completely precipitated from its cold aqueous solution on the addition of a few drops of hydrochloric acid. This modification is identical with the nitronaphthol which was first obtained by Dusart, and subsequently examined by Darmstädter and Nathan (vii. 841). It yields dinitro- α -naphthol, m. p. 138° , on nitration.

Potassium α -nitro- α -naphthol, $C^{10}H^6(NO^2).OK$, forms small orange-red crystals, easily soluble in water. *Sodium α -nitro- α -naphthol*, $C^{10}H^6(NO^2).ONa.2H^2O$, crystallises in fine carmine-red needles, easily soluble in water and alcohol; the anhydrous salt is blue-red. *Barium α -nitro- α -naphthol*, $(C^{10}H^6.NO^2.O)^2Ba.H^2O$, crystallises in glistening dark-red pointed needles, exhibiting a blue dichroism; it is easily soluble in water. *Calcium α -nitro- α -naphthol*, $(C^{10}H^6.NO^2.O)^2Ca.3H^2O$, forms dark-red fine interlaced needles, easily soluble in water. *Lead α -nitro- α -naphthol*, $[C^{10}H^6(NO^2).O]^2Pb$, is a brilliant scarlet-red difficultly soluble powder. Silver α -nitro- α -naphthol is a carmine-red powder which alters on exposure to the air (Biedermann).

β -Nitro- α -naphthol forms small greenish-yellow plates, difficultly soluble in dilute alcohol and still less soluble in water; it melts at 128° . On nitration it yields the same dinitro- α -naphthol as the isomeride.

Ammonium- β -nitro- α -naphthol crystallises from a hot aqueous solution in orange-red needles; the corresponding α -nitro- α -naphthol derivative is extremely soluble, and is occasionally obtained in the form of yellowish-red star-like groups on dissolving α -nitro- α -naphthol in a very concentrated solution of ammonia. *Barium β -nitro- α -naphthol*, $(C^{10}H^6.NO^2.O)^2Ba.3OH^2$, forms glistening red needles, which become brown-red when dehydrated (Liebermann a. Dittler).

Dinitro- α -naphthol, $C^{10}H^6(NO^2)^2.OH$.—This compound is formed on boiling dinitro- α -acetamidonaphthalene with a concentrated aqueous solution of sodium hydrate. Calcium dinitro- α -naphthol crystallises either in orange-yellow needles, or in plates of the same colour, the latter form being produced when it quickly separates from concentrated solutions. This salt readily loses water on exposure over sulphuric acid (Liebermann a. Dittler).

Nitro- β -naphthol, $C^{10}H^6(NO^2).OH$.—To prepare this body, hydrated nitroso- β -naphthol is suspended in ten times its weight of water, and an equal bulk of nitric acid of sp. gr. 1.25 is then added. In the course of an hour, the pure yellow colour of the nitroso-compound changes to a yellowish-grey, and the crystals become dense and non-coherent. They are then collected, washed thoroughly with water, and treated with 50 pts. of a cold very dilute solution of sodium hydrate (1 pt. 30 per cent. solution to 50 of water) and filtered from the insoluble residue. A slight excess of acetic acid is then added to the filtrate, and the bright yellow precipitate is collected, washed, and once or twice crystallised from boiling alcohol, in which it is very soluble.

Nitro- β -naphthol thus prepared crystallises from alcohol in orange-brown plates, scarcely distinguishable from nitroso- β -naphthol. It is precipitated from its solutions as a pale-yellow crystalline powder, apparently a hydrate. It melts at 96° and forms orange-coloured, crystalline ammonium, potassium and sodium derivatives. It is more soluble than nitroso- β -naphthol, but behaves very like the latter with concentrated sulphuric and nitric acids (Stenhouse a. Groves, *Chem. Soc. J.* xxxii. 51).

Trinitro- α -naphthol, $C^{10}H^4(NO^2)^3.OH$, may be produced by digesting dinitro- α -naphthol for several hours at 30° – 50° with an excess of a mixture of equal weights of concentrated and fuming nitric acids; only from one-fifth to one-fourth of the theoretical amount is obtained, however (Ekstrand, *Ber.* x. 1232). It is more readily prepared by suspending 1 pt. of dinitro- α -naphthol in 10–15 pts. of concentrated sulphuric acid, then slowly adding, with constant stirring, to the well-cooled liquid from $1\frac{1}{4}$ – $1\frac{1}{2}$ times as much fuming nitric acid dissolved in sulphuric acid as theory requires; the mixture is left to stand surrounded with cold water for about ten days, but well agitated several times daily. It is then poured into a large quantity of ice-cold water, and the crystalline mass which separates is well washed, pressed and dried, and then recrystallised from a large quantity of boiling acetic acid. On account

of its slight solubility in the cold acid, it is readily obtained pure, and for most purposes it suffices to extract the well-pulverised dry product two or three times with boiling acetic acid or alcohol in order to remove unattacked dinitro- α -naphthol.

Trinitro- α -naphthol melts at 177° . It is a brilliant yellow dye. When oxidised by an alkaline solution of potassium permanganate, it yields nitrophthalic acid (m. p. 212°). The potassium salt has the formula $C^{10}H^4(NO^2)_3.OK, H^2O$ (Diehl a. Merz, *ibid.* xi. 1661).

Nitrobromo- α -naphthol, $C^{10}H^5Br(NO^2).OH$.—This compound is obtained by boiling the nitrobromo- α -acetamidonaphthalene formed on nitration of bromo- α -acetamidonaphthalene with a concentrated aqueous solution of sodium hydrate, &c. It closely resembles α -nitro- α -naphthol, and melts at 142° (Biedermann a. Remmers, *ibid.* vii. 538).

Nitrosonaphthols.—Two isomeric *nitroso- α -naphthols*, $C^{10}H^6(NO).OH$, are formed by the action of nitrous acid on α -naphthol, but β -naphthol yields only a single nitroso-derivative. To prepare the former, 60 grams of α -naphthol are dissolved in a dilute solution of 40 grams potassium hydrate, which is then diluted with about 18 litres of water; after cooling the liquid to 10° – 5° , a solution of 70 grams potassium nitrite is added, and then, little by little, 85 grams of sulphuric acid in 1 litre of water. In a short time, a yellowish-brown flocculent precipitate is produced; after four-and-twenty hours, this is filtered off, washed and crystallised from water in order to separate a black resinous substance. By recrystallising the product thus obtained from benzene, it is separated into a more soluble yellow nitroso- α -naphthol, corresponding to β -nitro- α -naphthol, and a less soluble white isomeride corresponding to α -nitro- α -naphthol, the former being chiefly produced (Fuchs, *Ber.* viii. 626).

α -Nitroso- α -naphthol crystallises in dirty white or brownish coloured needles, melting with decomposition at 175° – 185° ; when precipitated from an alkaline solution by an acid, it has a pure white colour. It is easily soluble in acetone, alcohol and ether, but dissolves with difficulty in chloroform and carbon bisulphide, and is only sparingly soluble in hot benzene and toluene. It is oxidised with considerable difficulty by means of an excess of potassium ferricyanide in presence of alkali, and converted into α -nitro- α -naphthol (m. p. 164°); on treatment with nitric acid, it yields dinitro- α -naphthol.

β -Nitroso- α -naphthol crystallised from benzene has a yellowish-green or green colour; when precipitated from an alkaline solution, it has a pure sulphur-yellow colour. It melts, with decomposition, at 145° – 150° . It is easily soluble in acetic acid, alcohol, and acetone; less soluble in benzene, carbon bisulphide, chloroform and petroleum, and almost insoluble in cold water but more soluble in hot water. It crystallises best from acetic acid, benzene or water, and in fine needles. It is a body of considerable stability, dissolving in concentrated sulphuric acid but being reprecipitated by water, being unaltered by prolonged boiling with water, being unaffected by nitrous acid in the cold, and being merely converted into the potassium-derivative by prolonged boiling with an alcoholic solution of potassium hydrate. It is somewhat volatile in a current of steam. On oxidation with potassium ferricyanide in alkaline solution, it yields β -nitro- α -naphthol (m. p. 127°). Nitric acid converts it into dinitro- α -naphthol.

Potassium β -nitroso- α -naphthol, $C^{10}H^6(NO)OK$, may be prepared either by dissolving the nitrosonaphthol in an aqueous solution of potassium hydrate, saturating the excess of the latter with carbon dioxide, evaporating to dryness, and extracting with alcohol, or by adding an alcoholic solution of potassium hydrate to an alcoholic solution of the nitrosonaphthol. In the latter case, it is precipitated in glistening metallic green plates which, when dry, appear yellowish-red in transmitted light, the superficial colour being between copper-red and bran-yellow. It is moderately soluble in water, insoluble in a solution of potassium hydrate. *Sodium β -nitroso- α -naphthol*, $C^{10}H^6(NO)ONa$, crystallises from water in glistening prisms, which appear yellow-red by transmitted light and red-brown by reflected light. *Ammonium β -nitroso- α -naphthol* is precipitated on mixing alcoholic solutions of ammonia and of the nitrosonaphthol in fine glistening metallic-green needles, which give off ammonia on exposure to the air. *Barium β -nitroso- α -naphthol*, $[C^{10}H^6(NO)O]^2Ba, 2H^2O$, prepared by precipitating a solution of the nitrosonaphthol in dilute ammonia with barium chloride and recrystallising the precipitate from water, forms small glistening plates which exhibit pronounced yellowish-green and purple-red dichroism. The silver derivative is a brown-red pulverulent precipitate. The lead-derivative crystallises from alcohol in dark-brown glistening crystalline scales. The *methyl* derivative, $C^{10}H^6(NO).OCH^3$, prepared from the silver-derivative, crystallises from dilute alcohol in yellowish-green to steel-blue coloured needles, melting at 95° . The *ethyl* derivative crystallises in very thin, flat, glistening, greenish-yellow needles, melting at 101° . *Benzoyl β -nitroso- α -naphthol*, $C^{10}H^6(NO)O.CO.C^6H^5$, is produced by adding the sodium derivative to

cooled benzoic chloride. The semi-solid mass is heated for a few moments on the water bath, then digested with cold water for three to four hours, the benzoic acid extracted by boiling with water and alcohol, and the residue crystallised from a mixture of acetone and chloroform. It crystallises in short thick yellow needles, which decompose at 140° – 150° into benzoic acid and a black residue.

β -nitroso- α -naphthol appears to combine with bromine, forming a dibromide, $C^{10}H^6Br_2(NO).OH$, which crystallises in glistening silver-white plates, melting at 145° . On adding β -nitroso- α -naphthol to an alcoholic solution of aniline, long yellow needles of an extremely unstable body are obtained, probably a compound of the two substances. If, however, aniline be added to a solution of the nitrosonaphthol in acetic acid, and the liquid be then warmed on the warm bath, it gradually darkens in colour and finally becomes violet; on then pouring it into water, a solid dark-red product separates. After washing this with water, and extracting first with hot dilute ammonia, then with hot alcohol, a residue remains, which crystallises from a mixture of alcohol and benzene in fine needles, exhibiting while suspended in the liquid a magnificent cantharides-like lustre. This substance dissolves in acids forming magnificent violet-coloured solutions, from which it separates, on the addition of ammonia, as an orange-coloured precipitate. It has the composition $C^{22}H^{16}N^2O$, and is apparently formed in accordance with the equation:

Methyl and ethyl nitrosonaphthol behave in a similar manner with aniline, and a precisely similar product is obtained from paratoluidine (Fuchs, *ibid.* viii. 1022).

Nitroso- β -naphthol, $C^{10}H^6(NO).OH$.—This compound was first obtained by Fuchs (*ibid.* 1026). According to Stenhouse & Groves (*Chem. Soc. J.* xxxii. 47), the following is the most advantageous method of preparing it: 1 pt. of β -naphthol is dissolved in 10 pts. boiling water by means of 1 pt. by measure of a solution of sodium hydrate of sp. gr. 1.323 (a 30 per cent. solution); the liquid is then cooled and added to 100 pts. of water. This solution is at once mixed, with constant stirring, with a nitriting solution prepared by pouring 2 pts. by weight of a 15 per cent. solution of the compound $SO^2(NO^2)OH$ (*ibid.* xxxi. 545) into 200 of water. After standing for twelve to twenty hours, the precipitate of crude nitroso- β -naphthol which forms is collected on a linen filter and washed until the washings are no longer acid. The purification of this product is based on the insolubility of the barium-derivative, which is thrown down as a bulky green precipitate on the addition of barium chloride to a solution of the nitrosonaphthol in dilute alkali, and on the insolubility of the sodium-derivative even in comparatively dilute solutions of sodium hydrate. Sufficient water is added to the paste from the filter to make it up to 35 pts. by measure; 1 pt. of 30 per cent. solution of sodium hydrate diluted with 35 of water is then added, and the mixture agitated occasionally and filtered after standing about an hour. The clear filtrate is precipitated by a slight excess of a dilute solution of barium chloride—about 1.5 pts. of a cold saturated solution diluted with twice its weight of water—and the green precipitate collected on a fine cambric filter. After being thoroughly washed, it is suspended in about 35 pts. of water, and decomposed with hydrochloric acid in excess. The partially purified nitroso-compound is then washed until free from barium chloride, suspended in 15 pts. of water, and heated on the water bath with 5 pts. of 30 per cent. sodium hydrate solution; to the filtered liquid, one-tenth of its bulk of soda solution is then added: this causes the precipitation of the sodium nitroso- β -naphthol, which is collected, pressed, and decomposed by acid, the process of precipitation as sodium compound being repeated if necessary.

In this way, nitroso- β -naphthol is obtained in minute needles of a brilliant yellow colour, containing water of crystallisation, and becoming brown at a gentle heat, owing to loss of water. The anhydrous compound crystallises from alcohol, &c., in thin plates or short thick prisms of an orange-brown colour, melting at $109^{\circ}.5$. It is only slightly soluble in water, even when boiling, but dissolves readily in benzene, carbon bisulphide, acetic acid and hot alcohol; it is comparatively slightly soluble in light petroleum, even when boiling. It dissolves in cold concentrated sulphuric acid, forming a bright-red liquid, from which it is precipitated unaltered by water; on strongly heating the acid solution, the colour changes to brown, and water then no longer has any effect. It yields nitro- β -naphthol and a body insoluble in dilute alkaline solutions on careful treatment with dilute nitric acid; if alcohol be used instead of water, a somewhat different reaction appears to take place; concentrated nitric acid forms tarry products.

The ammonium and alkali metal derivatives of nitroso- β -naphthol are crystalline and of a bright green colour when in a finely divided state, although the masses of crystals deposited from a hot concentrated solution appear black by reflected light. The alkaline earth-metal derivatives are also of various shades of green.

Amidonaphthols. α -Amido- α -naphthol, $C^{10}H^6(NH^2).OH$.—This compound is formed on reduction of α -nitro- α -naphthol. To prepare it, the latter body is digested with tin and hydrochloric acid; the white crystals of the tin double salt which are then obtained are dissolved in water; the tin separated by means of hydrogen sulphide; and the solution concentrated out of contact with the air. On addition of hydrochloric acid to the concentrated liquid, α -amido- α -naphthol hydrochloride crystallises out in white needles or elongated needle-like plates, very easily soluble in water. It yields almost the theoretical amount of α -naphthaquinone on treatment with a variety of oxidising agents. On the addition of bromine water, even to very dilute solutions, a precipitate of yellowish-white needles is formed; this contains both nitrogen and bromine, and probably corresponds to the compound obtained by Schmitt a. Bennewitz from paramidophenol and chloride of lime (Liebermann a. Dittler, *Liebig's Annalen*, clxxxiii. 247).

β -Amido- α -naphthol.—The hydrochloride of this compound, obtained in a similar manner to the above from β -nitro- α -naphthol, crystallises in broad white plates. On the addition of alkali and agitation with air, its aqueous solution acquires a permanent grass-green colour, and after a time a green scum separates, which dissolves in alcohol to form a pure green-coloured liquid. The α -compound, when similarly treated, first exhibits a dirty-green coloration, which soon passes into yellow. It furnishes a yellowish to green precipitate with bromine water or ferric chloride, but no naphthaquinone is formed on heating (Liebermann a. Dittler).

Nitroso- β -naphthol appears to be converted on reduction into the corresponding amido-derivative, but this has not yet been examined (comp. β -naphthaquinone).

Triamido- α -naphthol, $C^{10}H^4(NH^2)^3.OH$.—This compound has not yet been isolated, but its sulphate and the tin double salt of its hydrochloride are known (Diehl a. Merz, *Ber.* xi. 1663). To prepare the latter, 8 pts. of the strongest hydrochloric acid are poured on a mixture of 1 pt. trinitro- α -naphthol and 4 pts. granulated tin, and heat is then carefully applied; a violent reaction soon takes place, and a clear brown solution is formed. When sufficiently concentrated, this deposits granules of prismatic crystals having the formula $C^{10}H^4(NH^2Cl)^3.OH.SnCl^2.H^2O$ (Eckstrand). If the solution of this salt be freed from tin by means of hydrogen sulphide and then sufficiently concentrated in a current of the gas, it deposits fine white needles of triamidonaphthol hydrochloride, but this salt is extremely unstable, and rapidly undergoes oxidation even when dry. The sulphate, $C^{10}H^4(NH^2)^3.OH.H^2SO^4.H^2O$, however, is more stable; it separates on addition of sulphuric acid to the very concentrated warm solution of the hydrochloride on cooling in yellow crystalline crusts, easily soluble in water. The dry salt is moderately stable in the air, but its solution rapidly assumes a red colour on agitation with air, and is immediately reddened by ferric chloride.

Dihydroxynaphthalenes, $C^{10}H^6(OH)^2$.—Four of these are known, viz.: 1. α -naphthaquinol or α -naphthahydroquinone (vii. 836); 2. β -naphthaquinol or β -naphthahydroquinone; 3. that derived from α -nitronaphthalene- α -sulphonic acid; and 4. that formed by fusing naphthalene- α -disulphonic acid with alkali. The last of these was first obtained, but in an impure state, by Dusart, and was subsequently examined by Darmstädter a. Wichelhaus (vi. 857); the pure substance has more recently been described by Ebert a. Merz.

β -Naphthaquinol, produced by the action of hydriodic acid or of sulphurous acid on β -naphthaquinone, crystallises in colourless needles. When alcoholic solutions of β -naphthaquinone and β -naphthaquinol are mixed, water added, and the liquid gently heated, dark-coloured crystals are deposited, resembling those obtained from the corresponding α -compounds under similar circumstances (Stenhouse a. Groves, *Chem. Soc. J.* xxxii. 53).

Dihydroxynaphthalene, prepared by heating potassium naphthalene α -disulphonate with potassium hydrate at 280° – 300° , crystallises from boiling benzene in long colourless needles, melting at 186° . It sublimes with partial decomposition in broad toothed plates; it scarcely volatilises with vapour of water. It is easily soluble in boiling water, and still more so in alcohol and ether; moderately soluble in benzene, toluene, and chloroform, and almost insoluble in carbon bisulphide and petroleum. An alkaline solution darkens rapidly on exposure to the air, and an ethereal solution behaves similarly. Its aqueous solution is coloured red temporarily by chloride of lime and more permanently by nitric acid. It appears to yield isomeric nitro- and haloïd-derivatives (Ebert a. Merz, *Ber.* ix. 609; Weber, *ibid.* x. 1233).

According to Cleve (*Bull. Soc. Chim.* xxiv. 513), the amido-acid formed on reduction of nitronaphthalene- α -sulphonic acid yields by Griess's method a dihydroxynaphthalene subliming in needles which do not fuse below 220° .

Dinaphthols.—According to Dianin (*ibid.* viii. 166), β -dinaphthol yields the compound $C^{10}H^{12}O$ when distilled with phosphoric pentoxide. This body crystallises in long yellow needles; it combines with a single molecular proportion of trinitrophenol.

Dinaphthyl- β -diquinol, $C^{20}H^{10}(OH)^4$.—This compound is formed by the reduction of β -dinaphthylidiquinone or the corresponding quinhydrone. When the diquinone is allowed to stand for some time in contact with sulphurous acid solution, it becomes converted into a mass of colourless crystals, apparently without the quinhydrone being formed as an intermediate product. A very convenient method of preparation is to convert β -naphthaquinone into the diquinhydrone by treatment with dilute sulphuric acid, and when the mixture is cold, to add about twice its bulk of a saturated aqueous solution of sulphurous acid; when the whole has stood about twenty-four hours, the black diquinhydrone will be found to have been entirely converted into a mass of snow-white needles of the diquinol, provided the β -naphthaquinone originally employed was quite pure; these merely require to be thoroughly washed to remove sulphuric acid, and crystallised once from dilute acetic acid to which a few drops of sulphurous acid solution have been added to be quite pure.

Dinaphthyl- β -diquinol forms colourless needles, which on drying become darkened from partial oxidation. It melts at 176° – 178° , is almost insoluble in water, moderately soluble in 30 per cent. acetic acid, easily in glacial acetic acid; it is only slightly soluble in benzene, carbon bisulphide and ether (Stenhouse a. Groves, *Chem. Soc. J.* xxxiii. 419).

Naphthaquinones. Monnet, Reverdin and Nölting (*Ber.* xii. 2305) have obtained α -naphthaquinone by direct oxidation of α -amidonaphthalene (naphthylamine), and also in small quantity by oxidation of naphthionic acid. 1 pt. naphthylamine was dissolved in 6 pts. sulphuric acid and 25 pts. water, and 2.5 pts. of finely pulverised potassium dichromate were then added gradually to the cooled solution; the resulting dark-brown precipitate was filtered off, dried over sulphuric acid, and extracted with ether, and the mother-liquor also extracted with ether. In one experiment, 40 per cent., in others only 15–20 per cent., α -naphthaquinone was obtained in this way; a variable amount of phthalic acid and a brown substance insoluble in almost all solvents are also formed. α -Naphthaquinone reacts with dimethylaniline, phenol, and resorcinol in presence of sulphuric acid to form coloured substances, which appear, however, to be of no technical value. According to Plimpton and Zincke (*Ber.* xii. 1644), it readily enters into reaction with primary monamines apparently in accordance with the equation:

The compounds obtained with aniline, paratoluidine and methylamine crystallise in beautiful red needles melting at 191° , 200° , and 225° respectively.

Dibromo- α -naphthaquinone, $C^{10}H^4Br^2O^2$, is produced by treating α -naphthol with iodine and an excess of bromine (Diehl a. Merz, *ibid.* x. 1066). α -Naphthol is mixed with double its weight of iodine and a considerable quantity of water and seven times its weight of bromine is then gradually added. This mixture is heated in a vessel attached to a reversed condenser for several hours. The product is boiled with a large quantity of alcohol or acetic acid, and the crystals which separate are purified by recrystallisation. It may also be obtained by treating dinitro- α -naphthol in a similar manner; in either case, about 50 per cent. of the theoretical amount is formed.

Dibromo- α -naphthaquinone crystallises in small granules consisting of hair-fine needles; when carefully heated, it sublimes with partial decomposition in yellow needles, melting at 151° .5. It is sparingly soluble in acetic acid, alcohol, benzene, and ether, but readily soluble in boiling alcohol or acetic acid.

β -Naphthaquinone, $C^{10}H^6O^2$ (Stenhouse a. Groves, *Chem. Soc. J.* xxxii. 47, xxxiii. 415).—This compound is produced by oxidation of the amidonaphthol formed on reduction of nitroso- β -naphthol. To prepare it, nitroso- β -naphthol is first converted into the barium-derivative by dissolving it (2 pts.) in a mixture of about 100 pts. water with 2 pts. 30 per cent. sodium hydrate solution, filtering, then adding a slight excess of barium chloride. The precipitate, after being collected and washed, is suspended in 140 pts. water, mixed with 3 pts. ammonia solution (sp. gr. 880), and the liquid supersaturated with hydrogen sulphide. The vessel containing the mixture is then tightly corked and allowed to stand several hours; subsequently, the precipitate is collected, washed with a very dilute solution of hydrogen sulphide, then added to 6 pts. of a saturated aqueous solution of sulphurous acid and 6 pts. of dilute sulphuric acid (1 vol. acid to 2 vols. water), the liquid filtered, and the filtrate immediately poured into a filtered solution of 3 pts. potassium dichromate in 20 pts. of water.

The quinone at once separates in slender needles of a bright orange colour. It is collected without delay, thoroughly washed with distilled water, and dried at the ordinary temperature; thus prepared, it is pure with the exception that it contains traces of chromium, which, however, cannot be removed by crystallisation from any solvent, as it decomposes very readily. Only from 62–65 per cent. of the weight of the nitrosonaphthol, instead of 91.9 per cent., is thus obtained, however.

β -naphthaquinone melts at 96°. If boiled for some time with dilute nitric acid, it is oxidised to phthalic acid.

Nitro- β -naphthaquinone, $C^{10}H^8(NO^2)O^2$.— β -Naphthaquinone dissolves readily in hot dilute nitric acid, and the solution on cooling deposits magnificent crimson-coloured needles of nitro- β -naphthaquinone. The latter may be prepared by adding 10 pts. of the quinone to 60 pts. by measure of nitric acid (of sp. gr. 1.2), agitating until a homogeneous paste is formed, and then plunging the flask into boiling water for a few minutes; the quinone dissolves, but very shortly afterwards a mass of crystals of the nitro-derivative separate out. When the conversion is complete, the flask is cooled, and after a couple of hours the product is collected and washed; it is then recrystallised from boiling benzene, and afterwards once or twice from boiling glacial acetic acid. From the latter solvent, it crystallises in magnificent crimson plates bearing a striking resemblance in point of colour and general aspect to chromic anhydride. It melts at 158°. It is insoluble in light petroleum, almost insoluble in carbon bisulphide, slightly soluble in ether, more so in benzene and in boiling alcohol, and very readily soluble in hot glacial acetic acid; boiling with alcohol, however, appears to decompose it.

Dinaphthyl- β -diquinonone, $C^{20}H^{10}O^4$ (Stenhouse a. Groves, *Chem. Soc. J.* xxxiii. 415).—When β -naphthaquinone (1 pt.) is intimately mixed with dilute sulphuric acid (10 pts. by measure of 1 vol. acid to 2 vols. water) so as not to leave any part unwetted, and allowed to remain in contact therewith for twenty-four hours, it is completely converted into its own weight of a compound which is analogous to quinhydrone, and in all probability has the formula $C^{20}H^{14}O^8$; the same change may be more rapidly effected by heating the mixture at about 55°. The product merely requires thorough washing with cold water.

Dinaphthyl- β -diquinhydrone is an indigo-black powder when dry, insoluble in water, carbon disulphide, and light petroleum, almost insoluble in benzene, but soluble in glacial acetic acid. By boiling with nitric acid, or with a solution of potassium dichromate and sulphuric acid, it is converted into dinaphthyl- β -diquinone, $C^{20}H^{10}O^4$. This compound is most conveniently prepared by pouring a solution of pure dinaphthyl- β -diquinol, $C^{20}H^{10}(OH)^4$, in boiling 30 per cent. acid into sufficient nitric acid (sp. gr. 1.45) to oxidise it. It is then precipitated in small lustrous prisms of a brilliant orange colour. Dinaphthyl- β -diquinone is but very slightly soluble, or insoluble, in all ordinary solvents; it is a very stable body, dissolving in boiling concentrated nitric acid, and crystallising out unchanged on cooling. It is also easily soluble in warm concentrated sulphuric acid, and is precipitated again on dilution.

Hydroxy- α -naphthaquinone or *Naphthalic acid*, $C^{10}H^4(OH)O^2$.—This compound, which is usually prepared by heating diimidonaphthol hydrochloride with hydrochloric acid at 120° in sealed tubes (vii. 836), is more readily prepared, according to Merz a. Diehl (*Ber.* xi. 1314) by adding the finely pulverised hydrochloride little by little to a moderately concentrated boiling solution of sodium carbonate; the product obtained on acidifying the filtered solution is sufficiently pure for most purposes. An insoluble dark-coloured substance is also formed in varying amount according to the purity of the hydrochloride employed. It is well to operate quickly and on a small scale, so as to avoid access of air as much as possible; using 40 to 60 grams of hydrochloride, from 75 to over 80 per cent. of the theoretical amount is obtained. Hydroxy- α -naphthaquinone is also formed on heating diamido- α -naphthol with dilute hydrochloric acid at 180°. Carefully crystallised hydroxy- α -naphthaquinone melts at 179°. If heated with an aqueous or alcoholic solution of ammonia at 100°–110°, it is converted into amidonaphthaquinone (Ludwig, *ibid.* iv. 970).

Bromohydroxy- α -naphthaquinone or *Bromonaphthalic acid*, $C^{10}H^4Br(OH)O^2$, is produced on treatment of dibromo- α -naphthaquinone, $C^{10}H^4Br^2O^2$, with a warm solution of sodium hydrate or with a boiling solution of sodium carbonate, and by the action of bromine on hydroxy- α -naphthaquinone (Diehl a. Merz, *ibid.* xi. 1066). It crystallises from hot alcohol in compact almost golden-yellow plates, melting at 196°–5.

The *potassium* derivative, $C^{10}H^4BrO^2K \cdot 4H^2O$, crystallises in granular masses of small dark-red needles, very soluble in water. The *barium* derivative, $(C^{10}H^4BrO^2)_2Ba$, is obtained as an orange-coloured precipitate on the addition of barium chloride to a

cold solution of the potassium derivative. Other metallic salts also produce coloured precipitates. Bromohydroxy- α -naphthaquinone yields phthalic acid on oxidation with nitric acid.

Nitrohydroxy- α -naphthaquinone or *Nitronaphthalic acid*, $C^{10}H^4(NO^2)(OH)O^2$.—The nitration of hydroxy- α -naphthaquinone presents difficulties, but may be effected by dissolving it in 10 pts. concentrated sulphuric acid and gradually adding the required amount of fuming nitric acid. The solution is left at rest for forty-eight hours, care being taken to keep it cool, and then poured into ice water. The product is collected, washed with ice-water, pressed and crystallised alternately from dilute alcohol and chloroform (Merz a. Diehl, *ibid.* xi. 1314).

Nitrohydroxy- α -naphthaquinone crystallises from hot chloroform in pale yellow plates or scales; from benzene it separates in large thin plates like crystals of sublimed naphthalene. It is easily soluble in hot water, alcohol, and ether, sparingly soluble in cold benzene, chloroform, or petroleum, and not very soluble in the hot liquids. It melts with decomposition at 157° ; it also decomposes if heated for some time at 140° , hydrocyanic acid being one of the products. Its aqueous solution is entirely decomposed by prolonged boiling, hydrocyanic acid, much fumus-like substance and a considerable amount of phthalic acid being produced. It is easily oxidised by hot dilute nitric acid and converted into phthalic acid.

The *potassium* derivative, $C^{10}H^4O^2(NO^2)(OK)$, crystallises in bundles of golden-yellow glistening needles, sparingly soluble in cold, easily in hot water. The *barium* derivative, $[C^{10}H^4O^2(NO^2).O]^2Ba$, crystallises from a hot solution in orange-red scales, very slightly soluble in water. The lead derivative crystallises according to circumstances in one or other of two modifications differing in the amount of water of crystallisation and solubility; it adheres in a remarkable manner to lead carbonate, and notwithstanding its solubility is with difficulty separated from the latter by boiling water.

Amidohydroxy- α -naphthaquinone or *Amidonaphthalic acid*, $C^{10}H^4O^2(NH^2)(OH)$, is produced by reduction of the foregoing compound, either by means of tin and hydrochloric acid or ammonium sulphhydrate (Merz a. Diehl). It crystallises from hot glacial acetic acid or alcohol in loosely aggregated dark-brown needles, moderately soluble in hot glacial acetic acid and alcohol, but sparingly in cold. It dissolves in solutions of ammonia and ammonium carbonate, and of the hydrates and carbonates of the alkali-metals, forming intense blue coloured liquids resembling an ammoniacal solution of a cupric salt; its alkaline earth and heavy metal derivatives are difficultly soluble or insoluble. It also exhibits basic properties, solutions of its metallic derivatives being precipitated by acetic but not by hydrochloric or sulphuric acids.

It is readily oxidised by nitric acid and converted into phthalic acid. When heated for $1-1\frac{1}{2}$ hours at $170^\circ-180^\circ$ with dilute hydrochloric acid, it is converted into *dihydroxy- α -naphthaquinone*, $C^{10}H^4O^2(OH)^2$. The latter crystallises from alcohol in fine red-brown needles, and from glacial acetic acid in dark-red plates; the crystals exhibit a brilliant metallic lustre in sunlight. It is abundantly soluble in hot alcohol and glacial acetic acid, although somewhat sparingly in the cold liquids; it is only slightly soluble in benzene and ether; it may be dissolved in a large quantity of water, but as the solution cools separates almost entirely in fine needles. A solution of the freshly precipitated substance in ammonia and alkalis has a dark violet-blue colour, similar to that of the higher methylated rosanilines. If somewhat rapidly heated it sublimes in bundles of vermilion-red needles, but much of it undergoes decomposition. The metallic derivatives of dihydroxy- α -naphthaquinone are all dark-coloured, and excepting those of the alkali-metals are only slightly soluble or insoluble. With alumina mordants it dyes violet, and with iron mordants dark-blue, and the colour withstands washing. It communicates to silk a brownish-violet colour and strong metallic lustre. It is dissolved on treatment with tin and hydrochloric acid, and apparently converted into *tetrahydroxynaphthalene*, $C^{10}H^4(OH)^4$.

Diacetoxy- α -naphthaquinone, $C^{10}H^4O^2(OC^2H^3O)^2$, produced by heating dihydroxy- α -naphthaquinone with an excess of acetic anhydride at about 160° for one to two hours, crystallises from hot dilute alcohol in small brown plates.

Diimido- and Oximido- α -naphthol.—These compounds have been represented by Graebe a. Ludwig by the following formulæ (vii. 841):

It appears probable, however, that both are derivatives of an 'imidoquinone,' intermediate in composition between naphthaquinone and the at present unknown diimido-naphthalene, so-called diimidonaphthol being *amido-* and oximidonaphthol *hydroxy-naphthimidoquinone*, thus:

The fact that the so-called diimidonaphthol unites with a single molecule of hydrochloric acid, and that oximidonaphthol is precipitated as such on the addition of hydrochloric acid to its solution in concentrated alkali, obviously supports this view.

Amidodiimido- α -naphthol.—According to Diehl a. Merz, the hydrochloride of this compound is produced on adding a slight excess of ferric chloride to a hot solution of triamidonaphthol hydrochloride, $C^{10}H^4(NH^2Cl)^3.OH$. It crystallises in lustrous dark-green plates, moderately soluble in cold water and alcohol, very sparingly in ether and concentrated hydrochloric acid. Its solutions are of an intense dark-red colour, and colour wool a brown-red and silk a similar but somewhat redder shade. Its aqueous solution is decomposed on prolonged boiling, and even the dry substance is not permanent.

On the addition of potassium dichromate to a solution of the hydrochloride, $C^{10}H^4N^3O.HCl$, the chromate, $C^{10}H^4N^3O.H^2CrO_4$, is thrown down as a flocculent or pulverulent brown-red precipitate. The platino-chloride, $(C^{10}H^4N^3O.HCl)^2PtCl_4$, is precipitated on the addition of platinum chloride to a solution of the hydrochloride as a dark-brown precipitate almost insoluble in water. The amidodiimidonaphthol itself, $C^{10}H^4N^3O$, is thrown down on the addition of alkali to a solution of the hydrochloride in brown-red flocculi consisting of extremely fine needles. It crystallises from hot alcohol in dark-brown needles, abundantly soluble in hot, but moderately in cold alcohol, and very slightly soluble in cold benzene, ether, and water.

It may be questioned whether the compound thus obtained is really an amidodiimidonaphthol of the formula $C^{10}H^4(N^2H^2)(NH^2)(OH)$, as Diehl a. Merz suppose, and whether it is not a diamidoimidoquinone, *i.e.* the amido-derivative of the so-called diimidonaphthol of Graebe a. Ludwig.

Amidonaphthalenes. *β -Amidonaphthalene* or *β -Naphthylamine*, $C^{10}H^7.NH^2$, the isomeride of ordinary *α -amidonaphthalene*, or *α -naphthylamine*, is produced on reduction of the bromonitronaphthalene obtained by brominating *α -acetamidonaphthalene*, nitrating the resulting bromo- *α -acetamidonaphthalene*, converting the nitrobromo-compound thus produced into nitrobromonaphthylamine, and finally displacing the amido-group in this latter compound by hydrogen by Griess's method (Liebermann a. Scheiding, *Liebig's Annalen*, clxxxiii. 258).

β -Amidonaphthalene volatilises in a current of steam; it crystallises from water in snow-white glistening plates melting at 112° . It is readily distinguished from the isomeride by failing to yield a coloration either with ferric chloride or with chromic acid, with bleaching powder, or alcohol containing nitrous acid and a little hydrochloric acid; it also has not the characteristic odour of *α -naphthylamine*. Its aqueous solution exhibits a blue fluorescence, but solutions of its salts are not fluorescent.

β -Naphthylammonium chloride, $C^{10}H^7.NH^2Cl$, forms colourless plates, very easily soluble in water and alcohol, difficultly soluble in dilute hydrochloric acid. The *platinochloride*, $(C^{10}H^7.NH^2Cl)^2PtCl_4$, forms yellow plates soluble in water. *β -Naphthylammonium sulphate*, $(C^{10}H^7.NH^2)^2SO_4$, crystallises from hot water in colourless plates; it is precipitated on the addition of sulphuric acid to a cold dilute solution of the hydrochloride, and as it is much less soluble than the *α -naphthylamine* salt, the two isomerides may be separated by means of their sulphates. *β -Naphthylamine* combines with trinitrophenol, forming a trinitrophenate, which crystallises in long yellow needles melting at 195° , easily soluble in alcohol.

β -Acetamidonaphthalene or *β -acenaphthalide*, $C^{10}H^7.NHC^2H^2O$, crystallises from water in elongated glistening plates, melting at 132° .

α -Amidonaphthalene. Reactions.—If a small quantity of an alcoholic solution of nitrous acid be mixed with a solution of *α -naphthylamine* in alcohol or glacial acetic acid and a little hydrochloric acid be then added, an intense violet to magenta colouration is produced if a considerable quantity of the base be present; if only a trace of the base be present, the liquid acquires a reddish colour (Liebermann).

An extremely delicate test for nitrous acid consists in adding to the suspected solution acidulated with pure sulphuric acid, a little sulphanilic acid, and about ten

minutes afterwards a few drops of a colourless solution of naphthylammonium sulphate; a more or less magenta-red colour is thus produced (Griess, *Ber.* xii. 426).

α -Naphthylamine forms a crystalline compound with mercuric chloride (O. Klein, *Ber.* xi. 743). It enters into reaction with dinitrochlorobenzene, especially on warming an alcoholic solution of the two bodies, but the product is not a well-characterised substance (Laubenheimer, *ibid.* xi. 1158).

When heated together in sealed tubes for three to four hours at 190° – 220° , naphthylamine hydrochloride and nitronaphthalene enter into reaction in accordance with the equation, $2(\text{C}^{10}\text{H}^7\text{.NH}^2) + \text{C}^{10}\text{H}^7\text{.NO}_2 = \text{NH}_3 + 2\text{H}_2\text{O} + \text{C}^{10}\text{H}^8\text{N}^2$, forming trinaphthylenediamine (Salzmänn a. Wichelhaus, *ibid.* ix. 1107).

If α -naphthylamine be heated with rather less than half its weight of urea at 120° for some hours, *dinaphthylcarbamide*, $(\text{C}^{10}\text{H}^7\text{.NH})^2\text{CO}$, is the sole product; but *mononaphthylcarbamide*, $\text{NH}^2\text{CO.NH.C}^{10}\text{H}^7$, is also formed on heating naphthylamine hydrochloride with urea at 150° – 170° (Pagliani, *Gazz. chim. ital.* ix. 28).

Methyl- α -naphthylamine, $\text{C}^{10}\text{H}^7\text{.NH(CH}^3)$, is produced, together with *dinaphthylamine*, $\text{NH(C}^{10}\text{H}^7)^2$, on passing a current of methyl chloride gas into α -naphthylamine heated at about 150° – 180° (Landshoff, *Ber.* xi. 638). The former boils at 293° . It rapidly becomes dark-coloured and untransparent on exposure to the air; its alcoholic solution yields a dark violet precipitate with ferric chloride. The monoacetyl-derivative crystallises from water in small white prisms melting at 91° ; although difficultly soluble in water, it separates very slowly from an aqueous solution.

Dimethyl- α -naphthylamine, $\text{C}^{10}\text{H}^7\text{.N(CH}^3)^2$, is produced in theoretical amount on heating a mixture of 1 mol. proportion of naphthylamine dissolved in methyl alcohol and 2 mol. proportions of methyl iodide in closed tubes at 140° during one day. It is a pale-yellow strongly refracting oil, having an odour like that of petroleum, boiling at 267° ; it exhibits an intense green fluorescence. On the addition of ferric chloride to its alcoholic solution, a violet coloration is produced, which passes into a beautiful violet on exposure to the air.

Trimethylnaphthylammonium iodide, $\text{C}^{10}\text{H}^7\text{.N(CH}^3)^3\text{I}$, formed by combining dimethylnaphthylamine with methyl iodide, crystallises from water in large slightly yellowish-green coloured needles, easily soluble in hot and cold water. At 164° it splits up into methyl iodide and dimethylnaphthylamine. It is not altered by sodium hydrate, but on digestion with silver hydrate is converted into the hydroxide, $\text{C}^{10}\text{H}^7\text{.N(CH}^3)^3(\text{OH})$.

Ethyl- α -naphthylamine, $\text{C}^{10}\text{H}^7\text{.NH(C}^2\text{H}^5)$, is formed on reduction of α -thiacetamidonaphthalene (Bernthsen a. Trompeter, *Ber.* xi. 1756).

Dinaphthylamine, $\text{NH(C}^{10}\text{H}^7)^2$.—On the addition of potassium nitrite to an acetic acid solution of this base, *nitrosodinaphthylamine*, $\text{N(C}^{10}\text{H}^7)^2(\text{NO})$, separates as a yellow oil which soon becomes solid. The product is dissolved in as little benzene as possible, and the solution then precipitated with dilute alcohol. It forms a crystalline powder, melting with decomposition at 260° – 262° (Landshoff, *Ber.* xi. 641).

α -Thiacetamidonaphthalene, $\text{C}^{10}\text{H}^7\text{.NH(CS.CH}^3)$.—This body, termed by Bernthsen a. Trompeter *acetanaphthylthiamide*, is obtained on heating the amidine $\text{CH}^3\text{C(NH).NH.C}^{10}\text{H}^7$ (viii. 71) with carbon bisulphide for several hours at 100° . It crystallises in yellowish-white tabular crystals, melting at 96° ; it dissolves, although with difficulty, in sodium hydrate solution, and is reprecipitated by hydrochloric acid.

α -Thiobenzamidonaphthalene, $\text{C}^{10}\text{H}^7\text{.NH(CS.C}^6\text{H}^5)$, prepared in a similar manner from the amidine, $\text{C}^{10}\text{H}^7\text{.NH.C(NH)C}^6\text{H}^5$, crystallises in yellow glistening plates melting at $147\cdot5^{\circ}$.

The amidines here referred to are obtained as hydrochlorides on heating naphthylammonium chloride with acetonitril and benzonitril respectively (see Bernthsen a. Trompeter).

Bromo- α -amidonaphthalene.—The acetyl-derivative of this compound is formed on the addition of the calculated amount of bromine to α -acenaphthalid suspended in carbon bisulphide. *Bromo- α -acetamidonaphthalene*, $\text{C}^{10}\text{H}^6\text{Br.NH.C}^2\text{H}^3\text{O}$, crystallises from hot alcohol, in which it is easily soluble, in long concentrically grouped needles melting at 193° . It is less readily decomposed than acenaphthalid by alkalis; by boiling it, however, with a solution of 3 pts. potassium hydrate and 2 pts. water, *bromo- α -amidonaphthalene* or *bromo- α -naphthylamine*, $\text{C}^{10}\text{H}^6\text{Br.NH}^2$, is produced. This compound crystallises from alcohol in aggregates of brown-coloured needles, melting at 94° , possessing an extremely unpleasant odour. It furnishes a very well crystallised hydrochloride and sulphate. As it may be converted into α -bromonaphthalene by displacement of the amido-group by hydrogen, it is an *aa*-derivative of naphthalene (Rother, *Ber.* iv. 850).

Chloro- α -amidonaphthalene, $\text{C}^{10}\text{H}^6\text{Cl.NH}^2$.—Seidler has observed the formation of

this compound, together with naphthylamine, on reducing nitronaphthalene with tin and hydrochloric acid; it appears to result from the action of the stannic chloride which is produced on the naphthylamine, as it may be obtained by exposing a mixture of these substances to the air for several weeks. The body thus produced crystallises in colourless odourless needles melting at 98° ; it is sparingly soluble in benzene, and may therefore by means of this solvent be separated from naphthylamine, but easily soluble in alcohol and ether. Its acetyl derivative, $C^{10}H^6Cl.NH.C^2H^3O$, crystallises in colourless needles melting at 184° , easily soluble in alcohol and ether (*ibid.* xi. 1201).

Nitro- α -amidonaphthalenes.—If a cold saturated solution of 3 pts. acenaphthalide in glacial acetic acid be mixed with 1 pt. of fuming nitric acid free from nitrous acid and the mixture allowed to stand several hours, a crystalline mass is deposited and a further quantity of crystals may be separated by mixing the supernatant liquid with water. The product is a mixture of two isomeric *nitro- α -acetamidonaphthalenes*, $C^{10}H^6(NO^2).NH.C^2H^3O$, which, however, are nearly of the same solubility; on this account, they have not been separated in a state of purity (Andreoni a. Biedermann, *Ber.* vi. 342; Liebermann a. Dittler, *Liebig's Annalen*, clxxxiii. 228).

α -Nitro- α -amidonaphthalene, $C^{10}H^6(NO^2).NH^2$.—On heating the mixture of nitro-acenaphthalids thus prepared with an alcoholic solution of potassium hydrate (4 pts. nitro-product to 1–1½ pt. KOH), and keeping the liquid in gentle ebullition for about an hour, a mixture of the corresponding nitronaphthylamines is obtained, consisting chiefly, however, of that melting at 164° , which is less soluble than the isomeric in alcohol, and may therefore be purified by repeated recrystallisation from this solvent. It crystallises in thin orange-coloured needles, often matted together, moderately soluble in alcohol and glacial acetic acid; it possesses considerable tinctorial power for wool, which it colours orange-yellow. It is almost destitute of basic properties, for, although it dissolves more readily on warming in acids than in water, it separates out unchanged as the solution cools.

When submitted to the action of nitrous acid in alcoholic solution, it yields a compound of the formula $C^{20}H^{13}N^3O^4$, which is probably the nitro-derivative of so-called azodinaphthylidiamine (vii. 849; comp. Martius, *Jahresb.* 1865, 436).

The diazo-derivative formed by the action of nitrous acid in presence of nitric acid, however, is converted into α -nitronaphthalene on boiling with alcohol: hence both the amido- and nitro-groups occupy α -positions.

β -Nitro- α -amidonaphthalene, which is formed together with the foregoing, has not been obtained quite pure; it very closely resembles the α -compound, but is more soluble, and appears to melt at about 158° . It yields a complex azo-derivative when submitted to the action of nitrous acid in presence of nitric acid (Liebermann a. Dittler).

An *α -nitroamidonaphthalene* isomeric with the above is obtained on reduction of α -dinitronaphthalene (m. p. 212°). This latter compound, however, is very readily converted into the corresponding diamidonaphthalene, and special precautions are necessary in preparing the amidonitro-derivative from it. Alcohol having been poured over it, a couple of grams of a concentrated solution of ammonia are added, and the cooled liquid is then saturated with hydrogen sulphide; when this is the case, the vessel is set aside until the odour of the gas has disappeared, and then hydrogen sulphide is again passed into the liquid. These operations are repeated until the flask has gained in weight to the extent required by the equation:

The solution is then mixed with water, and the precipitate extracted with boiling dilute hydrochloric acid; the hydrochloric acid solution having been concentrated, ammonia is added; the precipitate is dissolved in a large quantity of dilute sulphuric acid; and the crystals of the sulphate which separate as the solution cools are recrystallised from water acidulated with sulphuric acid. The free base may be obtained by treating the sulphate with ammonia. It crystallises from boiling water in glistening small red crystals, melting at 118° – 119° . The sulphate, $[C^{10}H^6(NO^2)(NH^2)]^2.H^2SO^4.2H^2O$, forms long glistening needles, very difficultly soluble in cold water. α -Nitronaphthalene is obtained from this nitroamidonaphthalene on displacing the amido-group by hydrogen (Beilstein a. Kuhlberg, *Liebig's Annalen*, clxix. 87).

$\alpha\beta$ -Dinitro- α -amidonaphthalene, $C^{10}H^6(NO^2)^2.NH^2$.—The acetyl-derivative of this compound is formed on nitration of acenaphthalide. A concentrated solution of the latter in glacial acetic acid is mixed with a quantity of fuming nitric acid free from nitrous acid equal in weight to that of the acenaphthalide employed, and the mixture heated for a short time on the water bath to such a temperature that a slight evolution of gas takes place; the crystalline product which separates on standing is then washed and recrystallised from alcohol or glacial acetic acid. *Dinitro- α -acenaphthalid*

crystallises in long yellowish needles, melting at 247° . When boiled with a solution of sodium hydrate, it yields dinitro- α -naphthol, $C^{10}H^5(NO^2)_2.OH$ (m. p. 138°); but if heated with an alcoholic solution of ammonia for three hours at 140° , dinitro- α -amido-naphthalene is formed. The latter crystallises in lemon-yellow needles, melting at 235° (Liebermann a. Hammerschlag, *Liebig's Annalen*, clxxxiii. 272).

β -Nitro- α -bromo- α -amidonaphthalene.—To prepare this compound, α -bromo- α -acenaphthalide, $C^{10}H^5Br(NHC^2H^3O)$, is nitrated, and 10 pts. of the resulting nitro-derivative, which crystallises in long pale-yellow needles melting at 232° , are boiled for two days with 2 pts. of potassium hydrate dissolved in 60 pts. anhydrous alcohol. It crystallises in long orange-coloured needles, melting at 200° ; on oxidation with nitric acid, it yields phthalic acid. It is abundantly soluble in concentrated sulphuric acid; after a time, colourless needles of the sulphate separate from the solution, but these are immediately decomposed by water (Liebermann a. Scheiding, *ibid.* clxxxiii. 258).

α -Benzamidonaphthalene, $C^{10}H^7.NH.COC^6H^5$, prepared by heating naphthylamine with benzoic chloride (Church), crystallises from alcohol, in which it is easily soluble, in glistening needles, melting at 156° (Ebell, *Ber.* vii. 1317; viii. 562). It yields two, if not three, isomeric mononitro-compounds on nitration. α -Nitro- α -benzamidonaphthalene, $C^{10}H^6(NO^2).NH.COC^6H^5$, crystallises from alcohol, in which it is difficultly soluble, in yellowish prisms melting at 224° . When boiled with potassic hydrate solution, it yields α -nitro- α -naphthol (m. p. 164°). On reduction with tin and hydrochloric acid, this compound is converted into the corresponding amido-benzamidonaphthalene, $C^{10}H^6(NH^2).NH.COC^6H^5$. The latter crystallises from alcohol in needles melting at 186° . Its hydrochloride forms fine colourless microscopic needles difficultly soluble in water and alcohol.

β -Nitro- α -benzamidonaphthalene, $C^{10}H^6(NO^2).NH.COC^6H^5$, crystallises in yellow glistening prisms, melting at 175° ; it is easily soluble in hot, but difficultly in cold water. It differs considerably from the isomeride in its behaviour on reduction with tin and hydrochloric acid, being converted into the hydrochloride of a base of the formula $C^{17}H^{12}N^2$ (so-called anhydrobenzoyldiamidonaphthalene). Probably the nitro-group is, in the first instance, reduced to the amido-group, the hydrogen-atoms of which then unite with the oxygen atom of the benzoyl group, forming water, thus:

The base in question forms well-defined yellow crystals, melting at 210° , difficultly soluble in water, easily in alcohol. It appears to combine directly with amyl iodide. The hydrochloride, $C^{17}H^{12}N^2.Cl$, crystallises in colourless microscopic needles, difficultly soluble in water and alcohol. The nitrate, $C^{17}H^{12}N^2.NO_3$, crystallises in long yellow needles.

$\alpha\beta$ -Dinitro- α -benzamidonaphthalene, $C^{10}H^5(NO^2)_2.NH.COC^6H^5$, produced on nitrating α -benzamidonaphthalene with strong nitric acid, crystallises in small needles melting at 252° , difficultly soluble in alcohol, benzene, and chloroform. By recrystallisation from glacial acetic acid, it is converted into dinitroacetamidonaphthalene. On reduction with tin and hydrochloric acid, it is converted into diamido- α -benzamidonaphthalene, $C^{10}H^5(NH^2)_2.NHCOC^6H^5$ (Ebell).

Succinamidonaphthalene.—See Hanemann (*Ber.* x. 1713).

Diamidonaphthalenes.—The properties of the diamidonaphthalenes formed on reduction of so-called α - and β -dinitronaphthalene have been further investigated and described by De Aguiar (*Ber.* vii. 307).

According to Beilstein a. Kuhlberg (*Liebig's Annalen*, clxix. 90), there is a great difference in the behaviour of α - and β -dinitronaphthalene with reducing agents, the latter being only slowly acted upon even by tin and hydrochloric acid (comp. Ladenburg, *Ber.* xi. 1651).

A third *diamidonaphthalene*, isomeric with those from the two dinitronaphthalenes, has been obtained from α -nitro- α -acetamidonaphthalene by Liebermann a. Dittler (*Liebig's Annalen*, clxxxiii. 233). To prepare it, the latter compound is treated with tin and hydrochloric acid, the dissolved tin is removed by means of hydrogen sulphide, &c., and the resulting α -amido- α -acetamidonaphthalene hydrochloride is boiled with a dilute solution of sodium hydrate; the base then separates as a resin. From this product, salts may be obtained by dissolving it in dilute acid and then precipitating

the filtered solution with the concentrated acid. The *chloride*, $C^{10}H^6(NH^2Cl)^2$, forms small white plates; on mixing its solution with a dilute solution of potassium dichromate or chromic acid, a green coloration is produced; more concentrated solutions furnish a similarly coloured precipitate. On boiling, the colour disappears, and naphthaquinone distils over. When the diamidonaphthalenes from α - and β -dinitronaphthalene are thus treated, not a trace of quinone is produced.

α -*Diamidonaphthalene* may be obtained by precipitating a moderately concentrated solution of the iodide with sodium hydrate; a white precipitate is produced, which may be purified by recrystallisation from alcohol or ether. It crystallises from alcohol, chloroform, and ether in glistening needles or prisms, which, as a rule, are colourless, and sublimes almost without decomposition in white feather-like forms. It melts at 189.5° . It is somewhat soluble in cold, and readily soluble in hot water, and still more in alcohol, ether, and chloroform. The dry substance does not alter, even on exposure to light. On the addition of ferric chloride to water in which crystals of the base are suspended, a blue-violet coloration is produced, and after a time a similarly coloured precipitate forms. A like coloration results on adding barium dioxide and hydrochloric acid, or potassium nitrite and sulphuric acid, to an alcoholic solution; potassium hypochlorite causes a red coloration and precipitate.

β -*Diamidonaphthalene* may be prepared in a similar manner, but a more concentrated solution of the iodide should be employed, and it is more difficult to purify: the precipitate is dissolved in cold strong alcohol, and the solution mixed with double the amount of distilled water; the base then separates out in white needles melting at 66.5° . It is more soluble than the α -compound in water, but less soluble in chloroform; it dissolves in alcohol and ether in all proportions, but cannot be obtained well crystallised from either of these solvents. No characteristic coloration is produced on the addition of barium dioxide and hydrochloric acid to the alcoholic solution, the liquid being at most slightly blackened; ferric chloride produces a dark chestnut-brown precipitate.

Both α - and β -diamidonaphthalene combine readily with oxalic acid. The α -oxalate crystallises from water in thin transparent plates; the β -oxalate in white glistening crystals like those of potassium iodide. The latter appears readily to undergo change, and is said by De Aguiar to furnish a substance resembling gold in appearance and lustre and of great stability, but the nature of this substance and the method of preparing it have not been described (comp. *Ber.* vii. 313).

The α -diamine is not appreciably acted upon by ethyl oxalate at 100° , but if the β -diamine be heated with 10 pts. of the oxalate in sealed tubes at 100° , a compound of the formula $C^{10}H^{12}O^2$ is produced, which crystallises from chloroform in magnificent red needles like chromic anhydride; this compound is soluble in water, alcohol, and benzene; it carbonises without melting if heated to 195° . It is regarded by De Aguiar

as *ethylnaphthaleneoxamide*, $C^{10}H^5(C^2H^5)\begin{matrix} \text{NH.CO} \\ | \\ \text{NH.CO} \end{matrix}$; the formula $C^{10}H^6\begin{matrix} \text{NH.CO} \\ | \\ \text{N}=\text{C.OC}^2H^5 \end{matrix}$

would, however, appear more probable.

If α -diamidonaphthalene or one of its salts be submitted to the action of nitrous acid or potassium nitrite, a brownish-black flocculent product is obtained. But if a solution of the sulphate of the β -diamine be mixed with a concentrated solution of a single molecular proportion of potassium nitrite, a voluminous red precipitate is produced, which may be recrystallised from warm benzene, in which it is easily soluble. It then forms extremely fine glistening red needles. This product has the composition $C^{10}H^7N^2$; its properties are altogether different, however, from those of the ordinary diazo-derivatives. It is a very stable compound in the free state, and may even be partially sublimed; the sublimed substance resembles alizarin in appearance. It forms compounds both with acids and with bases, but they are highly unstable, and at once decomposed by water. Thus if the moist substance be added to a mixture of equal volumes of water and sulphuric acid, a dark wine-red coloured solution is obtained which soon deposits long needle-like crystals of the same colour; the least trace of water, however, turns these crystals vermilion-red, the parent substance being regenerated.

According to Ladenburg (*Ber.* xi. 1650), the β -diamine alone reacts in the manner characteristic of orthodiamido-compounds with benzoic aldehyde.

Naphthydreneglycol, $C^{10}H^{10}(OH)^2$ (Grimaux, *Compt. rend.* lxxv. 351, lxxvi. 575; *Bull. Soc. Chim.* [2], xviii. 205; xix. 396). The dichlorinated derivative of this alcohol is produced by prolonged boiling of naphthalene tetrachloride with water; it crystallises from the concentrated solution in brownish granules or crystalline plates, but may be rendered colourless by means of animal charcoal. It dissolves in about 30 pts. of boiling water, but is sparingly soluble in cold water; alcohol and ether

dissolve it readily. It separates from an ethereal solution in hard prisms of considerable size, melting at 155°–156°. The *diacetyl* derivative, $C^{10}H^6Cl_2(OC^2H^3O)^2$, crystallises from ether in plates or short prisms melting at 130°–131°; the corresponding *dibenzoate*, $C^{10}H^6Cl_2(OC^2H^3O)^2$, melts at 148°–150°.

On distillation with hydrochloric acid, dichloronaphthylidene glycol furnishes a small amount of a monochloronaphthol, $C^{10}H^6Cl.OH$, crystallising in long fine needles melting at 109°. If an aqueous solution be distilled with zinc-dust, α -naphthol is produced in accordance with the equation $C^{10}H^6Cl_2(OH)^2 + 2H = C^{10}H^7.OH + 2HCl + H^2O$. If heated with 30 pts. of water at 150° for twenty-four hours, it yields a resinous product, together with a crystalline substance, which is apparently α -naphthoquinol. On oxidation with dilute nitric acid, it is converted into phthalic acid.

Naphthylpurpuric Acid, $C^{11}H^7N^3O^4$. The salts of this acid are formed in precisely the same manner as the corresponding isopurpurates (iii. 433) from the potassium salt obtained by the action of potassium cyanide on dinitronaphthol in alcoholic solution (Sommaruga, *Ber.* iv. 94):

They are dark golden-brown with metallic reflex; the potassium salt is crystalline; the 'acid' itself cannot be isolated. On oxidation with nitric acid, they yield a mixture of mono- and dinitronaphthol; when heated with potassic hydrate they form hemimellithic, phthalic, and benzoic acid.

If, in preparing potassium naphthylpurpurate, aqueous solutions be employed instead of alcoholic, a second body, so-called *indophan*, $C^{22}H^{10}N^4O^4$, is also obtained. To prepare this compound, about 30 grams of dinitronaphthol are added to about 2 litres of water, and sufficient ammonia mixed with the boiling liquid to dissolve the dinitronaphthol. A hot concentrated solution of 45 grams pure potassium cyanide is then added. The reaction is complete within about ten minutes. The whole is then placed on a good filter, and the solid residue washed with boiling water until the liquid runs through colourless. The product is a mixture of indophan with its potassium derivative. After further prolonged washing with boiling water, it is removed from the filter and heated with very dilute hydrochloric acid, again filtered and washed until the filtrate no longer contains chlorine. If it be desired to prepare the potassium derivative, the crude product is heated with potassic hydrate solution, filtered, and then washed until freed from alkali.

Indophan is a violet-coloured powder with a green metallic lustre. It is insoluble in the ordinary solvents, but moderately soluble in sulphuric or warm glacial acetic acid; it does not crystallise from these solutions, however; and, unlike indigo, cannot be sublimed. It is oxidised by nitric acid, but cannot be reduced by ferrous sulphate and lime. It yields the same products as naphthylpurpuric acid on fusion with potassic hydrate. The potassium and sodium derivatives, which closely resemble indigo in outward appearance, contain only a single atom of metal.

CONSTITUTION OF NAPHTHALENE AND ITS DERIVATIVES.

The adaptability of the formula originally proposed for naphthalene by Erlenmeyer in 1866 (*Liebig's Annalen*, cxxxvii. 346), but first established on the basis of experimental evidence by Graebe in 1869 (vi. 212), has been entirely confirmed by all recent researches (comp. Ladenburg, *Ber.* vii. 1137). Wreden, however, has proposed (*ibid.* ix. 590) the following as a substitute for the Erlenmeyer-Graebe formula:

but there does not appear to be the slightest experimental evidence to justify the use of this symbol.

In discussing the constitution of the naphthalene derivatives, it is convenient, as in the case of the benzene derivatives, to disregard the mode of union of the carbon atoms, and merely to employ a double hexagon as the symbol of naphthalene, numbering the 'positions' in the one hexagon 1, 2, 3, and 4, and the corresponding 'positions' in the other hexagon 1', 2', 3', and 4', thus:

The data as yet accumulated are not sufficient to furnish a complete solution of the problem of the constitution of the naphthalene derivatives, but they are sufficient for the preliminary discussion of the problem and well worthy of consideration in detail.

On reference to the naphthalene symbol, it will be obvious that two, but only two, mono-derivatives are possible, viz.: one formed by the displacement of the hydrogen atoms in the positions 1, 4, 1' or 4', the other formed by the displacement of those in the positions 2, 3, 2' or 3'. Also that two, but only two, 'symmetrical' di-derivatives are possible, in which the positions 1 : 4' (= 1' : 4) or 2 : 3' (= 2' : 3) are occupied; in like manner, there may be two symmetrical tetra-derivatives.

The two isomeric (α and β) naphthalenesulphonic acids, formed simultaneously by the action of sulphuric acid on naphthalene, are respectively representative of these two kinds of mono-derivatives.

Ordinary nitronaphthalene and the amidonaphthalene (naphthylamine) derived from it, α -naphthol, α -cyanonaphthalene, the bromonaphthalene formed by the direct action of bromine on naphthalene and α -naphthoic or naphthalene- α -carboxylic acid are all to be regarded as members of the same series of mono-derivatives as the so-called naphthalene- α -sulphonic acid: since α -naphthol is obtained by directly displacing the sulpho-group in this acid by the group OH; since α -naphthol may be formed by Griess's method from amidonaphthalene (naphthylamine); and since naphthalene- α -carboxylic acid may be obtained on the one hand from the cyanonaphthalene derived from the α -sulphonic acid, and on the other from ordinary bromonaphthalene by the combined action of sodium and ethyl chloroformate, $\text{Cl.COO}^{\text{C}}\text{H}^{\text{E}}$ (Eghis). Ordinary chloronaphthalene is doubtless also an α -derivative, as it corresponds in all particulars to ordinary bromonaphthalene.

Naphthalene- β -sulphonic acid is the only β -derivative as yet obtained by a direct process from naphthalene. To it correspond β -naphthol, β -cyanonaphthalene, naphthalene- β -carboxylic acid, β -naphthylamine, and the chloro- and bromonaphthalene formed from this latter by Griess's method.

The positions 1, 4, 1' and 4' in the naphthalene symbol are to be regarded as α -positions, i.e. it is by the displacement of a hydrogen atom in one of these positions that the α -mono-derivatives are formed, and the positions 2, 3, 2' and 3' are to be regarded as β -positions. The evidence on which these two propositions are based is briefly as follows:

Supposing any di-derivative of naphthalene in which both the radicles substituted for hydrogen are in the same hexagon, and in which both radicles are either in α -positions or in β -positions, be taken and the relative positions of these two radicles be determined, then, if the two radicles be found to occupy the relative positions 1 : 2, it follows that the hydrogen atom in the positions marked 2 and 3 in the above symbol have been displaced; while if they occupy the relative positions 1 : 4, those marked 1 and 4 in the symbol have been displaced. Now Liebermann a. Dittler have shown (*Liebermann's Annalen*, clxxxiii. 228) that by nitrating acetamidonaphthalene (acetanaphthalid), $\text{C}^{10}\text{H}^{\text{A}}.\text{NH}(\text{C}^{\text{O}}\text{H}^{\text{O}})\text{O}$, prepared from ordinary or α -amidonaphthalene, then converting the acetamidonitronaphthalene, which is the chief product of the reaction (comp. p. 1371), into amidonitronaphthalene, and displacing the amido-group in this latter by hydrogen by Griess's method, a nitronaphthalene is obtained in all respects identical with ordinary or α -nitronaphthalene; in other words, both radicles in the acetamidonitronaphthalene in question occupy α -positions. By reducing the same acetamidonitronaphthalene, then converting the resulting acetamidoamidonaphthalene into diamidonaphthalene, $\text{C}^{10}\text{H}^{\text{A}}(\text{NH}^{\text{O}})^2$, and oxidising this latter, naphthaquinone, $\text{C}^{10}\text{H}^{\text{Q}}(\text{O}^{\text{O}})$, is produced: hence each of the oxygen-atoms in naphthaquinone is in the α -position, and as naphthaquinone yields phthalic acid on oxidation, the substituting radicles in the various derivatives referred to are in the one hexagon. There can be little doubt, from the complete similarity of their properties, that naphthaquinone and benzoquinone are similarly constituted; and since it has been shown that the oxygen-atoms in the latter occupy relatively the positions 1 : 4, it is in the highest degree probable that naphthaquinone is also a 1 : 4 derivative. If this deduction be accepted, it necessarily follows that the positions 1, 4 and also those marked 1' 4' in the naphthalene symbol are α -positions; and therefore that the positions 2, 3 and 2' 3' are β -positions, thus:

But, as Reverdin a. Nölting have pointed out (*Ber.* xiii. 36), the force of this argument is somewhat diminished by the fact that two naphthoquinones are known. The following argument which these chemists have brought forward is, however, perfectly conclusive. Obviously only two isomeric nitrophthalic acids are possible, viz. :

Two such acids have actually been prepared, both being formed on nitration of phthalic acid (Miller, *Ber.* xi. 1191); they melt respectively at 212° and 165°. Now, Miller has shown that the modification which melts at 165° is convertible into a hydroxyphthalic acid which Schall has proved to have the constitution $\text{OH} : \text{COOH} : \text{COOH} = 1 : 3 : 4$; hence it follows that the nitrophthalic acid melting at 212° is represented by fig. I., and that melting at 165° by fig. II., and since the former may be obtained by oxidation of nitronaphthalene (Beilstein a. Kurbatow, *Ber.* xii. 688), which is an α -derivative, it follows that the α -position in the symbol of naphthalene is the position next the carbon atom common to the two hexagons.

Constitution of the Haloid-derivatives of Naphthalene. Chloronaphthalenes.—The dichloronaphthalene melting at 68° (so-called β), obtained from naphthalene tetrachloride, undoubtedly contains both chlorine atoms in the same C^{α} -group in the relative positions 1 : 4, since it may be obtained from α -nitro- α -naphthol and yields a dichlorophthalic acid on oxidation. The isomeric dichloronaphthalene (m. p. 35°, so-called α) obtained from the same tetrachloride, is perhaps the 0-1 : 3 modification, for, from the general behaviour of naphthalene, it might be expected that this modification, rather than the isomeric 0-2 : 3 dichloronaphthalene, would be formed by the removal of the elements of two molecules of hydrogen chloride from the tetrachloride, which it is obvious may furnish three dichloronaphthalenes. If, however, the dibromonaphthalene obtained by Meldola is isomeric with that of Jolin, it is more probable that it is the 0-2 : 3 modification :

Naphthalene
tetrachloride.

0-1 : 4 (β) Dichloro-
naphthalene.

0-1 : 3 (? α) Dichloro-
naphthalene.

0-2 : 3 Dichloro-
naphthalene.

The dichloronaphthalene melting at 107° (so-called γ) is shown, by its behaviour on oxidation, to contain the chlorine atoms in different C^{α} -groups; both chlorine-atoms, however, are in α -positions, since it may be obtained both from nitronaphthalene- α -sulphonic acid and from α -nitronaphthalenesulphonic acid. Both β - and γ -dichloronaphthalene, however, may be converted into so-called δ -trichloronaphthalene by distilling their mono-nitro-derivatives with PCl_5 ; and hence it follows that the three chlorine-atoms in δ -trichloronaphthalene are all in α -positions. But δ -trichloronaphthalene is also obtained on treatment of β -dinitronaphthalene with PCl_5 , so that indirectly it may be said to be formed by further chlorination of ζ -dichloronaphthalene (m. p. 83°), as this latter is produced on simply displacing the nitro-groups in β -dinitronaphthalene by chlorine; hence ζ -dichloronaphthalene is also an α -derivative (Atterberg). But if β -dichloronaphthalene be the 0-1 : 4 modification, γ -dichloro-

δ -Trichloronaphthalene.

β -Dichloronaphthalene.

γ - and ζ -Dichloronaphthalene.

naphthalene must be the 1-4', and ζ -dichloronaphthalene the 1-1' modification, or *vice versa*.

It is most probable that the γ -modification is the 1-4' compound, as it is derived from the dinitronaphthalene which is the chief product of the action of nitric acid on naphthalene, it being apparently the tendency in the naphthalene series for the more symmetrically constituted compound (*i.e.* the more symmetrical as far as the symbol is concerned) to be formed in preference. The difference in the behaviour of the diamidonaphthalenes obtained from α - and β -dinitronaphthalene also tends to support this conclusion.

The above conclusions derive further support from the following considerations. By submitting nitro- γ -dichloronaphthalene to reduction, an amidochloronaphthalene is obtained which necessarily corresponds either to β - or ζ -dichloronaphthalene, since the nitro-derivative in question is convertible into δ -trichloronaphthalene. It is isomeric, however, with the amidochloronaphthalene (m. p. 85°) which corresponds to the former, and therefore corresponds to the latter, which may, in fact, actually be obtained from it by Griess's method (Atterberg).

The existence of three dichloronaphthalenes having their chlorine-atoms all in α -positions is also a proof of the existence of four α -positions in naphthalene. Chlorine and the nitro-group respectively occupy the same position in chloronaphthalene and nitronaphthalene, since the latter may be directly converted into the former by displacement of the NO_2 -group by Cl. But, on the one hand, chloronaphthalene yields a nitro-derivative which is directly convertible into β -dichloronaphthalene. Nitronaphthalene, on the other hand, is convertible into two isomeric dinitronaphthalenes, corresponding respectively to γ - and ζ -dichloronaphthalene. Hence β -, γ - and ζ -dichloronaphthalene each contain an atom of chlorine in the same position as the NO_2 group in nitronaphthalene; but the second chlorine-atom must occupy a different position in each relatively to the first, otherwise they would not be isomeric: consequently there must be at least four α -positions in naphthalene (Atterberg).

The constitution of the remaining dichloronaphthalenes cannot at present be conjectured with any great degree of certainty. The η -modification (m. p. 48°) is not improbably a 2-1' or 2-4' derivative, as it is derived from naphthalene- β -sulphonic acid, and it is probable from the behaviour of the α -sulphonic acid on nitration that the nitro-group in the nitro- β -sulphonic acid occupies an α -position in the C⁶-group which is not occupied by the sulpho-group.

δ - and ϵ -dichloronaphthalenes, which are derived from the isomeric naphthalene-disulphonic acids, are probably, one or both, $\beta\beta$ -derivatives. Both probably are derived from the β -monosulphonic acid; but supposing this to be the case, and that the β -disulphonic acid contains both sulpho-groups in β -positions, there are still three formulæ which may be applied to it, viz.:

I.

II.

III.

According to Ebert a. Merz, the naphtholsulphonic acid formed on fusing the β -disulphonate with potassium hydrate is identical with that produced from β -naphthol and sulphuric acid; if this be the case, the first of the above formulæ would appear to be the most probable, for as the action of sulphuric acid and bromine on the phenols is similar in so far as the constitution of the resulting compounds is concerned, as β -naphthol yields a bromo-derivative in which both bromine and the OH-group are in the same C⁶-group (Smith), it is probable that the sulpho-acid derived from β -naphthol would contain both the OH- and the sulpho-group in the same C⁶-group. If, however, the β -disulpho acid were thus constituted, the dicarboxylic acid derived from it should be identical with naphthophthalic acid, $\text{C}_{10}\text{H}_6(\text{COOH})_2$, which is not the case. It is therefore a question whether the naphtholsulphonic acid from the β -disulphonic acid and that from β -naphthol are identical, as Ebert a. Merz have stated, or whether isomeric change does not take place in some of the reactions above referred to. The fact that it is the C⁶-group which does not contain the sulpho-group that is attacked when naphthalene- α - and β -sulphonic chlorides are submitted to the action of chlorine, or when naphthalene- α -sulphonic acid is treated with nitric acid, renders it probable that the naphthalenedisulphonic acids also contain the sulpho-groups in distinct hexagons, and such a conclusion would appear to harmonise well with their general behaviour and that of the compounds derived from them. On this assumption, the second and third of the formulæ given above are the most probable expressions of the constitution of the α - and β -disulphonic acids respectively.

1378 NAPHTHALENE-DERIVATIVES, CONSTITUTION OF.

α -Trichloronaphthalene is perhaps the 0-1:2:4 modification, as it yields a nitrotrichlorophthalic acid on oxidation with nitric acid (Widmann). δ -Trichloronaphthalene, as already pointed out, is a 1:4-1' derivative. β - and γ -Trichloronaphthalene are probably both derived from the same nitronaphthalene tetrachloride, and, supposing this to be the case, there are only two formulæ which can be assigned to them, since the third modification which can be formed from such a tetrachloride is a body of the formula of δ -trichloronaphthalene, thus:

The β -compound is not improbably the 1-1':3, and the γ -compound the 1-2':3' modification. ζ -Trichloronaphthalene being formed by a reaction similar to that by which the γ -compound is produced, excepting that the β - instead of the α -sulphonic chloride is employed, may be regarded as the 2-2':3' modification.

From the manner in which they are formed, and from their behaviour with nitric acid, it may be suggested as more or less probable that the remaining chloronaphthalenes are bodies of the following constitution:

α -Tetrachloronaphthalene, m. p.	1:4-2':3'
β " "	1-2':3':4'
γ " "	1:4-1':3'
δ " "	1-1':2':4'
ϵ " "	1:4-1':4'
α -Pentachloronaphthalene, "	1-1':2':3':4'
β " "	1:4-1':2':4'

Bromonaphthalenes.—It is to be supposed that these correspond in constitution with the chloronaphthalenes prepared by similar methods. According to Guareschi, however (*Gazz. chim. ital.* vii. 24), the dibromonaphthalene melting at 81° (that termed β -dibromonaphthalene by Jolin) yields a bromophthalic acid on oxidation with nitric acid, and Meldola finds that the same acid is obtained by reducing the mononitro-derivative of the dibromonaphthalene in question and oxidising the product (*Ber.* xii. 1963). This result, as the latter points out, appears to indicate that the bromine-atoms in β -dibromonaphthalene are not both in the same C⁶-group. Its production from nitro- α -bromonaphthalene and from α -bromonaphthalenesulphonic acid, and the fact that the latter acid is converted into β -dichloronaphthalene when distilled with PCl_5 (Jolin), seem, however, to negative this assumption.

Nitronaphthalenes and Nitrochloronaphthalenes.—The conversion of the two dinitronaphthalenes produced by nitration of naphthalene into γ - and ζ -dichloronaphthalene would appear to indicate that the so-called α -compound is the 1-4', and the β -compound the 1-1' modification. The third isomeride obtained by Liebermann a. Hamerschlag is undoubtedly the 0-1:3 modification.

The constitution of the nitrochloronaphthalenes may be inferred from that of the chloronaphthalenes into which they are converted on distillation with PCl_5 , of course only in so far as these latter are bodies of known constitution.

Constitution of the α -Naphthol and α -Naphthylamine derivatives.—The researches of Liebermann and his pupils more especially leave no doubt that these compounds behave as the corresponding mono-derivatives of benzene, phenol and aniline. Thus both furnish two isomeric mono-derivatives, that produced in largest amount being formed by the displacement of an atom of hydrogen in the para-position relatively to the OH or NH_2 group (or rather to the $\text{NH.C}^2\text{H}_5\text{O}$ group, since in most cases acenaphthalid and not naphthylamine is employed); and although it has not yet been directly proved, it can scarcely be doubted, that the isomeride which is formed at the same time contains the displacing radicle in the ortho-position relatively to the OH or NH_2 group. Both of these mono-derivatives furnish the same di-derivative when further acted upon, but the remaining hydrogen-atom, occupying the meta-position, resists displacement, and under what may be termed ordinary conditions di-derivatives only are obtained.

At present nothing is known of the laws which govern substitution in the case of the β -mono-derivatives of naphthalene.

H. E. A.

NAPHTHYLAMINES. See NAPHTHALENES, AMIDO- (p. 1369).

NAPHTHYL-KETONES. See KETONES (p. 1156).

NARCEINE, $C^{23}H^{29}NO^9$. This base dissolves sparingly in water, very easily in potash and in ammonia, and crystallises from aqueous solution with 2 mol. water, which are easily given off at 100° . At 140° another molecule of water is evolved, and the fused residue dissolves with moderate facility in dilute hydrochloric acid, forming a solution from which ammonia throws down amorphous flocks. The reaction, which takes place according to the equation $C^{23}H^{29}NO^9 = H^2O + C^{22}H^{27}NO^8$, yields probably four, and certainly three, products, of which all but one (*i.e.* three or two respectively) are amorphous and basic; the remaining substance, especially in alcoholic solution, gives a splendid blue colour with ferric chloride, but does not consist of gallic acid (O. Hesse, *Deut. Chem. Ges. Ber.* vii. 105).

Narceine, treated with *zinc* and *hydrochloric acid*, is converted into a base, $C^{23}H^{29}NO^8$, or $C^{22}H^{27}NO^8$, which is amorphous, and forms amorphous salts (Beckett a. Wright, *Chem. Soc. J.* xxviii. 629).

Acetic anhydride appears to exert a dehydrating action on narceine. In two experiments, in which a distinct odour of nitrous acid was perceived and red fumes were given off, two bases soluble in ether were produced, one crystallised, $C^{22}H^{27}NO^7$, the other amorphous, $C^{23}H^{27}NO^8$ (Beckett a. Wright).

When narceine is heated to 140° – 150° for fifteen to twenty hours with *water* in a sealed tube, it chars and becomes decomposed, but does not form either meconin, opianic acid, or hemipinic acid, or any solid base soluble in ether; a trace of methylamine is however produced.

Narceine, oxidised by *potassium dichromate* and *sulphuric acid*, gives off carbon dioxide, and yields about 10 p. c. of hemipinic acid and methylamine; with *ferric chloride*, considerable quantities of hemipinic but no opianic acid. Hemipinic acid is also produced, though in smaller quantity, by the action of sulphuric acid and manganese dioxide, or of potassium permanganate, on the aqueous solution of narceine.

Dilute solutions of potassium hydroxide and potassium carbonate act on narceine in such a manner as to form ammonia and trimethylamine, but no pyridine or allied volatile bases; also small quantities of an acid which is easily soluble in ether and in hot alcohol, sparingly soluble in water, and forms small white crystals melting at 210° . This acid has approximately the composition $C^{23}H^{23}NO^8$, and its formation from narceine may be represented by the equation $C^{23}H^{29}NO^9 - H^2O - 2H^2 = C^{23}H^{23}NO^8$. By fusion with potash, it yields an acid exhibiting all the reactions of protocathechuic acid, which latter is also formed, and in considerable quantity, when narceine is heated to 230° – 240° with potassium hydroxide, methylnormeconin being formed as an intermediate product.

These results lead to the representation of narceine by the formula:

differing from that of oxynarcotine (p. 1383) only in the character of its nitrogenous radicle.

Hydrochlorides (A. Petit, *Bull. Soc. Chim.* [2], xviii. 534).—Narceine hydrochloride, as met with in commerce, contains a variable quantity of hydrochloric acid associated with the base. When narceine is dissolved in excess of acid, and the whole evaporated to dryness, the hydrochloric acid retained is smaller in quantity the longer the evaporation has been continued; if the base is dissolved in just sufficient acid, the solution does not deposit crystals if more water than 50 parts to 1 of narceine be present; with 25 to 1, crystals are deposited, the formula of which is $2(\bar{N}.HCl).5H^2O$; * if 1 part of narceine be dissolved in 70 parts of dilute acid containing 3 grams to the litre mixed with 30 of water, crystals form on cooling, which have the composition $5\bar{N}.HCl$; whilst if 30 of this acid and 70 of water be employed, the crystals are $10\bar{N}.HCl$. This latter product is also obtained by the action of water on either of the hydrochlorides, $2(\bar{N}.HCl).5H^2O$, or $5\bar{N}.HCl$.

Narceine dissolves in 769 parts of water			
\bar{N}	+ HCl	277	"
\bar{N}	+ $2HCl$	150	"
\bar{N}	+ $3HCl$	130	"
\bar{N}	+ $4HCl$	50	"

Wright (*Chem. Soc. J.* xxvii. 109) finds that narceine hydrochloride, obtained from a solution containing 8 to 10 mols. hydrochloric acid to 1 mol. narceine, which

* $\bar{N} = C^{22}H^{27}NO^8$.

gives off water of crystallisation when heated to 100° , but recovers it over sulphuric acid—contains altogether a proportion of water larger than that assigned to it by Petit ($2\frac{1}{2}\text{H}_2\text{O} = 8.26$ p. c., and $3\text{H}_2\text{O} = 9.75$ p. c.). By cooling a solution of N.HCl in 50 pts. water, a crystalline salt, 6N.HCl , was obtained, which, when treated with cold water, finally retained 0.76 p. c. chlorine, answering to Petit's compound 10N.HCl , this quantity, however, being reduced by further digestion to 0.4 p. c. The last portion of chlorine could not be removed, even by precipitation with alkali and repeated crystallisation. When, however, narceine hydrochloride was boiled with strong hydrochloric acid, no compound was formed analogous to chlorocodide (vi. 480), but—according to the equation $\text{C}^{23}\text{H}^{29}\text{NO}^9.\text{HCl} = \text{H}_2\text{O} + \text{C}^{23}\text{H}^{27}\text{NO}^8.\text{HCl}$,—the hydrochloride of a new base, which is amorphous, slightly soluble in ether, easily in alkalis and alkaline carbonates. Its salts give with ferric chloride a dark blue-violet colour, afterwards turning brownish, and with potassium chromate and sulphuric acid, a reddish-violet colour.

Sulphates (Beckett a. Wright, *loc. cit.*)—The small quantity of chlorine which adheres so obstinately to narceine precipitated from the hydrochloride, is completely removed by solution in hot dilute sulphuric acid (8–10 p. c.) and repeated crystallisation of the resulting sulphate. The crystals thus purified, then drenched with fifty times their volume of water, and washed with alcohol and ether, have the composition $7\text{C}^{23}\text{H}^{29}\text{NO}^9.4\text{SO}^4\text{H}^2 + 10\text{H}_2\text{O}$. This salt crystallised from a warm mixture of sulphuric acid and water in equal volumes, yields crystals having the composition of a bibasic sulphate; and by repeatedly crystallising the first-described salt from a large quantity of water, products more and more basic are obtained containing 3, 4, and 5 mols. narceine to 1 mol. SO^4H^2 . The narceine sulphates are distinguished from the hydrochlorides—which they otherwise closely resemble—by the fact that they are completely decomposed by solution of sodium carbonate, and yield the free base perfectly pure.

Narceine Ethiodide, $\text{C}^{23}\text{H}^{29}\text{NO}^9.\text{C}^2\text{H}^3\text{I}$, prepared like the corresponding morphine and narcotine-compounds, may be obtained by evaporating the product to dryness and dissolving the amorphous residue in absolute alcohol, in granular crystals, which, when dried at 100° , have the composition $\text{C}^{23}\text{H}^{29}\text{NO}^9.\text{C}^2\text{H}^3\text{I}$. The mother-liquor, though no longer crystallisable, has the same composition. By exposure to air and light, the compound is ultimately converted into a blue substance resembling iodide of starch. From solution in ten times its volume of boiling alcohol of 90 p. c., the ethiodide separates on cooling quite unaltered, and in combination with 2 mols. water of crystallisation. Treated in alcoholic solution with moist silver oxide, it yields an alkaline liquid having the composition $\text{C}^{23}\text{H}^{29}\text{NO}^9.\text{C}^2\text{H}^3\text{OH}$, which however decomposes partially, even on spontaneous evaporation, into narceine and alcohol. A platinum salt prepared from it showed an amount of platinum approaching very nearly to that of the platinum-chloride of narceine.

On the whole, therefore, it seems that while narceine ethiodide is more stable than the salts of narceine with inorganic acids, the addition-derivatives of narceine, as a class, seem to be marked by a tendency to break up into narceine and the additive-substance employed. An analogous behaviour is also characteristic of narcotine; indeed it is probable that there is some constitutional similarity between these two bases, as each of them may be made to yield derivatives of protocatechuic acid (Beckett a. Wright, *Chem. Soc. J.* xxviii. 703).

NARCOTINE, $\text{C}^{22}\text{H}^{29}\text{NO}^7$. Narcotine heated on the water-bath with excess of dilute sulphuric acid (equal volumes of H_2O and H^2SO^4) is converted into dimethylnornarcotine (vi. 863), according to the equation

The methylsulphuric acid formed at the same time is further resolved into sulphuric acid and methyl alcohol. The reaction takes place exactly in the manner above represented, if the heating be interrupted as soon as the mass becomes flesh-coloured. By further heating, a second, and perhaps also a third atom of methyl may be removed from the narcotine, but the product is always impure (Armstrong, *Chem. Soc. J.* xxiv. 56).

On the action of *hydrogen sulphide* on narcotine in alcoholic solution, see ALKALOIDS (p. 56).

Hydrochloride of Narcotine, like the corresponding narceine salt (p. 1379), becomes more basic the oftener it is recrystallised from hot water, the salts $5\text{C}^{22}\text{H}^{29}\text{NO}^7.\text{HCl}$, $7\text{C}^{22}\text{H}^{29}\text{NO}^7.\text{HCl}$, and $8\text{C}^{22}\text{H}^{29}\text{NO}^7.\text{HCl}$, being formed in succession (Beckett a. Wright, *Chem. Soc. J.* xxix. 164).

Oxidation-products of Narcotine.

Cotarnine, $C^{12}H^{18}NO^3$, and **Hydrocotarnine**, $C^{12}H^{18}NO^3$ (Beckett a. Wright, *Chem. Soc. J.* 1875, 573-585; 1876, i. 164-174, 281-309, and 461-474). Cotarnine prepared by oxidising narcotine with sulphuric acid and manganese dioxide, melted at 126° , and when crystallised from benzene was found to have exactly the composition $C^{12}H^{18}NO^3 \cdot H^2O$, the molecule of water not being separable without simultaneous decomposition of the base. The *platinochloride*, $(C^{12}H^{18}NO^3 \cdot HCl)^2PtCl^4$, may however be obtained anhydrous by prolonged desiccation over sulphuric acid.

Hydrocotarnine, first obtained by Hesse from the mother-liquors of the preparation of morphine by the Robertson-Gregory process (vii. 876), is also formed by the action of granulated zinc on cotarnine dissolved in dilute hydrochloric acid, the reaction being continued for several days, and the liquid all the time being kept slightly acid. The hydrocotarnine may then be separated by addition of excess of ammonia, and agitation with ether, from which it crystallises in prisms often an inch long. It dissolves easily also in alcohol and in benzene; melts at 55° when pure, at lower temperatures when impure (50° according to Hesse); gives off water of crystallisation at 60° , and then does not solidify till after some time. The base prepared as above gave with sulphuric acid the dirty red-violet coloration described by Hesse. Its solution in hydrochloric acid yielded on evaporation over sulphuric acid crystals having the composition $C^{12}H^{18}NO^3 \cdot HCl + H^2O$. Hesse found $1\frac{1}{2}H^2O$, probably because the last portions of water are somewhat obstinately retained, and can be driven off only by reducing the salt to fine powder and leaving it to stand for some time.

Hydrocotarnine may be prepared from all the solutions obtained in the purification of cotarnine, and directly from the crude cotarnine-solution filtered from the crystals of opianic acid formed at the same time. It is also formed, to the amount of 2 to 5 per cent., in the oxidation of narcotine: hence Beckett a. Wright regard it as an original product of the decomposition of narcotine, which is for the most part converted, by further oxidation, into cotarnine. It may in fact be converted into cotarnine by the action of ferric chloride, of potassium dichromate and sulphuric acid, or of manganese dioxide and sulphuric acid, the cotarnine obtained with the first of these reagents being very nearly pure.

Narcotine treated with *zinc and dilute hydrochloric acid* is completely converted into hydrocotarnine (m. p. $54^\circ-5$) and meconin, without any formation of opianic acid. Narcotine heated to boiling with a quantity of *baryta-water* sufficient to form a clear solution, gave off methylamine, and the solution was found to contain *meconin*, but no cotarnine, hydrocotarnine, or opianic acid. When narcotine was heated with water in sealed tubes to $140^\circ-150^\circ$, hydrocotarnine in small quantity could be detected if the heating had been continued only for 6 or 7 hours, but not a trace when the heating was prolonged for 21 to 28 hours. In the latter case 20 per cent. of meconin was obtained, and a smaller quantity after heating for a shorter time.

From these results Beckett a. Wright infer that the older equations

do not explain with sufficient simplicity the facts hitherto known, but that a much more satisfactory explanation is afforded by the equations proposed by Hesse, viz.:

The fact that Anderson, by acting on narcotine with nitric acid, obtained meconin, may be reconciled with the results above stated, if it be supposed that the meconin was formed from opianic acid, a reaction indeed actually observed by Matthiessen a. Foster:

Hydrocotarnine Ethiodide, $C^{12}H^{18}NO^3 \cdot C^2H^3I$, is formed by heating hydrocotarnine to 100° with excess of ethyl iodide and absolute alcohol, and crystallises from alcoholic solution on cooling in anhydrous white micaceous plates slightly soluble in water, more freely in alcohol, especially at the boiling heat. When agitated with water and

silver oxide, it yields an alkaline liquid which precipitates metallic salts, especially those of mercury and silver, rapidly absorbs carbonic acid from the air, and then yields on evaporation crystals of hydrocotarnine ethylecarbonate, $(C^{12}H^{15}NO^3.C^2H^3)^2CO^2 + 4H^2O$, which are soluble in water and in alcohol, but not in ether.

The ethioidide, agitated with water and recently precipitated silver chloride, is converted into the ethylochloride, $C^{12}H^{15}NO^3.C^2H^3Cl$, which forms feathery crystals, melts at 100° to a vitreous mass solidifying in the crystalline form on cooling, and yields a platinochloride, $(C^{12}H^{15}NO^3.C^2H^3Cl)^2PtCl^4$. The ethioidide is not altered by heating with excess of ethyl iodide.

Narcotine, heated as above with ethyl iodide and absolute alcohol, yields an amorphous, easily decomposable ethioidide, $C^{12}H^{15}NO^3.C^2H^3I$, convertible like the preceding into chlorine- and hydroxyl-compounds, which are also easily decomposable.

Cotarnine forms an amorphous very hygroscopic ethioidide, convertible into an amorphous hydroxyl-derivative. The corresponding ethylochloride and platinum salt are likewise amorphous.

Acetic anhydride does not act upon either narcotine, cotarnine, or hydrocotarnine.

Bromine-derivatives of Cotarnine and Hydrocotarnine (Wright, *Chem. Soc. J.* xxxii. 525).—Hydrocotarnine hydrobromide treated with bromine yields the following products of decomposition:—

1. $C^{12}H^{15}NO^3.HBr + Br^2 = HBr + C^{12}H^{14}BrNO^3.HBr$
Bromhydrocotarnine
hydrobromide.
2. $C^{12}H^{14}BrNO^3.HBr + Br^2 = 2HBr + C^{12}H^{12}Br^2NO^3.HBr$
Bromocotarnine
hydrobromide.
3. $C^{12}H^{12}Br^2NO^3.HBr + Br^2 = C^{12}H^{10}Br^3NO^3.HBr$
Tribromhydrocotarnine
hydrobromide.

The formation of the first two of these bodies is preceded by that of the unstable addition-products, $C^{12}H^{15}Br^2NO^3.HBr$ and $C^{12}H^{14}Br^2NO^3.HBr$. The third addition-product, tribromhydrocotarnine hydrobromide, forms well-defined permanent crystals.

Bromhydrocotarnine and bromocotarnine are similar in their general properties to hydrocotarnine and cotarnine respectively. The former is anhydrous, and melts at 76° ; the latter has the composition $C^{12}H^{12}BrNO^3 + H^2O$, and gives off its water at 100° with decomposition. Its hydrobromide, $C^{12}H^{13}BrNO^3.HBr + H^2O$, crystallises well, and dissolves easily in water. The hydrobromide of bromhydrocotarnine is anhydrous and sparingly soluble in water.

When bromocotarnine hydrobromide is heated above 200° it melts, gives off hydrogen bromide, and a combustible vapour (probably CH^3Br), and forms a small quantity of the bromide of a new base, $C^{11}H^8NO^3$, called tarconine, together with an indigo-blue substance which is the hydrobromide of the base $C^{10}H^{11}N^2O^4$. These two bases and their salts are insoluble in water, ether, alcohol, benzene, carbon sulphide, and petroleum, slightly soluble at the boiling heat in aniline and glacial acetic acid, with which they form dark blue solutions. Strong sulphuric acid dissolves them, forming with the latter the sulphate $(C^{10}H^{11}N^2O^4)^2H^2SO^4$, the solution of which has a colour like that of magenta, equally beautiful and possessing great tinctorial power.

Tribromhydrocotarnine Hydrobromide melts at 200° , and is at the same time resolved into hydrogen bromide, methyl bromide, and bromotarconine hydrobromide, as shown by the equation

Bromotarconine forms slender scarlet crystals, $C^{11}H^8BrNO^3.2H^2O$, which when heated to 100° give off their water and assume a crimson colour, and retain that colour if immediately recrystallised from perfectly anhydrous alcohol, but crystallise out with scarlet colour if the slightest trace of moisture is present. The salts of bromotarconine have a faint-yellow colour, crystallise well, and dissolve sparingly in cold water. The hydrobromide and hydrochloride crystallise each with $2H^2O$.

Cotarnine Hydrobromide, $C^{12}H^{15}NO^3.HBr + 2H^2O$, is very soluble in water, and forms with bromine the addition-product, *dibromhydrocotarnine hydrobromide*, $C^{12}H^{14}Br^2NO^3.HBr$, which, when further treated with bromine, yields tribromocotarnine hydrobromide identical with that which is formed from hydrocotarnine. By the action of water, dibromhydrocotarnine hydrobromide is resolved into hydrobromic acid and bromocotarnine hydrobromide. Bromocotarnine treated with zinc and hydrochloric acid takes up 2 at. hydrogen and is converted into bromhydrocotarnine, identical with that which is formed from hydrocotarnine.

Oxynarcotine, $C^{22}H^{23}NO^8 = N \equiv [C^{11}H^{11}(CH^3)O^3].CO.C^6H^2\left\{\begin{smallmatrix} COOH \\ (OCH^3)^2 \end{smallmatrix}\right\}$. This base, of which narcotine may be regarded as the aldehyde, was obtained by Beckett a. Wright (*Chem. Soc. J.* xxix, 461) from crystals which remained undissolved in the process of purifying narceine. It probably does not exist in opium ready-formed, but is formed from narcotine by the action of atmospheric oxygen. To purify it, the crude base is treated with the exact quantity of sulphuric acid required to dissolve it; the solution is treated with the exact quantity of caustic soda required to precipitate the base; the precipitated crystals, forming a mass very much like paper-pulp, are repeatedly boiled with water, which takes up admixed narceine and finally leaves sandy crystals which must be repeatedly boiled with alcohol; and the base thus far purified is finally converted into the hydrochloride, and precipitated in the pure state by addition of a slight excess of caustic potash. By applying the same treatment to the mother-liquors obtained in the separation by water, as above described, it is easy to effect the separation of the oxynarcotine from the narceine.

Oxynarcotine is but sparingly soluble in water and in alcohol even when hot, and nearly insoluble in benzene and in chloroform. It is precipitated from the solutions of its salts by the fixed alkalis and their carbonates, but redissolved by an excess of the precipitant. Its solution in hot hydrochloric acid yields soft crystals of the hydrochloride, $C^{22}H^{23}NO^8.HCl + 2H^2O$, which become anhydrous at 100° , and are resolved by boiling with water into basic salt and acid.

By oxidation with ferric chloride and other reagents, oxynarcotine is resolved into hydrocotarnine and hemipinic acid:

without formation of opianic acid. It is decomposed by heating with water in a sealed tube to 140° – 150° for 15 to 20 hours, but the product does not contain opianic acid, hemipinic acid, meconin, or any alkaloid soluble in ether (Beckett a. Wright).

Hemipinic and Opianic Acids. Orientation of Narcotine-derivatives.

Hemipinic acid, $C^{10}H^{10}O^6$, was obtained, together with meconin, by fusing opianic acid with three times its weight of potassium hydroxide, the two being separated by Matthiessen a. Foster's process (iii. 142). The meconin thus obtained fused at 102° – 102.5° . Crude hemipinic acid, partially purified by conversion into the lead salt, always contains small quantities of methylnormeconin, $C^9H^8O^4$, which gives a blue coloration with ferric chloride, and is difficult to separate by recrystallisation, but may be easily removed by oxidation with chromic acid mixture. Pure hemipinic acid may also be obtained by washing its ammonium salt, dried at 100° , with alcohol, dissolving it in hydrochloric acid, and extracting with ether. Hemipinic acid, heated for an hour to 180° and crystallised from alcohol, is converted into hemipinic anhydride, which forms shining needles melting at 166° – 167° (corr.). The acid containing methylnormeconin melts at 10° – 15° , and its anhydride at 6° – 7° . The ease with which hemipinic acid is converted into the anhydride points to the conclusion that it belongs to the phthalic series—in other words, that it is an ortho-compound.

Sodium hemipinate heated in a retort with twice its weight of *soda-lime* yielded, together with a watery distillate, a heavy oil boiling at first between 200° and 210° , but after two rectifications between 204° and 206° (corr.) This oil is identical in all its reactions with the dimethylpyrocatechin, $C^6H^4.OCH^3.OH$, which Marasse obtained from beech-tar creosote (vi. 504), and is resolved by heating with hydriodic acid into methyl iodide and pyrocatechin.

Hemipinic acid heated with six to seven times its weight of *potassium hydroxide* and a little water to 200° – 220° —the temperature rising in about fifteen minutes to 235° – 240° —is converted into protocatechuic acid, $C^6H^3(OH)^2.CO^2H + H^2O$ [$CO^2H : OH : OH = 1 : 3 : 4$]. Hence hemipinic acid may be regarded as carboxylated dimethylprotocatechuic acid, $C^6H^2(CO^2H)^2(OCH^3)^2$, in which the two carboxyl-groups are probably in the positions 1, 2, the methoxyl-groups in 3, 4 or 4, 5. By heating with *soda-lime*, it is converted into $2CO^2$ and $C^6H^4(OCH^3)^2$; by heating alone into the anhydride $C^6H^2(OCH^3)^2\left\{\begin{smallmatrix} CO \\ CO \end{smallmatrix}\right\} > O$; and by fusion with potassium hydroxide, into carbonic acid, protocatechuic acid, and methyl alcohol, which suffers further decomposition:

Hemipinic acid cautiously heated with *hydriodic acid* is converted into methyl-norhemipinic acid, $C^6H^8O^6 + 2H^2O$, which gives off its water at 100° , with partial decomposition. It is very unstable, as are also its salts; melts with decomposition at 150° – 155° , and is identical with Liechti's *isopinic acid* (vi. 882), to which however Liechti assigned a different formula.

Methylnorhemipinic acid, fused with potassium hydroxide at 240° , till a sample no longer gives a blue colour with ferric chloride, is converted into protocatechuic acid; when heated above its melting point, it gives off carbon dioxide; and when distilled with pumice-powder it yields methylprotocatechuic acid (m. p. 249° corr.), together with an oily substance, probably guaiacol. Methylnorhemipinic acid, heated for half an hour to 160° – 170° , yields an acid which may be purified by conversion into the ammonium salt, dissolves easily in hot, sparingly in cold water, is coloured blue-violet by ferric chloride, and is perhaps identical with Liechti's *opinic acid*. When heated with dilute hydrochloric or hydriodic acid, it yields methylprotocatechuic and protocatechuic acid.

Hemipinic acid, heated for ten hours with excess of strong hydrochloric acid, yields *monomethylprotocatechuic acid*, melting at 251° (corr.) (*comp.* Matthiessen a. Foster, *Chem. Soc. J.* xvi. 354). This acid yields a dimethyl-derivative which is identical with *dimethylprotocatechuic acid*, but, contrary to Kölle's statement (vii. 432), crystallises with 1 mol. H_2O .

Meconin, fused with potassium hydroxide, yields methylnormeconin, $\text{C}^9\text{H}^8\text{O}^4$, as an anhydrous crystalline body, which melts at 125° , and is turned blue by ferric chloride. The same compound is produced in like manner from narcotine. By further fusion with potash, it is converted with evolution of hydrogen into protocatechuic acid.

Meconin and methylnormeconin may be represented by the following formulæ:

Hypogallie acid is regarded by Beckett a. Wright as a mixture of opianic and hemipinic acids, probably with addition of protocatechuic acid (p. 1083).

Reactions of Opianic Acid.—Sodium opianate, mixed with soda-lime (caustic baryta yields a smaller product), dried at 130° – 140° , and distilled in a retort, yields, together with a watery distillate, a heavy oil, the portion of which boiling above 260° contains a fraction which passes over at 280° – 285° (uncorr.), and solidifies in a freezing mixture to a mass which melts at 41° . On one occasion, the whole of the crude products distilled over at 260° , but mostly the greater part passed over below 200° . The oil has the composition $\text{C}^9\text{H}^{10}\text{O}^3$, and agrees in all respects, except its melting point, with Tiemann's methyl-vanillin (p. 306). When heated with very dilute sulphuric acid, with gradual addition of potassium dichromate, it yielded a small quantity of an acid which melted at 171° , gave no colour-reaction with ferric chloride, and when heated to 220° with potassium hydroxide, was converted into an acid exhibiting the reactions of protocatechuic acid. This oxidation-product of methyl-vanillin is therefore doubtless dimethylprotocatechuic acid.

When methyl-vanillin is heated for ten hours with strong hydrochloric acid, methyl chloride is formed, and the liquid on cooling deposits a dark-coloured tar; and on dissolving this in ether, agitating the solution with caustic potash, separating the dark-coloured alkaline liquid, acidifying with hydrochloric acid, exhausting with fresh ether, and evaporating the ethereal solution, an oily residue is left, which on standing yields crystals having the composition $\text{C}^9\text{H}^8\text{O}^3$, smelling like vanilla, sparingly soluble in cold, easily in hot water, melting at 80° , and identical in every respect with Tiemann a. Haarmann's vanillin. The quantity of vanillin thus obtained is, however, very small, so that the preparation of this substance from opium is not likely to be successful as a commercial operation.

The formation of dimethyl-protocatechuic aldehyde by the action of heat on a mixture of sodium opianate and soda-lime shows that the COOH radicle eliminated from opianic acid by the action of soda-lime is in the same position as that removed from hemipinic acid by the action of caustic potash at 240° .

From the character of the alternative formulæ thus deducible for opianic acid, viz.:

it follows that narcotine must have one of the two structures :

the CO-group which links the benzene radicle to the cotarnine nucleus, corresponding in position with the CO.OH eliminated from opianic acid by soda-lime, and with that removed from hemipinic acid by heating with potash at 240°.

Opianic acid, treated with hydrochloric acid gas, is resolved, according to Matthiesen a. Foster (vi. 892), into methyl chloride and methylnoropianic acid, $\text{C}^8\text{H}^8\text{O}^3$, which, when distilled with soda-lime, might be expected to yield vanillin; experiment shows, however, that a more thorough decomposition takes place, the greater part of the opianic acid being completely charred.

Opianic acid, treated with a large quantity of *hydriodic acid*, yields nearly the theoretical amount of methyl iodide, in accordance with the equation :

The noropianic acid crystallises with $2\text{H}_2\text{O}$, and is isomeric with that obtained by Tiemann (*infra*).

Isopianic and Isohemipinic acids, and other acids related to them, isomeric with those just described as derived from narcotine, have been obtained by Tiemann a. Mendelsohn (*Deut. Chem. Ges. Ber.* x. 393), starting from aldehydovanillic acid, $\text{C}^9\text{H}^8\text{O}^5$, which, as already observed (p. 201), has the structure represented by the

formula $\text{C}^9\text{H}^8\text{H.OCH}^3\text{OH.CO.H.H}$. The acids thus obtained belong to the isophthalic series; those obtained from narcotine, to the phthalic series. With regard to aldehydovanillic or methylnorisopianic acid, Tiemann a. Mendelsohn observe that its aqueous solution does not reduce either silver nitrate or Fehling's solution at the boiling heat. It forms two series of salts. The *potassium, sodium, and ammonium* salts are soluble in water, the solution having a characteristic yellow colour. From a strongly ammoniacal solution of the acid, barium and calcium chlorides throw down slightly soluble (possibly basic) *barium* and *calcium salts*; and the acid, neutralised with ammonia, forms with silver nitrate a yellowish-white *silver salt*; with cupric sulphate, a green *copper salt*, soluble with green colour in excess of ammonia. A crystalline *lead salt* is precipitated from the aqueous solution of the acid by lead acetate, the precipitate increasing on addition of ammonia.

The mono- and di-methylic ethers of methylnorisopianic acid are formed simultaneously by digesting 1 mol. of the acid at 100° with 2 mols. KHO, methyl alcohol, and excess of methyl iodide, and may be separated from one another by agitating their ethereal solution with a very dilute alkaline ley. The monomethylic ether or *methylic methylnorisopianate*, $\text{C}^8\text{H}^7(\text{COH})(\text{OH})(\text{OCH}^3)(\text{COOCH}^3)$, is precipitated from the alkaline solution on acidulation in flocks of yellow needles, which, after recrystallisation from water, melt at 134°–135°, and dissolve in solution of sodium carbonate, but without evolution of carbon dioxide. The dimethylic ether or *methyl isopianate*, $\text{C}^8\text{H}^6(\text{COH})(\text{OCH}^3)^2(\text{COOCH}^3)$, is obtained by spontaneous evaporation of the ethereal solution, in the form of an oil, which soon solidifies to a crystalline mass. When recrystallised from boiling water, in which it is but slightly soluble, it forms slender, white felted needles, having a characteristic aromatic odour, and melting at 98°–99°.

Isopianic acid, $\text{C}^8\text{H}^7(\text{COH})(\text{OCH}^3)^2(\text{COOH})$, obtained from the dimethylic ether by boiling with alkalis, crystallises from boiling water in slender white needles, melting at 210°–211° (uncorr.), and dissolves readily in alcohol and in ether. In strong sulphuric acid it dissolves with deep yellow colour, in alkalis without coloration: no colour-reaction with ferric chloride. With *sodium bisulphite* it forms a sparingly soluble compound. The isopianates of ammonia and the fixed alkalis are easily soluble in water. The solution of the ammonium salt is not precipitated by chloride of barium or calcium. Cupric sulphate precipitates from it a bluish-white *copper salt*, soluble with blue colour in excess of ammonia; lead acetate forms a sparingly soluble *lead salt*; silver nitrate, a white *silver salt*, which may be crystallised from hot water

without decomposition. By oxidation with dilute solution of potassium permanganate, at 70°, isopianic acid is converted into isohemipinic acid (*infra*).

Isonoropianic or *Aldehydoprotocatechuic acid*, $C^6H^2(COH)(OH)^2COOH$, is produced by heating aldehydovanillic acid with dilute hydrochloric acid to 170°–180°, and crystallises from hot water in yellowish needles, which melt at a temperature above 240°, dissolve without much difficulty in cold water, easily in hot water, alcohol, and ether. The aqueous solution, mixed with an alkali, immediately turns yellow, and after long standing or after heating, reddish-yellow; with ferric chloride it produces a dark-green colour, suddenly changing to reddish-violet on addition of alkalis. It reduces Fehling's solution at the boiling heat; silver nitrate only on addition of ammonia. Hence it follows that isonoropianic acid is not identical, but isomeric, with Hlasiwetz's quercimeric acid (v. 5).

Isohemipinic acid, $C^6H^2(OCH^3)^2(COOH)^2$, formed, as above mentioned, by oxidising isopianic acid with a dilute solution (1 : 5) of potassium permanganate at 70°, crystallises from hot water in white needles which dissolve easily in alcohol and ether, without much difficulty in hot water, but are nearly insoluble in cold water. It melts at 245°–246°, and sublimes at a higher temperature without formation of anhydride. It is bibasic. The *potassium, sodium, ammonium, barium, and calcium* salts are easily soluble and crystallise well. The ammonia salt, neutralised with an acid, yields with copper sulphate, a bluish-white *copper salt*, with lead acetate, a white *lead salt*, and with silver nitrate, a white *silver salt* which dissolves in hot water without alteration (Tiemann & Mendelsohn).

NATROLITE. See ZEOLITES.

NECTAR. This name is applied to the sweet-tasting fluid secreted within the cups of insect-fertilised flowers. On the amounts of cane- and fruit-sugar contained in the nectar of various flowers, see A. S. Wilson (*Chem. News*, xxxviii. 93; *Chem. Soc. J.* xxxiv. 997).

NEFIEDEWITE. This name is given by P. Pusirewsky (*Jahrb. f. Min.* 1873, 420) to a white to rose-red amorphous substance resembling lithomarge, occurring, together with fluor spar, in limestone at Nertschinsk in Siberia. Hardness = 1·5. Sp. gr. = 2·335 at 18°. The substance gives off 11·13 per cent. water over sulphuric acid, 19·13 at 250°, and 4·73 at a still higher temperature. A certain proportion of it (0·2 per cent.) dissolves in water with alkaline reaction (Na^2O), and may be regarded as an admixture. Pusirewsky assigns to this substance the formula $H^1MgAl^1Si^2O^{16}$, but the analyses from which he deduces this formula differ considerably from one another.

NEGRO COFFEE. The seeds of *Cassia occidentalis*, from the French colonies in Africa, are known by this name. According to an analysis by J. Clouet (*Pharm. J. Trans.* [3], vi. 909) they contain in 100 pts.:

Fat (Olein and Margarin)	4·9
Tannic acid	0·9
Gum	28·8
Sugar	2·1
Starch	2·0
Cellulose	34·0
Water	7·0
Calcium sulphate and phosphate, Chrysophanic acid	0·9
Malic acid, Sodium chloride, Magnesium sulphate, Iron,	
Silica	5·4
Achrosin	13·58

Achrosin, perhaps a mixture of several substances, is extracted from the seeds by alcohol. The seeds have a purgative action, and are used as a remedy for fever. They lose their purgative properties by roasting, and an infusion of the roasted seeds smells and tastes like one of roasted coffee-beans.

NEOCHRY SOLITE. A mineral found in the cavities of the Vesuvian lava of 1631. It is crystallographically identical with olivine, and differs from it chemically only by its higher amounts of iron and manganese, which replace nearly the whole of the magnesium (A. Scacchi, *Zeitschr. Kryst.* ii. 104).

NEOGEN. An alloy containing:

Cu	Zn	Ni	Sn	Al	Bi
58	27	12	2	0·5	0·5 = 100

To prepare it the constituent metals are separately fused and very carefully trituated together (Saurage, *Dingl. pol. J.* ccxv. 377).

NEOLITE. According to Frenzel (*Jahrb. f. Min.* 1874, 676) the crust of the Freiberg pseudomorphs of iron pyrites and magnetic pyrites is a mineral nearly related to neolite, and having the composition A. The values B are calculated from the formula $4\text{FeO} \cdot \text{SiO}_2 + \text{Al}_2\text{O}_3 \cdot \text{SiO}_2 + 3\text{H}_2\text{O}$:

SiO_2	Al_2O_3	Fe_2O_3	FeO	MnO	CaO	MgO	H_2O	
22.28	16.82	2.44	41.19	4.23	1.82	1.31	8.88	= 98.97
21.25	18.20	—	50.99	—	—	—	9.56	= 100

NEPHELIN. On nephelin from Latium, J. Strüver (*Zeitschr. Kryst.* i. 240) observed the forms 0P , ∞P , ∞P_2 , ∞P_3 , $\frac{1}{2}\text{P}$, 2P , 2P_2 . The measurements agreed well with those of nephelin from Somma (iv. 31). The crystals, which are mostly colourless, white, or grey, rarely green or flesh-coloured, occur in geodes of the lavas and ejected blocks.

Rammelsberg (*Berl. Akad. Ber.* 1876, 695) discusses the chemical constitution of nephelin on the basis of new analyses (1–4) of Vesuvian nephelin, the only material sufficiently definite in composition to be available for the decision of the question. He assumes the formula $\text{R}^2(\text{Al}^3)_2\text{Si}^2\text{O}^{26}$, which, accordingly as $\text{K} : \text{Na} = 1 : 5$ or $1 : 6$, gives the values (5) or (6) (*infra*), the lime present being attributed to admixture of augite and garnet. According to this, nephelin should be represented by the formula:

For $\text{K} : \text{Na} = 1 : 5$, the formula of nephelin may also be written in the form:

the first member of which is the silicate occurring in sodalite, &c., and the second leucite:

	SiO_2	Al_2O_3	Na_2O	K_2O	CaO	Total	Sp. gr.
1 (found)	44.77	34.94	15.33	4.47	0.50	100.01	2.600
2 „	44.88	34.37	15.40	4.87	0.54	100.06	to
3 „	44.63	34.39	15.31	4.93	0.67	99.93	
4 „	45.65	34.27	16.35	4.32	trace	100.59	2.6087
5 (calc.)	45.17	33.10	16.67	5.06	—	100

See also H. Rauff (*Jahrb. f. Min.* 1878, 745; *Chem. Soc. J.* xxxvi. 606).

For distinguishing between nephelin and apatite in a microscopic section of a rock, the following reactions are given by A. Streng (*Jahrb. f. Min.* 1877, 94): Nephelin is decomposed by very strong hydrochloric acid, the cavities of the etched crystals becoming gradually filled with cubes of sodium chloride; apatite, treated with a concentrated solution of ammonium molybdate in nitric acid, yields small yellow octohedrons and rhombic dodecahedrons, which spread over the entire field of view, excepting the part occupied by the apatite itself, at which the reaction is prevented by the excess of phosphoric acid present.

Nephelin picrite is the name given by E. Boricky (*Jahrb. f. Min.* 1877, 539) to a rock from the Devine near Wartenberg in Bohemia, distinguished from Tschermak's picrite by the constant presence of nephelin and perowskite, the latter mineral forming sharp-edged crystals, 0.01 to 0.02 mm. in diameter.

On the nephelin-rock of Meiches in the Odenwald, see v. Klipstein (*Jahrb. f. Min.* 1878, 722; *Chem. Soc. J.* xxxvi. 607).

NEPHRITE. Four nephrites, collected by H. v. Schlagintweit in Central Asia, have been analysed by L. R. v. Fellenberg (*Münch. Akad. Ber.* iii. 277). They were found imbedded in gneiss in clefts in the neighbourhood of Gulbâshên, a halting place on the right side of the river Karkâsh, in the Künlün range, lat. $36^\circ 13' \text{N}$, long. $78^\circ 15' \text{E}$. of Greenwich, at a height of 3725 met.:

	SiO_2	Al_2O_3	Fe_2O_3	FeO	MnO	CaO	MgO	K_2O	SiF_4	H_2O	
1.	59.30	0.53	—	0.70	0.55	10.47	25.64	1.02	1.28	0.82	= 100.11
2.	59.50	0.75	—	1.35	0.79	11.60	24.24	1.57	—	0.85	= 100.65
3.	58.42	0.70	—	0.67	0.46	13.85	24.39	0.10	0.60	1.20	= 100.39
4.	59.21	0.50	0.34	0.97	0.53	14.61	23.55	0.19	—	0.78	= 100.68

Sp. gr. of 1 = 2.972 at 4.4° ; of 2 = 2.957 at 7.5° ; of 3 = 2.980 at 17° ; of 4 = 2.974 at 20° .

The analyses give, for silica = SiO_2 , values comprised between the limits:

$$\text{SiO}_2 : \text{MgO} : \text{CaO} = 3 : 3 : 1 \text{ and } 10 : 10 : 4.$$

These nephrites, when first removed from the bed, are soft enough to be easily worked, whereas older specimens have a hardness of 6.5.

H. Fisher (*Min. Mitth.* 1873, 155) describes the breaking up of a refractory block of nephrite by ignition and rapid cooling, and is of opinion that this mode of treatment, which is known to be adopted for the disintegration of other hard minerals, may throw light on the working of nephrite in prehistoric times.

NEPTUNIUM. See NIUBIUM.

NEURINE. According to J. Mauthner (*Liebig's Annalen*, clxxv. 178) an aqueous solution of neurine dissolves blood-fibrin to a clear liquid which does not blacken lead acetate, is not precipitated by alcohol, but yields a precipitate of fibrin on gradual addition of an acid. On the putrefactive decomposition of neurine in the bile, see p. 324.

NICKEL. *Occurrence.*—Metallic nickel occurs to the amount of 0.75 per cent. in the magnetic platinum ore of Nischne-Tagilsk in the Ural (Terreil, *Compt. rend.* lxxxii. 1116).

On the sulphide of nickel and iron, $4\text{Fe}^2\text{S}^3.\text{Ni}^2\text{S}^3$, occurring at Horbach in the Schwarzwald, see HORBACHITE (p. 1041).

Statistical reports of the extraction of nickel from its ores in Europe and America are given in the *Hannoversches Wochenblatt für Handel und Gewerbe*, 1873, No. 36; *Dingl. pol. J.* ccx. 75; *Jahresb. f. Chem.* 1873, 994. On the Metallurgy of Nickel, see also Lundborg (*Dingl. pol. J.* cccxvi. 643).

Coating of other Metals with Nickel.—Electrodeposition.—A nickel-bath, much used for this purpose in France, is prepared by dissolving 4 pts. nickel nitrate in 4 pts. aqueous ammonia and 150 pts. water holding in solution 50 pts. acid sodium sulphite. With the aid of a very feeble current, the deposition is completed in a few minutes. There is no necessity for interrupting the process in order to clean the surface and thereby insure the desired thickness of the deposit, the nickelled objects merely requiring to be dried in sawdust (Boden, *Dingl. pol. J.* ccxvii. 256). Another nickel-bath consists of 87.5 pts. nickel sulphate, 20 ammonium sulphate, 17.5 nitric acid and 2 litres of water (Hesse, *ibid.*) Martin a. Delamotte dissolve 1250 grams of citric acid, 500 sal-ammoniac (or ammonium sulphate), and 500 ammonium nitrate in 15 litres of water; heat the solution to 80°C . and saturate it gradually with recently precipitated nickel hydrate; then add 2.5 litres of aqueous ammonia; dilute to 25 litres; and after cooling, add 500 grams of ammonium carbonate; leave the precipitate to settle, and filter the liquid. The solution thus obtained contains about 50 grams of nickel in the litre, and has a density of 11°B . The nickel may be conveniently precipitated from it at 50° . The addition of potash or soda renders it possible to obtain thicker electro-deposits of nickel. See also O. Silvestri (*Ber.* x. 889) and A. Kayser (*Chem. Centr.* 1878, 127; *Chem. Soc. J.* xxxiv. 537).

On the coating of Iron with Nickel, see p. 1118.

Malleable Nickel.—The addition of magnesium in the proportion of $\frac{1}{3}$ per cent. to nickel or cobalt renders the metal malleable and ductile, and susceptible of a high polish. The alloy does not alter in the air, and is well fitted for making harness, &c. It can be welded to iron or steel at a white heat, and rolled into thin plates without separating therefrom. It is prepared by dropping the magnesium through a hole in the cover of a crucible in which the nickel or cobalt is heated, a few pieces of charcoal having been previously introduced to remove oxygen (J. Fleitmann, *Ber.* xii. 454).

On the Magnetic relations of Nickel, see MAGNETISM (p. 1248).

On the Manufacture of large Castings of Nickel, see Winckler (*Dingl. pol. J.* cccxii. 175; *Chem. Soc. J.* xxxi. 238).

Detection.—To distinguish between nickel, cobalt, manganese, and zinc, A. H. Allen (*Chem. News*, xxiii. 290) adds potassium ferricyanide in excess to an ammoniacal solution of the metal containing ammonium chloride. Manganese then gives a brown precipitate; cobalt, dark red; nickel, copper-red in a hot solution, no precipitate in the cold; zinc, no precipitate either in hot or in cold solution.

R. H. Davies (*ibid.* xxxii. 44) modifies this method by adding ferrocyanide as well as ferricyanide of potassium, or the ferrocyanide alone. On adding the ferricyanide to a solution of nickel and cobalt till the resulting precipitate is redissolved, and then the ferrocyanide, a precipitate of nickel ferrocyanide is obtained, especially if the ammonia has previously been partly neutralised by a few drops of hydrochloric acid. The cobalt being more soluble is not thrown down till a larger quantity of acid has been added, whereupon the red-brown colour of the solution disappears, and a yellowish-white precipitate of cobalt ferrocyanide is produced. The same result is obtained when ferrocyanide alone is employed. Nickel may also be easily recognised by the greenish colour produced on adding the ferrocyanide to its solution, even when

extremely dilute, this colour being very different from that which is produced in like manner by traces of ferrous salts.

Estimation by Electrolysis (A. Riche, *Ann. Chim. Phys.* [5], xiii. 508).—Nickel may be rapidly and accurately estimated by decomposing its salts either in an acid or in an alkaline solution, and weighing the precipitated metal. The apparatus used consists of a platinum crucible in which is suspended a hollow truncated cone of platinum with small openings in the side: this cone serves as the negative pole, the crucible forming the positive pole. The decomposition may take place at the ordinary or at a higher or lower temperature. From a solution slightly acidulated with sulphuric acid at 60°–80° nickel may be precipitated by a current of two Bunsen's cells. The precipitation is generally complete the first time, but to ensure accuracy, it is always advisable to subject the solution to the current a second time.

The same method may be applied to the analysis of alloys of nickel.

Nickel and Copper.—Only the copper is deposited when an acid (sulphuric or nitric acid) solution is subjected to the action of one Bunsen's element; the solution containing the nickel is made alkaline with ammonia, and then slightly acid; on passing the current the nickel is deposited.

Nickel and Lead.—The lead is first precipitated as dioxide from a nitric acid solution by means of a Leclanché's element, and the nickel is determined afterwards.

Nickel and Manganese.—The nickel is completely precipitated on the negative pole when a current is passed through an acid (sulphuric acid) solution, and may be washed and weighed. The action is then continued, if necessary, until the manganese is completely precipitated as dioxide on the positive pole.

Nickel and Magnesium.—The separation is effected in a solution made acid with sulphuric acid.

G. P. Schweder (*Zeitschr. anal. Chem.* 1877, 344) recommends that the nickel be precipitated by a powerful current from a strongly ammoniacal solution not containing much sal-ammoniac—iron, if present, having been previously precipitated as basic ferric sulphate.

On the analysis of Nickel Coins by the Electrolytic method, see E. Busse (*Zeitschr. anal. Chem.* xvii. 53; *Chem. Soc. J.* xxxiv. 338).

Estimation of Nickel in Pyrrhotites and Mattes.—The following method of determining nickel in these substances is based upon the fact that nickel phosphate is completely soluble, while phosphate of iron is almost insoluble, in acetic acid in the presence of an excess of sodium phosphate.

The ore is dissolved in hydrochloric acid, with addition of a little nitric acid; the solution is treated with hydrogen sulphide and filtered; the filtrate boiled; the iron oxidised with nitric acid; and ammonia is added until a permanent precipitate begins to form. Acetic acid is then added until the precipitate is redissolved. To this boiling hot solution a hot concentrated solution of ordinary sodium phosphate is added in excess, and the nearly white precipitate is filtered off and washed with hot water containing acetic acid. The filtrate is heated nearly to boiling, and caustic potash added until the odour of ammonia is distinctly perceptible. The apple-green precipitate of nickel phosphate is partially washed and dissolved in a little dilute sulphuric acid; the solution rendered strongly alkaline by ammonia; and the nickel precipitated by the battery. If more than 3 per cent. of nickel is present, the precipitate of iron phosphate must be redissolved and treated as before, as it may contain a little nickel (Margaret S. Cheney a. Ellen S. Richards, *Sill. Am. J.* [3], xiv. 178).

Separation of Nickel from other Metals.—Wöhler's method of separating nickel (and cobalt) from arsenic, without the use of hydrogen sulphide, has already been described under COBALT (p. 541); also Phipson's method, which consists in precipitating the two metals together as xanthates, and dissolving up the nickel salt with dilute ammonia. According to A. Guyard (*Chem. News*, xxxiv. 255), recently precipitated nickel sulphide dissolves very readily in very dilute solutions of *alkaline cyanides*, whereas cobalt sulphide does not, so that this reaction may be used for the quantitative separation of the two metals. For this purpose, the recently precipitated sulphides are suspended in water, and a very dilute solution of potassium cyanide is added in slight excess. The whole of the nickel then remains in solution, and may be precipitated as cyanide by dilute sulphuric or hydrochloric acid. The insoluble cobalt sulphide, after filtration and washing, is perfectly pure.

From iron, in the form of ferric salt, nickel may be separated by adding to the solution a quantity of ammonia not sufficient to precipitate all the iron as ferric oxide, and then *acetic acid*. From the clear solution thus obtained, the whole of the iron may be precipitated by sodium phosphate, and the nickel estimated in the filtrate (M. S. Cheney a. E. S. Richards, *Sill. Am. J.* [3], xiv. 178).

From zinc, nickel may be separated by evaporating the solution mixed with *sal-ammoniac* to dryness, and gradually heating the residue till all the *sal-ammoniac* and all the zinc chloride are volatilised. No loss of nickel is likely to occur (R. Fresenius, *Zeitschr. anal. Chem.* 1873, 66).

Compounds of Nickel.

Nickel may be *amalgamated* in the same way as iron (p. 1097), namely, by placing it, together with some pieces of zinc, in contact with mercury covered with dilute sulphuric or hydrochloric acid (Casamajor).

According to W. A. Ross (*Chem. News*, xxxiv, 150), melting nickel is capable of taking up a large quantity of *silver*, whereas melting silver does not unite with nickel. This difference perhaps depends upon the difference of the melting points of the two metals.

Nickel Arsenide, Ni^3As^2 , obtained by reduction of the arsenate, is a crystalline substance, having a metallic lustre and sp. gr. = 7.71. By fusing with boric oxide, it is converted into Ni^2As , or Ni^3As^2 , which can also be prepared by fusing together a mixture of potassium cyanide, metallic arsenic, and nickel oxide (A. Descamps, *Compt. rend.* lxxxvi, 1065).

Combination with Carbon and Silicon.—According to W. E. Gard (*Sill. Am. J.* [3], xiv, 274), commercial nickel always contains appreciable quantities of carbon and silicon, the latter being probably derived from silica in the charcoal by which the nickel is reduced, or from the crucible. Pure nickel oxide, mixed with half its weight of finely pounded quartz and heated to fusion with charcoal, yielded a white non-metallic regulus of sp. gr. 7.73, and containing 9 to 9.5 per cent. carbon and 6 to 6.2 per cent. silicon. In another experiment, half a pound of granulated commercial nickel was slowly heated to fusion between two layers of charcoal. The metal thus obtained was strongly magnetic, soft, malleable to a certain degree, had a density of 8.04, and contained 2.105 p.c. carbon, of which 2.03 was in the form of graphite, and 0.36 silicon. Nickel and cobalt heated to redness in a stream of *marsh gas* increased perceptibly in weight without exhibiting any actual deposition of carbon: hence it would appear that the carbon entered into chemical combination with the metal. [May not the increase in weight have been due, at least in part, to occluded hydrogen?]

Experiments have also been made by Boussingault (*Compt. rend.* lxxxvi, 509) with the view of ascertaining whether nickel acquires by carburisation and tempering the same properties as iron. To determine whether nickel, like iron, takes up carbon by cementation, a plate of nickel was exposed in a cementation furnace from April 25 till March 17; when put in it contained no carbon, but small quantities of iron, arsenic, and copper; when taken out it was perfectly clean, showing no blisters, and possessing the same hardness as before. The plate weighed before cementation 1384 grams; after 1389.25, having gained 5.25, and contained .004 of combined carbon, without a trace of graphite. After being again cemented in a box of sheet iron filled with carbon, it was found by analysis to contain .006 of carbon, which is about the same proportion as in soft steel. By fusing this metal in a crucible lined with charcoal, a button was obtained, containing .0080 of combined carbon, and .0165 graphite; total carbon, .0245. Notwithstanding this high carburisation, corresponding to hard steel, the nickel had the same appearance and ductility as before fusion. It is remarkable that the whole carbon taken up by the metal in this last operation was in the state of graphite. A small bar of forged nickel was also cemented, when it contained 98.29 per cent. of nickel, and 0.85 of combined carbon, besides small quantities of iron and silicon. The bar was placed in a clay crucible, surrounded with carbon, and exposed in the hottest part of a cementation furnace for a month; before cementation it weighed 201.907 grams, afterwards 201.857; it therefore lost .050 gram, but notwithstanding this, .504 grams combined carbon, and .303 graphite were taken up. The carbon was in the same form as in tool steel; the bar showed no sign of blistering; it had kept its colour, density, ductility, and softness. From these experiments it would appear that, although nickel combines with carbon, it does not thereby acquire steel-like properties.

On the *Ferrocyanides of Nickel* according to Wytroboff, see CYANIDES (p. 612).

Fluoride, $\text{NiF}^2 \cdot 3\text{H}^2\text{O}$. See FLUORIDES (p. 799).

Mercaptide, $\text{N}(\text{S} \cdot \text{C}^2\text{H}^3)^2$. See MERCAPTIDES (p. 1276).

Oxides. An oxide, Ni^2O^4 , analogous to magnetic iron oxide, is formed by passing oxygen over nickel chloride heated to 350° – 440° , the product assuming a blackish colour and giving off chlorine. The change is more quickly effected by moist oxygen, the chlorine being then eliminated in the form of hydrochloric acid, and the chloride being completely transformed in a few hours into a greyish oxide having a metallic aspect, and exhibiting under the microscope crystals having the form of spinel. The

oxide thus formed has no magnetic properties, and is not even attracted by the magnet. It dissolves in hydrochloric acid with evolution of chlorine. When very strongly heated, it gives off 6.6 per cent. oxygen, and is converted into the monoxide NiO, which, when thus prepared, is no longer capable of taking up oxygen and passing to a higher state of oxidation, wherein may be seen an explanation of the well-known fact, that nickel and its salts, when oxidised at high temperatures, never yield an oxide higher than the monoxide (A. Baubigny, *Compt. rend.* lxxxvii. 1082).

A higher oxide, Ni^2O^3 , is precipitated when a solution of a nickel salt mixed with excess of soda is oxidised by sodium hypochlorite. It is very unstable, beginning to decompose as soon as the liquid from which it has been precipitated is decanted off; and when dried in a vacuum over sulphuric acid, it leaves a residue having the composition $\text{Ni}^2\text{O}^{11} \cdot 9\text{H}^2\text{O}$. When the liquid decanted from the oxide Ni^2O^3 is boiled, the salt contained in it is decomposed without formation of stable lower oxides (T. Bayley, *Chem. News*, xxxix, 81).*

A hydrated oxide of nickel and cobalt, called heubachite, is found in thin soot-like deposits, or in the form of dendritic foil and fine globular masses, on clefts in baryta at the St. Anton Mine in the Heubachthal near Wittichen (p. 1029).

A phosphide, Ni^2P^2 , has been prepared by R. Schenk in the same manner as the corresponding iron phosphide. See PHOSPHIDES (vii. 950).

Salts. The following method of preparing pure nickel salts from the commercial metal is given by A. Terreil (*Compt. rend.* lxxix. 1495). The metal, usually containing copper, iron, and small quantities of arsenic, is dissolved in 7 or 8 pts. of aqua regia, the solution is evaporated to dryness, and the residue extracted with water. The solution is then filtered from insoluble iron arsenate, and the filtrate is treated with metallic iron, on which the whole of the copper is immediately deposited. The dissolved iron is then brought to the state of ferric salt by means of chlorine or nitric acid, and the solution is mixed with a quantity of sulphuric acid sufficient to convert all the iron and nickel into sulphates. The hydrochloric acid is next expelled by evaporation to dryness, the residue is redissolved in water, and the iron precipitated at the boiling heat by barium carbonate, which at the same time throws down the last traces of arsenic. The filtrate now contains nothing but nickel sulphate, which by evaporation to dryness may be obtained in a state of perfect purity.

A hydrated nickel-magnesium silicate, from Nouméa, the capital of New Caledonia, examined by A. Liversidge (*Chem. Soc. J.* 1874, 613), occurs, together with chrome-iron ore and steatite, on veins of serpentine, and is traversed by veins of a white silicate, so that it lies in the network like honey in the comb. It has an apple-green colour, is unctuous to the touch, cleaves to the tongue, and splits into small pieces under water. Hardness = 2.5 to 3. The following analyses lead to the formula $10(\text{NiO}, \text{MgO}) \cdot 8\text{SiO}^2 \cdot 3\text{H}^2\text{O}$:

SiO^2	$\text{Al}^2\text{O}^3, \text{Fe}^2\text{O}^3$	NiO	MgO	CaO	H^2O
47.276	1.560	23.960	21.583	trace	5.212 = 99.591
47.197	1.776	24.060	21.738	trace	5.320 = 100.091

NICOTINE, $\text{C}^8\text{H}^7\text{N}$ or $\text{C}^{10}\text{H}^{14}\text{N}^2$. *Occurrence.*—Heubel maintains—contrary to the statements of Vohl a. Eulenberg (vii. 851)—that nicotine is present in tobacco smoke, in the form of a salt which, at high temperatures, is more stable than the base itself. He states that he has detected it both by chemical and by physiological experiments (*Dingl. pol. J.* ccvii. 343). According to Preobraschensky (*Russ. Zeitschr. Pharm.* 1876, 705), Indian hemp contains an alkaloid closely resembling nicotine.

Preparation.—W. Kirchmann (*Arch. Pharm.* [3], ix. 209) prepares nicotine by distilling tobacco moistened with solution of sodium carbonate from a tinplate vessel on the water-bath, in a current of carbon dioxide, and collects the alkaloid which passes over in alcohol mixed with sulphuric acid. The colourless solution thus obtained is evaporated to dryness with caustic baryta, and the alkaloid is extracted from the residue by ether.

On the reaction of Nicotine with hydrogen sulphide, see ALKALOIDS (p. 56). On its detection in a mixture of alkaloids, see PLANT-BASES. For the volumetric estimation of nicotine, Zinoffsky adopts the same process as for emetine (p. 732), the number of cubic centimeters of the reagent used being, however, multiplied by 0.00405, instead of 0.189.

* The cobalt oxide, Co^2O^3 , is formed in the same manner as the corresponding nickel oxide, and is somewhat more stable than the latter. When the liquid in which it is formed is boiled, the salt contained in it is decomposed, with evolution of oxygen, and formation of the oxide $\text{Co}^{12}\text{O}^{13}$, intermediate between Co^2O^3 and Co^3O^4 . The oxides Co^2O^3 and $\text{Co}^{12}\text{O}^{13}$ appear to be stable at a low red heat. The following hydrates of the former have been prepared: $\text{Co}^2\text{O}^3 + 4\text{H}^2\text{O}$, dried over sulphuric acid; $\text{Co}^2\text{O}^3 + 3\text{H}^2\text{O}$ at 100° ; $\text{Co}^2\text{O}^3 + 2\text{H}^2\text{O}$ at 138° , and probably $\text{Co}^2\text{O}^3 + \text{H}^2\text{O}$ at 300° (Bayley).

A concentrated acid solution of nicotine sulphate, saturated with aluminium hydroxide, deposits octohedral crystals of nicotine-alum (Kirchmann).

Oxidation.—When pure nicotine, boiling at 240° – 242° (uncorr.; thermometer in vapour) is oxidised by potassium permanganate, added as long as it is decolorised, (10 grams nicotine in 500 c.c. of water require about 60 grams of permanganate dissolved in 2000 c.c. of water), it yields carbonate and *pyridine-carboxylate* of potassium. Free pyridine-carboxylic acid, $C^6H^5NO_2$, or $C^6H^5N.COOH$, is obtained by filtering the solution from manganese dioxide, evaporating to dryness, taking up with alcohol, converting the dissolved potassium salt into silver salt, and decomposing it with sulphuretted hydrogen. After crystallisation from hot alcohol or water, it forms colourless crystals, melting at 225° – 227° (uncorr.), and only sparingly soluble in ether and chloroform. This compound unites both with acids and with bases. Its *platinichloride*, $(C^6H^5NO_2)^2 \cdot 2HCl.PtCl^4 + 2H^2O$, forms large well-defined crystals which give off their water at 115° . The *potassium salt*, $C^6H^5KNO_2$, is anhydrous; the *calcium salt*, $(C^6H^5NO_2)^2Ca + 5H^2O$, is obtained by slow evaporation of the aqueous solution in large crystals which effloresce slowly at ordinary temperatures, and give off the whole of their water at 115° . The *silver salt* has a constant composition only after recrystallisation from hot water. The salts distilled with lime yield a large quantity of pyridine.

Pyridine-carboxylic acid is identical with the *nicotinic acid* which Huber obtained (vii. 866) by oxidising nicotine with chromic acid mixture (Laiblin, *Deut. Chem. Ges. Ber.* x. 2136). Its formation from nicotine shows that this base may be regarded as dipyridine, $C^{10}H^{10}N^2 + 4$ atoms of hydrogen (Cahours a. Etard).

Action of Sulphur.—When 100 parts of nicotine were heated to 140° with 20 pts. of sulphur, hydrogen sulphide was evolved, and continued to escape as the temperature rose to 155° . At 160° – 170° , the highest temperature attained, the perfectly fluid mass assumed a chrome-green colour; and when left at rest for some days, deposited yellow prismatic crystals, which, after being purified by washing with cold alcohol, and then recrystallised from boiling alcohol, had the composition $C^{20}H^{18}N^4S$. These crystals are of a sulphur-yellow colour, slightly soluble in cold, but readily in hot alcohol, insoluble in water, slightly soluble in benzene, and still less so in ether. They melt at 155° , and on cooling form a resinous yellow mass, which, when subjected to dry distillation, evolves sulphuretted hydrogen, whilst carbon is deposited, and a small quantity of a volatile oil distils over.

The compound $C^{20}H^{18}N^4S$ has a perfectly neutral reaction, but nevertheless forms definite salts with acids. The *hydrochloride*, $C^{20}H^{18}N^4S \cdot 2HCl$, crystallises in fine golden yellow needles. The *sulphate* has not yet been obtained in a definite crystalline form. In solutions of the hydrochloride, *platinum tetrachloride* gives an amorphous yellow precipitate of the salt $C^{20}H^{18}N^4S \cdot 2HCl.PtCl^4$. *Mercuric chloride* gives a chloromercurate, $C^{20}H^{18}N^4S.HCl.HgCl^2$, soluble in hydrochloric acid, and crystallising in yellow needles. *Picric acid* gives a salt soluble in water, and also crystallising in yellow needles. *Auric chloride* gives an amorphous precipitate, soluble in hot water, from which it separates in brilliant scales. Potassium dichromate, ferro-, and ferricyanide, iodide, and cyanide, all give yellow precipitates.

In the formation of this compound, it appears probable that the nicotine is first transformed into *tetrapyridine*, $C^{20}H^{20}N^4$, by removal of hydrogen: $2(C^{10}H^{14}N^2) + 2S^2 = 4H^2S + C^{20}H^{20}N^4$, and that a substitution of sulphur for hydrogen then takes place according to the equation, $C^{20}H^{20}N^4 + S^2 = H^2S + C^{20}H^{18}N^4S$. The substance is therefore *thiotetrapyridine*. Its relation to nicotine may be shown by the formula $(C^{10}H^9N^2)^2S$. The action of an excess of sulphur at a higher temperature gives rise to another body not yet isolated (Cahours a. Etard, *Compt. rend.* lxxxviii. 99).

NIOBIUM, Nb = 94. Metallic niobium is obtained by passing the vapour of the pentachloride mixed with hydrogen through a red-hot tube. It has a steel-grey colour and splendid metallic lustre; is not attacked at ordinary temperatures by hydrochloric acid, nitric acid, or a mixture of the two, but dissolves quickly in strong sulphuric acid, forming a colourless solution. When heated in a stream of air it burns to the pentoxide, Nb_2O_5 . It does not unite with chlorine at ordinary temperatures, but when heated in the gas it is converted into the pentachloride, together with a small quantity of oxychloride (Roscoe, *Chem. News*, xxxvii. 25).

Niobium trichloride, $NbCl_3$, is obtained by passing the vapour of the pentachloride through a red-hot tube, and is deposited on the sides of the tube in the form of a black crystalline film, having the aspect of iodine. It is neither volatile nor deliquescent, and is not decomposed either by water or by ammonia, but nitric acid converts it into niobic acid.

When the vapour of niobium oxychloride mixed with carbon dioxide is passed over

red-hot charcoal, no decomposition takes place, but if the carbon dioxide be replaced by chlorine, niobium pentachloride is formed. When the trichloride is heated in a stream of carbon dioxide, a white sublimate of niobium oxychloride is produced, together with carbon monoxide. This is the first known instance of the decomposition of carbon dioxide by a metallic chloride (Roscoe).

Carbonitrides.—When a mixture of niobium pentoxide and sodium carbonate, or a niobate containing a little alkali, is heated with charcoal, an olive-coloured crystalline mass is obtained, having, according to the duration of the heating, the composition $\text{NbC} \cdot \frac{1}{2} \text{NbN}$ or $\text{NbC} \cdot \frac{2}{3} \text{NbN}$. If the heat be kept up for six or seven hours at the melting point of nickel, long, highly lustrous, grey-blue needles are obtained, consisting of $\text{NbC} \cdot \frac{1}{2} \text{NbN}$. At intermediate temperatures intermediate products are formed. These several carbonitrides treated with chlorine yield nothing but niobium chloride without a trace of oxychloride, a proof that in their preparation from the pentoxide the whole of the oxygen has been expelled. At the same time there is formed a small quantity of carbon hexachloride, and finely divided charcoal. The carbonitrides heated with copper oxide or lead oxide are completely burned and give off the whole of their nitrogen. When roasted in the air they yield a very bulky pentoxide of niobium. Similar compounds are formed with tantalum (*q. v.*) (A. Joly, *Compt. rend.* lxxxiii. 1195).

On the *Ferrocyanides of Niobium*, see CYANIDES (p. 613).

Niobic Oxide, Acid and Salts. The following hydrates and salts are described by B. Santesson (*Bull. Soc. Chim.* [2], xxiv. 52).

The hydrate, $4\text{H}^2\text{O} \cdot 3\text{Nb}^2\text{O}^5$, is prepared from the crude hydrate (obtained by fusing niobium pentoxide with potassium bisulphate and treating the melt with water) by dissolving it in hydrochloric acid and precipitating with ammonia. Another hydrate, $7\text{H}^2\text{O} \cdot \text{Nb}^2\text{O}^5$, is prepared by precipitating a boiling solution of sodium niobate with dilute sulphuric acid.

Potassium Niobate (*a*), $2\text{K}^2\text{O} \cdot 4\text{Nb}^2\text{O}^5 + 11\text{H}^2\text{O}$, is obtained by fusing equal parts of niobium pentoxide and potassium carbonate, and treating the fused mass with water, which leaves the niobate insoluble.

(*b*) $2\text{K}^2\text{O} \cdot \text{Nb}^2\text{O}^5 + 11\text{H}^2\text{O}$, is prepared by fusing the preceding salt with a large excess of potassium carbonate, and subsequent treatment with water.

Sodium Niobate (*a*), $\text{Na}^2\text{O} \cdot \text{Nb}^2\text{O}^5 + 6\text{H}^2\text{O}$, obtained by boiling niobic acid with sodium hydrate. The residue is separated from the alkaline solution, and dissolved in water. After some time the salt is deposited in small crystals.

(*b*) $2\text{Na}^2\text{O} \cdot 3\text{Nb}^2\text{O}^5 + 9\text{H}^2\text{O}$, obtained by fusing niobium pentoxide with sodium hydrate, and subsequent treatment with boiling water, which leaves the salt insoluble.

Zinc fluoniobate, $\frac{\text{Zn}^2}{\text{H}^2} \left\{ \text{Fl}^{30} \text{Nb}^5 + 28\text{H}^2\text{O} \right\}$, obtained by dissolving equivalent quantities of zinc carbonate and niobic acid in concentrated hydrofluoric acid, crystallises, by evaporation, in well-formed prisms, which are insoluble in cold water, decomposed by boiling water, and in the air evolve hydrofluoric acid.

The fluoniobates of cadmium, manganese, cobalt, and nickel are obtained in the same way as the above, and have a corresponding composition.

Iron fluoniobate, $\frac{\text{Fe}^3}{\text{H}^3} \left\{ \text{Fl}^{20} \text{Nb}^5 + 19\text{H}^2\text{O} \right\}$, obtained by dissolving equivalent quantities of metallic iron and niobic acid in hydrofluoric acid, crystallises in slender prisms of a yellowish colour.

Copper fluoniobate, $\frac{\text{Cu}^2}{\text{H}} \left\{ \text{Fl}^{10} \text{Nb}^5 + 9\text{H}^2\text{O} \right\}$, forms broad flat crystals of a bluish colour, which are decomposed by water.

Mercury fluoniobate, $\text{Hg}^2 \text{Fl}^{11} \text{Nb}^5 + 8\text{H}^2\text{O}$, is prepared from a solution of equal quantities of mercury oxide and niobic acid in hydrofluoric acid. Mercury fluoride is first deposited, then a white mass, and finally, when the solution is concentrated, the above salt in short prismatic crystals, which are decomposed by water (Santesson).

According to A. Joly, niobic acid forms four series of salts represented by the formula

which may be prepared by fusing the pentoxide with a metallic chloride, and keeping the mixture for several hours at a temperature a little below the volatilising point of the chloride. In some cases the chloride was replaced by a mixture of a metallic fluoride with a chloride of alkali-metal.

Magnesium Niobate, $4\text{MgO} \cdot \text{Nb}^2\text{O}^5$, prepared as above, is obtained in large trans-

parent hexagonal plates, with a fatty lustre, like that of mica. Sp. gr. = 4.3. A prismatic niobate, $3\text{MgO} \cdot \text{Nb}_2\text{O}_5$, was prepared in like manner.

Calcium Niobates.—The dicalcic salt, $2\text{CaO} \cdot \text{Nb}_2\text{O}_5$, was obtained by fusing the pentoxide with a large excess of calcium chloride, in the form of very distinct rhomboidal prisms. The monocalcic salt, $\text{CaO} \cdot \text{Nb}_2\text{O}_5$, was obtained by fusing together at a bright red heat for four or five hours, a mixture of niobic acid, calcium fluoride, and potassium chloride, the latter in large excess; but if the fluoride was in excess, the salt, $2\text{CaO} \cdot \text{Nb}_2\text{O}_5$, was formed, together with an oxyfluoride of niobium.

Manganese Niobate.—Manganous fluoride, reacting on niobic acid, gives rise to manganese niobate, which is obtained in transparent, rose-coloured, right rhomboidal prisms. The action of ferrous fluoride does not produce a corresponding salt.

Yttrium Niobate was prepared by fusion, in the form of very small octohedrons, having the composition $\text{Y}_2\text{O}_3 \cdot \text{Nb}_2\text{O}_5$, which, according to Rammelsberg, corresponds exactly with the formula of native yttrium niobate, *fergusonite*.

The substitution of tantalic acid for niobic acid gave analogous results in almost every instance (see TANTALUM).

Native Niobates.—The following have been examined by J. L. Smith (*Sill. Am. J.* [3], xii. 361). *Columbite from North Carolina*.—Found in Mitchel Co., and Yancey Co., in rocks belonging to the same epoch as those in which samarskite was discovered. Occurs either in crystals, or in masses weighing from 5 to 100 grams. Sp. gr. of the crystals = 5.562; of the massive variety = 5.485. The following is the analysis of the two forms:—

	Massive	Crystals
Niobic oxide	80.82	80.06
Tungstic and stannic oxides	1.02	1.21
Ferrous oxide	8.73	14.14
Manganous oxide	8.60	5.21
Cupric oxide	trace	—
	99.17	100.62

Columbite from Colorado.—Some crystals of amazon-stone from El Paso Co. were found to have small, black, acicular crystals imbedded beneath the surface. These latter were found to have the specific gravity 5.15. Their composition is as follows:— $\text{Nb}_2\text{O}_5 = 79.61$, $\text{FeO} = 14.14$, $\text{MnO} = 4.61$; loss by heat = 0.5.

Samarskite.—Occurs principally in a mica mine, Mitchel Co., N. Carolina. It is crystalline, black, brittle; fracture conchoidal; lustre vitreous; hardness = 5.5 to 6. Sp. gr. = 5.72. Composition as follows:—

	1	2	3
Niobic oxide	55.13	54.96	{ 37.20 18.60
Tantal oxide	—		
Tungstic and stannic oxides	0.31	0.16	0.08
Yttria	14.49	12.84	14.45
Cerium oxides (?)	4.24	5.17	4.25
Uranium oxide	10.96	9.91	12.46
Manganous oxide	1.53	0.91	0.75
Ferrous oxide	11.74	14.02	10.90
Magnesia	trace	0.52	0.55 CaO
Loss on ignition	0.72	0.66	1.12
Insoluble residue	—	1.25	—
	99.12	100.40	100.36

Finkener a. Stephans (*Verhand. Min. St. Pet.* 1863, 13) found 4 per cent. zirconia and 6 per cent. thorina in this mineral.

Eucenite.—Found associated with samarskite, of a hair-brown colour, giving an ash-coloured powder, translucent in thin splinters. Fracture sub-conchoidal and irregular; lustre resinoid. Sp. gr. (mean) = 4.608. No crystals were found. Analysis gave the following numbers:—

Nb_2O_5	WO_3 and SnO_2	Yttrium and cerium oxides	CaO	UO_3	MnO	FeO	H_2O
54.12	0.21	24.10	5.53	9.53	0.08	0.31	5.70 = 99.58

Fergusonite.—Found in the granite quarries of Rockport, particularly at the intersection of two trap dykes.

The mineral is of a fine, dark brown colour, with a clear conchoidal fracture, and resinous lustre. Hardness 6; sp. gr. 5.681; streak light brown; powder ash-coloured. When heated to bright redness for 15 minutes, it changes to light greenish-

yellow, with loss of 1.5 per cent. $\text{Nb}_2\text{O}_5 = 48.75$, $\text{Y}_2\text{O}_3 = 46.01$, $\text{CeO}_2 = 4.23$, Fe_2O_3 , and $\text{UO}_3 = 0.25$, $\text{H}_2\text{O} = 1.65$.

Aeschynite and Samarskite (Rammelsberg, *Jahrb. f. Min.* 1878, 529).—

1. *Aeschynite*, sp. gr. 5.16, gave by analysis:—

Nb_2O_5	TiO_2	ThO_2	$\text{Ce}_2\text{O}_3, \text{La}_2\text{O}_3, \text{D}_2\text{O}_3$	$\text{Y}_2\text{O}_3, \text{Er}_2\text{O}_3$	Fe_2O_3	CaO
32.51	21.20	17.55	19.41	3.10	3.71	2.50 = 99.98

Hence the formula $\text{R}^2\text{Nb}^2(\text{Ti}, \text{Th})^3\text{O}^{14}$, or else $\text{R}^2\text{Nb}^2(\text{Ti}, \text{Th})^4\text{O}^{20}$.

2. *Samarskite*, (a.) from Miask, sp. gr. = 5.672; (b.) from Mitchell County, North Carolina, sp. gr. = 5.839. In neither case could Rammelsberg detect the presence of acids of zirconium or thorium, which, according to some authorities, exist in this mineral:—

SnO_2	TiO_2	SiO_2	Ta_2O_5	Nb_2O_5	Y_2O_3	Er_2O_3	$\text{Ce}_2\text{O}_3(\text{Di})$	$\text{Fe}_2\text{O}_3(\text{Mn})$	UO_3
a. 0.22	1.08	—	—	55.34	8.80	3.82	4.33	14.30	11.94 = 99.83

SnO_2	TiO_2	SiO_2	Ta_2O_5	Nb_2O_5	Y_2O_3	Er_2O_3	$\text{Ce}_2\text{O}_3(\text{Di})$	$\text{Fe}_2\text{O}_3(\text{Mn})$	UO_3
b. 0.16	—	0.36	14.36	41.07	6.10	10.80	2.37	14.61	10.90 = 100.93

The mineral therefore consists essentially of a heminiobate (tantallate) isomorphously mixed with a uranate; and as $\text{U} : (\text{Nb}, \text{Ta}) = 1 : 10$ nearly, the formula of samarskite is $\frac{8\text{R}^2\text{Nb}^2\text{O}^{21}}{\text{R}^4\text{U}_5\text{O}^{21}}$, or,

Hatchettolite, a new mineral from North Carolina, occurs, associated with euxenite and samarskite, in the combination $\text{O} \infty \text{O} \infty .3\text{O}_3$, of yellow-brown colour with greyish shimmer, greenish-yellow after heating. It was regarded by Dana as pyrochlore, but differs from that mineral by containing a larger proportion of uranic oxide.

Rogersite occurs as a deposit, in white botryoidal crusts—evidently a product of decomposition—on euxenite, and more rarely on samarskite. Hardness = 3.5. Analyses 1, 2, 3, Hatchettolite; 4 and 5, Rogersite.

	Nb_2O_5	WO_3 and SnO_2	UO_3	CaO	YO	FeO	K_2O	Loss on ignition	Lead	
(1.)	66.01	0.75	15.20	7.72	2.00	2.08	0.50	5.16	trace	= 99.42
(2.)	67.86	0.60	15.63	7.09	0.86	2.51	1.21	4.42	trace	= 100.18
(3.)	67.25	0.91	16.01	7.11	0.64	2.12	—	5.02	trace	= 99.06
(4.)	18.10	—	—	—	60.12	—	—	17.41		
(5.)	20.21	—	—	—	—	—	—	16.34		

Rogersite is interesting as being the first niobate in which so large a proportion of water has been found (J. L. Smith, *Compt. rend.* lxxxiv. 1036).

An elaborate paper on the metals of the tantalum group has been published by R. Hermann (*J. pr. Chem.* 1877, [2], xv. 105–150; abstr. *Jahresb. f. Chem.* 1877, 288; *Chem. Soc. J.* xxxii. 166), in which—contrary to the view deduced from the experiments of Marignac a. Blomstrand in 1865, and now adopted by all other chemists—he regards these metals as heptads [niobium fluoride, NbF_7 , niobic oxide, Nb_2O_7 , &c.] He further still maintains the separate existence of the metal to which, in 1846, he gave the name ‘ilmenium’ (iii. 244), and is of opinion that the metal which Marignac obtained in 1868 (*Compt. rend.* lxxvi. 180) by the reduction of the double fluoride, which he supposed to be potassium-niobium fluoride, was really not niobium, but ilmenium.

Lastly, Hermann announces the discovery of a new metal of this group, which he names ‘Neptunium.’ Its atomic weight, determined by the analysis of potassium-neptunium fluoride, $4\text{KF.Np}^2\text{F}^7 + 2\text{H}_2\text{O}$, he estimates at 118. Neptunium fluoride is described as resembling tantalum fluoride in giving with caustic soda an amorphous precipitate insoluble in boiling water, whereas the fluorides of niobium and ilmenium form with soda-ley crystalline precipitates of sodium salts soluble in 25 pts. of boiling water. From tantalum, neptunium is said to be especially distinguished by the fact that its fluoride forms with potassium fluoride an easily soluble double salt, whereas the fluoride of potassium and tantalum requires 200 pts. of boiling water to dissolve it. A characteristic reaction of neptunium is the wine-yellow colour imparted by neptunic oxide, and the golden-yellow colour by sodium neptunate, to a bead of phosphorus-salt, tantalic oxide giving therewith a colourless, niobic oxide a blue, and ilmenic oxide a brown bead. A further distinction is afforded by the reactions of the

corresponding acids with gallotannic acid, tantalic acid giving a sulphur-yellow, niobic acid an orange, ilmenic acid a brick-red, and neptunic acid a cinnamon-brown precipitate.

NITRACETANILIDE, $C^6H^3.NH.C^2H^2(NO^2)O$. Both this compound and the nitraniline prepared from it (mixture of *o*- and *p*-nitraniline, see p. 198), when boiled with strong soda-ley, are converted, with copious evolution of ammonia, into para-nitrophenol (m. p. 114°), whereas meta-nitraniline prepared from ordinary dinitrobenzene cannot in any way be converted into the corresponding nitrophenol (P. Wagner, *Ber.* vii. 76).

NITRACETHIAMIDE, $C^2H^4N^2O^2S = H^2(NO^2)C.OS.NH^2$ (A. Steiner, *Deut. Chem. Ges. Ber.* viii. 1177; ix. 779). This body is formed, together with ammonium thiocyanate, when dry hydrogen sulphide is passed into anhydrous ether in which mercuric fulminate is suspended. The ether filtered from mercuric sulphide leaves on spontaneous evaporation, nitracethiamide, free sulphur, and an aqueous solution of ammonium thiocyanate and oxalic acid. The nitracethiamide may be separated from the last-mentioned substances by levigation and washing with water, and obtained in the pure state by dissolving it out from the mercuric sulphide with ether.

Nitracethiamide, when examined by the microscope, appears to be made up of prisms. It is quite insoluble in water, moderately soluble in alcohol and ether, and can be separated from these solutions only by spontaneous evaporation of the solvent, since it is decomposed, with separation of sulphur, even below the boiling point of ether. It is quickly decomposed on gentle heating with water, still more quickly with aqueous ammonia, into carbon dioxide and ammonium thiocyanate, with separation of sulphur if the heat be quickly applied. When treated in ethereal solution with hydrogen sulphide, it is resolved into oxalic acid, ammonium thiocyanate, and sulphur:

The product did not appear to contain any amines formed by reduction of the nitro-group. Nitracethiamide, heated with chloride of lime, yields chloropirrin.

NITRACETONAPHTHALIDES, $C^{10}H^7.NH.C^2H^2(NO^2)O$. Three isomeric bodies of this composition are formed by the action of nitric acid on acetone-naphthalene dissolved in acetic acid (see NAPHTHALENE). Two of them, α and β , separate from the resulting solution by slow crystallisation, the α -modification in thick prismatic crystals, the β -modification in needles which may be removed by elutriation. Both melt at 171° , and are converted by alcoholic potash into nitro-naphthylamines, by boiling with caustic soda into nitronaphthols. The mother-liquor from which the α - and β -compounds have separated deposits, on addition of water, a third or γ -nitraceto-naphthalide which crystallises in long needles melting at 189° , and reacts like the α - and β -modifications. The following table exhibits a comparative view of the crystalline forms and melting points of these isomeric compounds:

Nitraceto-naphthalide	Needles	Prisms	Needles
	m. p.		
Nitronaphthylamine	171°	171°	189°
Nitronaphthol	191°	158° – 159°	191°
Nitronaphthalene	194°	128°	164°
Amidonaphthol hydrochloride	58°	—	58°
Naphthoquinone	Needles	Scales	Needles
	125°		125°

(Liebemann a. Dittler, *Ber.* vi. 947; vii. 240); compare p. 1362.

NITRACETONITRIL, $C^2H^2(NO^2)N = CH^2(NO^2).CN$. When finely pulverised ammonium fulminate is gradually treated with five to six times its weight of ordinary sulphuric acid, the mass becomes warm and gives off carbon dioxide, and if it be further heated, and not stirred, nitracetonitril is also given off, and may be condensed in drops which solidify in the crystalline state. It then forms long colourless crystals which melt at a temperature a little above 40° , and dissolve readily in alcohol and in ether. In water, the compound forms heavy oily drops. When heated on platinum-foil, it burns with a very bright flame. If the action of sulphuric acid on ammonium fulminate be moderated by cooling and agitation, and heat applied from time to time only, then, on diluting with a large quantity of water, after the mass has cooled and the evolution of carbon dioxide has ceased, a white crystalline precipitate is formed consisting of an isomeric or polymeric nitracetonitril, and the mother-liquor contains ammonia. This nitracetonitril dissolves in hot water and in strong nitric and sulphuric acids, but is insoluble in cold water, also in ether and in alcohol. It melts, with decomposition, at 216° , and detonates when heated on platinum foil. Its aqueous solution has an acid reaction, and forms, with mercuric nitrate, a white precipitate,

and with silver oxide a white precipitate which soon turns black. The mercury-compound, probably $(\text{C}^2\text{H}\text{N}^2\text{O}^2)^2\text{Hg}$, is sparingly soluble in hot water, and detonates when heated on platinum foil. Boiling baryta-water decomposes the nitracetonitril, with rapid evolution of ammonia and formation of barium carbonate, the resulting solution containing a crystallisable barium salt. By tin and hydrochloric acid, the nitracetonitril is quickly reduced to a primary amine (Steiner).

NITRACETOPHENONE. See PHENYL-METHYL KETONE.

NITRACETOXYLIDIDE, $\text{C}^{10}\text{H}^{12}\text{N}^2\text{O}^3$. See XYLIDINE.

NITRACETYLMESSIDENE. See MESITYLENES (AMIDO-), p. 1283.

NITRANIL, $\text{C}^6(\text{NO}^2)^4\text{O}^2$, syn. with TETRANITROQUINONE. See QUINONE.

NITRANILIC ACID, $\text{C}^6\text{H}^2(\text{NO}^2)^3\text{O}^4$, syn. with DINITRO-DIOXYQUINONE. See QUINONE.

NITRANILINES. See BENZENES (NITRAMIDO-), p. 198.

NITRIFICATION. The occurrence of nitre in various parts of the earth's surface has been known from the earliest times. It is found in certain cases as an efflorescence on soil, on the sides of caves (generally those frequented by animals), and on old walls, especially those of stables. From this mode of occurrence, the name of 'Saltpetre' is doubtless derived. Large quantities of effloresced nitre are collected in certain districts of North India from the soil surrounding the house drains of the villages (W. J. Palmer, *Chem. Soc. J.* 1868, 318); this nitre, when recrystallised, forms the well-known East Indian saltpetre. Other well-known nitre-yielding districts occur in Algeria (where the mounds covering the sites of ancient villages are lixiviated for nitre), at Saragossa and Murcia in Spain, at Tacunga in Ecuador, and above all on the tableland of Tamaragual in Peru, where an enormous formation of sodium nitrate is found.

Chemical analysis has shown that nitrates are far more widely distributed than would appear from these instances of their marked production; that, in fact, nitrates are generally to be found in all soils and porous rocks on the earth's surface, and especially in fertile well-manured soils. The amount of nitrates present is extremely variable, depending not only on the nature of the soil, but still more on the immediately preceding weather. Nitrates are found in maximum amount after long continued dry weather, when the water of the subsoil has been brought to the surface by capillary attraction, and the salts held in solution have accumulated there as the water evaporates. They are found in minimum quantity after heavy rain, by which they are washed out of the surface soil into the sub-soil, a part being in most cases permanently lost by drainage into rivers, and finally into the sea. The facts relating to the rise and fall of nitrates in a soil are of the greatest importance in practical agriculture, as plants derive their chief supply of nitrogen from the nitrates which the soil contains. A soil, or porous rock, may be very rich in nitrates without yielding the efflorescence characteristic of nitre-bearing strata; an efflorescence generally occurs only when the nitric acid is combined with potassium; the nitrate most commonly present in soil is nitrate of calcium, and this is too deliquescent in its nature to appear as a dry salt, even under favourable conditions of climate.

The conditions under which nitrates may be formed in soil have been long known. The necessity of obtaining nitre for the manufacture of gunpowder led to an early attention being given to the subject, and in most countries of continental Europe the artificial production of nitre has been conducted on a large scale, and brought to considerable perfection. This manufacture is now superseded by the production of nitre by means of the reaction between Peruvian nitrate of sodium and chloride of potassium.

The earliest manufacture of nitre was simply by the lixiviation of old plaster, and of the earthen floors of stables, cottages, &c., wood ashes being added to convert the nitrate of calcium into nitrate of potassium. The actual production of nitre seems to have been first successfully accomplished by Glauber in the seventeenth century. Numerous investigations on the subject were made during the next century in Sweden, Germany, and France, the work being stimulated by the offer of large prizes by the respective governments for the best method of producing saltpetre. The various methods thus brought into use were quite similar in principle; they all aimed at accomplishing in a more rapid manner, and on an exaggerated scale, the process by which nitre is naturally produced in soil.

The materials used for constructing an artificial nitre bed consisted, in the first place, of a rich porous soil, that remaining from the lixiviation of a former bed being far superior to any other. To this soil were added limited quantities of farmyard manure, various kinds of animal and vegetable refuse, and wood ashes or calcareous

matter; straw was added, if required, to keep the mass porous, and the whole was watered with urine. In this first stage of the process no nitre is formed, putrefactive change being inimical to the production of nitrates; the object in view is simply to obtain a soil extremely rich in nitrogenous humic matter.

Such a soil having been prepared, it is, on the French plan, formed into a long mound under a shed erected for the purpose. If the mound of soil is very large, aération may be provided for by tunnels of open woodwork penetrating the mass at regular intervals; with smaller heaps it is sufficient to stir the earth from time to time with a rake, or turn it with a spade. The watering of the earth is a matter requiring great judgment, a certain degree of moisture being most suitable for nitrification; with an excess of water nitrification will cease altogether, while if the soil is too dry the nitrification proceeds but slowly. Urine may be used at first for watering the mass, but as the operation advances water only must be employed, and in diminishing quantity. At the end of two years from the formation of the mound the soil will be ready for extraction: 1000 lbs. of the nitrified soil may be expected to yield 5 lbs. of crude nitre.

On the German plan the prepared soil is built into thick walls, 6 or 7 feet high; one side of the wall is plane, the other is disposed in gutter-shaped terraces; each wall is roofed with straw. A series of these walls is arranged on an impervious terrace, freely exposed to the weather. The earth is watered when necessary on the terraced side of the wall; any drainage which may occur during heavy rain is collected, and applied to the earth in dry weather. As the earth becomes rich in nitre this salt tends to effloresce on the plane side of the wall; this side is then from time to time scraped off, the earth thus removed is lixiviated, and returned with fresh soil to the terraced side of the wall. The production of nitre on this plan proceeds with tolerable regularity, and the walls gradually march across the terrace.

The experience thus gained by practice revealed many of the conditions necessary for the production of nitrates in soil. For a soil to nitrify it must have—1. Free access of air; 2. A suitable amount of moisture; 3. A suitable temperature (10° – 25° according to Dumas); 4. The presence of a salifiable base, with which the nitric acid might combine; 5. The presence of nitrogenous organic matter, which must however have passed the first putrefactive stage of decomposition. To these conditions we might perhaps add—6. Darkness,—light being necessarily excluded from the interior of a mass of soil.

We must now turn to the various theories by which the process of nitrification has been explained.

As nitre is continually found as an efflorescence upon the surface of the nitrifying matrix, it was assumed by the alchemists that nitre was of aerial origin, and this theory has been more or less held down to the present day. J. Davy, as the result of his examination of the nitre caverns in Ceylon, concluded that the nitric acid was formed from the nitrogen and oxygen of the air. Longchamp fully enunciated this theory. He regarded the combination of the atmospheric nitrogen and oxygen dissolved in the water of moist porous bodies as the only source of nitric acid. De Saussure and Proust also held that the nitrogen of the air is oxidised to nitric acid during nitrification. Clôez, in his excellent lecture on nitrification (*Leçons de Chimie et de Physique professées en 1861 à la Société chimique de Paris*), considers that such a combination of nitrogen and oxygen is induced by the presence of other matter undergoing oxidation, and believes that this oxidation of the nitrogen of the atmosphere is one of the sources of nitric acid in the nitrification of soil.

A very similar theory has been held by many chemists to explain the nitrification of organic matter. The organic matter during its decomposition is considered to evolve nitrogen, and this in its 'nascent' state is oxidised by the oxygen of the air, which may be present in a condensed form on the surface of porous bodies. This explanation is the one given by Hofmann (*Exhibition Report*, 1862, 47).

The above theories have also been modified by the substitution of ozone for oxygen. According to Schönbein free nitrogen can be oxidised by ozone into nitric acid. The same view has been held quite recently by S. W. Johnson. Ozone is assumed to be formed during the oxidation of the organic matter of the soil, this ozone then attacking the free nitrogen present and producing nitric acid.

The truth or fallacy of the theories of nitrification we have just sketched is of the greatest importance to practical agriculture, for if the nitrogen of the air can be oxidised to nitric acid in the soil, it is clear that we have in nitrification an actual creation of plant-food. The weight of evidence is however apparently against the views just noticed. Nitrogen and oxygen certainly combine at a very high temperature, as that given by the electric spark (Cavendish), or produced by heating platinum to its melting point (H. Davy), or by the combustion of hydrogen in oxygen; but at somewhat lower temperatures, as that of hydrogen burning in air, no nitrous or nitric

acid is produced if the materials used are perfectly free from ammonia (L. T. Wright, *Chem. Soc. J.* 1879, xxxv. 42). Porous bodies also appear to be without effect in inducing the combination of nitrogen and oxygen. Neither charcoal (L. H. Wood) nor spongy platinum (Kuhlmann) is capable of bringing about the combination of oxygen and nitrogen, even at a high temperature. Ozone also appears incapable of oxidising nitrogen. Lawes, Gilbert and Pugh found that no nitric acid was produced by passing ozonised air for several months over alkaline pumice. Carius has also recently shown that ozone is without effect on gaseous nitrogen. A further proof that the nitrogen of the atmosphere takes no part in the process of nitrification is afforded by one of the experiments of Boussingault (*Compt. rend.* lxxvi. 22). He determined the total amount of nitrogen in a soil rich in humic matter, and then placed two weighed quantities of this soil, one mixed with a small quantity of cellulose, in large glass vessels containing an abundant excess of air; the vessels were then closed and kept in a cellar for eleven years. At the end of this time the contents of the vessels were analysed. The soils had in each case formed a large amount of nitric acid, but the total nitrogen, determined by combustion with oxide of copper, was found to have somewhat diminished; the nitrogen of the air had thus not entered into combination.

The second group of theories we have to notice regards the oxidation of ammonia as the source of the nitric acid formed in soil. This view was partly held by several of the older chemists, but was first strongly insisted upon by Kuhlmann. He proved by many experiments with powerful oxidising agents that ammonia might readily be converted into nitric acid, and concluded that by the action of the porous bodies contained in the soil the oxidation of ammonia might be effected and nitric acid produced. This simple explanation of the phenomenon has been held by some down to the present day. Thus Dehérain (*Würtz, Dict. Chim.* ii. 564) regards the formation of nitre in the walls of stables as due to the simple oxidation of the ammonia vapours in the porous brickwork. This theory has also been modified by assuming that the oxidation is induced by the disposing influence of other oxidising actions, and by the substitution of the action of ozone for that of the oxygen of the air. A further modification of the above theory regards ferric oxide as the agent for the conversion of ammonia into nitric acid. The latter view has been held by P. Thenard, Knop, Haarstick, and Pesci. On the whole, the explanation of nitrification as due to the oxidation of ammonia has been perhaps the opinion most generally held by modern chemists.

Respecting this group of theories it will suffice to state that the oxidation of ammonia by ozone has apparently been established by Baumert, Houzeau, and Carius (*Liebig's Annalen*, clxxiv. 31), but that there is very little evidence of the production of nitric acid from ammonia by the action of the oxygen of the air at ordinary temperatures. The power of ferric oxide to convert ammonia into nitric acid is denied by Millon and Storer.

Though, however, the oxidation of ammonia has not been satisfactorily accomplished in the laboratory, save by means of powerful reagents, or at high temperatures, there is no doubt that ammonia is rapidly oxidised in a fertile soil, and that this oxidation of ammonia is a considerable cause of the production of nitric acid. An excellent illustration of the oxidation of ammonium salts by soil is afforded by the analyses of the drainage waters from the experimental wheat field at Rothamsted. The following table shows the composition of the drainage water running from the plots of this field immediately before and immediately after the application of ammonium salts. The ammonium salts were applied between March 10 and 13, 1879.

Nitrogen, existing as Nitrates, per million of Drainage water.

Date of running	Plots with no ammonia					Plots receiving 400 lbs. ammonium salts per acre							
	3 & 4	5	16	17		7	10	11	12	13	14	18	
February 16	3.4	3.7	4.2	3.3		3.5	5.2	4.8	4.1	3.8	4.8	4.2	
April 7	3.6	2.9	3.6	2.3		39.0	45.4	41.8	25.4	29.4	33.0	40.4	

On February 16 the proportion of nitric acid in the drain-water is uniformly low throughout the plots. At the next running of the drains the plots which had received no ammonium salts have somewhat diminished their yield of nitrates, while in the case of those plots receiving ammonium salts in the interval the proportion of nitrates in the drainage water has enormously increased. This loss of nitrates by

drainage is a serious cause of diminished fertility to the soil. Further striking illustrations of the oxidation of ammonia by soil will be found in Frankland's experiments on the intermittent filtration of sewage (*Rivers' Pollution Commission*, 1868, First Report, p. 60).

Besides the oxidation of free nitrogen and of ammonia, it has naturally been assumed that the oxidation of nitrogenous organic matter is a further source of nitric acid. The organic matter has been supposed either to yield in the first place nascent nitrogen or ammonia, and these to be subsequently oxidised, or the organic nitrogen has been regarded as directly converted into nitric acid. The production of nitrates by the action of alkaline permanganate of potassium on nitrogenous bodies has been held to support the latter view. That nitrogenous organic matter does contribute to the formation of nitrates in soil there can be no doubt. In some of Boussingault's experiments (*Compt. rend.* lxxxii. 477) 50 per cent. of the nitrogen of rape cake, and 90 per cent. of the nitrogen supplied as horn filings, were converted into nitric acid after mixture with soil.

The theories explanatory of nitrification just reviewed have satisfied many chemists. Clôez, writing in 1861, says: 'The question of nitrification appears to me to be at present completely elucidated.' The facts however would be more truly stated by saying that chemists had entirely failed, when working with pure substances in the laboratory, to produce nitric acid under the conditions known to occur in soils. Boussingault truthfully sums up his own work by saying 'It is remarkable that in a very large number of experiments made with the view of nitrifying nitrogenous substances, I have never been able to discover the least production of nitric acid in the absence of vegetable earth.'

We turn now to the latest theory of nitrification, which holds that the oxidation of ammonia and of organic nitrogen in the soil is the work of a living organism.

The first suggestion of the possibility of such an explanation was made by Pasteur in 1862. The oxidation of alcohol to acetic acid by the agency of mycodermis appeared to him sufficiently analogous to the phenomena of nitrification to call for a fresh study of the subject from this point of view. An opinion of the same character was expressed by A. Müller in 1873. He observed that the ammonia of sewage, and of certain impure well waters, often changed spontaneously into nitric acid, while similar solutions of pure ammonium salts and urea remained unchanged; he suggested that the first-named liquids probably contained a ferment which was absent from the pure solutions prepared in the laboratory.

To Schloesing and Müntz belongs the credit of establishing this hypothesis by experiment; their first paper on the subject (*Compt. rend.* lxxxiv. 301) was published early in 1877. They found that sewage might be slowly filtered through a porous column of pure sand and limestone without nitrification at first taking place; after twenty days nitrification set in, and the ammonia of the sewage was after this time entirely converted into nitric acid. On allowing chloroform vapour to pour on the surface of the column of sand and limestone, nitrification was wholly suspended, and did not recommence during seven weeks after the chloroform had ceased to be applied. The surface of the column was then seeded by the addition of a little vegetable earth known to nitrify with ease; the result was that nitrification of the sewage at once recommenced as strongly as before. The evidence is here of two kinds—first, the oxidation of the ammonia was entirely prevented by chloroform, which, as Müntz had previously shown, suspends the action of all organised ferments—second, the oxidation of the ammonia was induced by adding to the porous column a few particles of vegetable soil. In a second paper (*Compt. rend.* lxxxv. 1018), Schloesing and Müntz show that heating soil to 100° destroys its capacity for nitrification. If soil is heated to 100°, or treated with chloroform, and then exposed to pure air in a moist state, carbonic acid and ammonia are produced, but no nitrates. Nitrification can however be again started by the addition of a little unheated earth. A porous medium is also not necessary for nitrification; sewage, or a weak solution containing ammonium salts, sugar, and cinereal matter, may be nitrified by passing over polished pebbles, if a little vegetable earth be added as seed.

Between the publication of the two papers just mentioned the investigation of the subject was commenced at Rothamsted (*Chem. Soc. J.* 1878, xxxiii. 44); the results were entirely confirmatory of the ferment theory of nitrification. Moist garden soil contained in glass tubes was exposed to a current of washed air for several weeks, the air in some cases bearing the vapour of chloroform, bisulphide of carbon, or carbolic acid. With washed air alone the proportion of nitrates in the soil increased to five or six times its original amount, while where chloroform or bisulphide of carbon vapour was introduced no nitrification took place; the carbolic acid also hindered nitrification, but being retained by the upper portion of the moist soil its action was less considerable. A further set of experiments was made with a weak solution of chloride

of ammonium, containing about 80 mg. per litre, with small quantities of tartrate and phosphate of potassium, and some precipitated carbonate of calcium. Two bottles of this solution were placed in a window, and two in a dark cupboard, one of each set being seeded by the addition of a little pasture soil. After three months it was found that the unseeded solutions remained unchanged, the seeded solution in darkness had completely nitrified, while the corresponding solution in daylight contained no nitric acid. The conclusions of Schloesing and Müntz were thus entirely confirmed, and the additional fact made known that light is inimical to the work of the nitrifying organism.

This previously unsuspected action of a living organism throws great light on many of the earlier attempts to produce nitrification; former experiments resulting in the production of nitric acid are now clearly valueless as proof of the inorganic character of nitrification, unless the conditions of the experiment were such as to preclude the existence of living organisms.

The evidence on which nitrification in soil and waters is attributed to the action of an organised ferment has been fully stated, the subsequent results obtained by Schloesing and Müntz (*Compt. rend.* lxxxvi. 892; lxxxix. 891, 1074) and at Rothamsted (*Trans. Chem. Soc.* 1879, 429) may be more briefly noticed; the subject is still but incompletely investigated.

The precise nature of the ferment has been sought for by the French experimenters; they found that *Penicillium glaucum*, *Aspergillus niger*, *Mucor mucedo* and *racemosus*, and *Mycoderma vini* and *aceti* are all incapable of producing nitric acid. The results obtained at Rothamsted also show that the ordinary forms of *Bacteria* contained in the atmosphere are also incapable of effecting nitrification.

Schloesing and Müntz in one of their later communications describe the organism which acts as the nitrifying ferment. They obtained it in a pure condition by systematic cultivation. In the first place a sterilised solution (consisting either of sewage, or of artificial mixtures containing ammonium salts with organic and cinereal matter) was seeded by the addition of a few particles of vegetable earth. When nitrification was accomplished a fresh solution was seeded from that just nitrified. By proceeding thus a number of times the nitrifying organism was separated from the numerous other organisms contained in soil.

The organism thus isolated consists of extremely minute, round, or slightly elongated corpuscles, existing either singly or joined in couples; it is of slow growth, and multiplies apparently by budding. It thus apparently belongs to the great bacteria family, the different members of which effect, as is well known, such powerful and divers changes in organic matter. In Cohn's classification it would probably be described as a *Micrococcus*. The nitrifying organism is not easily distinguishable from other organisms of the same class.

The nitrifying bacterium is abundant in soils; it is rare to find a particle of arable soil which is not effective as seed. It is also found abundantly in sewage, but only to a small extent in running water; in the latter it is found attached to the surfaces of solid bodies, and collects at the bottom of the vessel when the water is allowed to stand. Air and rain are apparently, as a rule, free from this organism.

One of the characteristics of the nitrifying organism is the comparative ease with which it may be destroyed by heat; Schloesing and Müntz found exposure to 90° sufficient for this purpose. Desiccation, according to the French experimenters, also destroys the organism, even when the drying is conducted at ordinary temperatures; soil may thus lose all power of nitrification by drying at the temperature of the air. Long deprivation of oxygen is also fatal. In mediums rich in organic matter *mucor* is the chief enemy to nitrification, and until this fungus has run its course, no nitrification will occur.

The investigations at Rothamsted on the conditions under which nitrification occurs were made with solutions of ammonium chloride, containing phosphates, and generally potassium tartrate; the solutions were placed in wide-mouthed pint bottles filled to the shoulder, giving thus at starting a depth of about 5 inches of fluid; the solutions were seeded with a small quantity of a solution already nitrified, and generally placed in the dark. The conclusions arrived at were as follows.

A solution of suitable composition will not nitrify when seeded if no salifiable base be present. A trace of nitrous acid may be formed, but the action soon comes to an end. If a salt of an organic acid is present, as, for example, a tartrate, nitrification will proceed slowly in proportion as the organic acid is consumed by the organisms present and the base set free. Active nitrification was obtained only in presence of calcium carbonate. The nitric fermentation is in this respect analogous to the lactic and butyric. Alkali carbonates, including carbonate of ammonium, are, according to Schloesing and Müntz, equally capable of assisting nitrification, but if they amount to more than two or three thousandths of the solution, they retard or com-

pletely arrest the action. Boussingault, in his experiments with soil, did not find that the addition of lime increased the rate of nitrification; the soils he employed were, however, never quite free from lime, and the quantity artificially added possibly produced an excessive alkaline condition.

The presence of organic carbon should be essential for nitrification if this process is really a function of the growth of an organism of low character. Besides the humic matter of soil, tartaric acid and sugar have been found effective as organic food; alcohol, glycerin, and albumin were also found suitable by the French experimenters. The minimum proportion of organic carbon required has not yet been ascertained, but 3 pts. of carbon present as tartrate have proved sufficient for the nitrification of 10 pts. of nitrogen present as chloride of ammonium.

Light certainly hinders nitrification; in many experiments light has stopped the action altogether, and in others retarded it. The nitrifying organism is not apparently killed by exposure to light.

The addition of a small quantity of seed to a suitable solution is not immediately followed by nitrification; a period of inaction follows, which is shorter at high temperatures than at low ones. Thus in the case of 400 c.c. of an 80 mg. per litre chloride of ammonium solution, seeded with 1 c.c. of a solution already nitrified, nitrification commenced in about thirty-eight days at 7°, and in about ten days at 30°. An increase in the concentration of the solution considerably lengthens the period of inaction; in a solution of about eight times the unit strength, the preliminary period of rest was about doubled.

The limits of temperature within which nitrification will take place are, as at present ascertained, as follows. At Rothamsted a purely nitrous fermentation has proceeded with some briskness in very weak solutions at 3°, while a nitric fermentation in a similar solution almost ceased at 5°. Below 5° Schloesing a. Müntz found nitrification to be excessively feeble; at 12° they state it begins to be active. Activity rapidly increases with a further rise of temperature, reaching a maximum at 37°, at which point nitrification is ten times more rapid than at 14°. Above 37° the rate of action rapidly diminishes, and at 45° nitrates are formed less rapidly than at 15°. At 50° very little nitrate is produced, and beyond 55° there is absolutely no action. These determinations of Schloesing a. Müntz differ from the results obtained at Rothamsted, where no nitrification was obtained at 40°, though the solutions were kept fifty-four days at this temperature and twice seeded. The experiments of Schloesing a. Müntz were apparently made with thin layers of solution, exposing a large surface to the air; at Rothamsted the solutions had a considerable depth and small surface; it seems possible that the supply of oxygen was in the latter case insufficient for the requirements of a high temperature.

In experiments made at various temperatures at Rothamsted, the rate of nitrification did not increase so rapidly with the rise in temperature as found by the French investigators. Thus with an 80 mg. solution of ammonium chloride, nitrification occupied about thirty-seven days at 11°, and about eight days at 30°. At a fixed temperature the length of time required for complete nitrification appears to vary almost directly with the degree of concentration of the solution.

The rate of nitrification is not uniform throughout its course; it appears to commence slowly, gradually attains a maximum of energy, and then becomes slow again towards the conclusion of the action.

The product of nitrification is not uniform, sometimes nitrous, and sometimes nitric acid being produced. Nitrites are produced rarely in soil but frequently in liquids; according to the French observers, their occurrence is determined by an insufficient degree of aëration, or by the temperature being too low. They state that a thin layer of liquid (1 or 2 mm.), will yield nitrates, and a thicker layer nitrites. The experience at Rothamsted has been of a different kind; a purely nitric fermentation has been obtained only in the case of weak solutions nitrified at low temperatures; in the case of strong solutions or high temperatures, nitrous acid was chiefly, if not entirely, produced, and was afterwards converted into nitric acid at the end of the reaction. In some cases, however, depending on the character of the ferment used, the result of the action has been merely nitrous acid, even in the case of cold dilute solutions; and in these cases the nitrous acid is permanent, and is not afterwards changed into nitric. The original ferment obtained from pasture soil yields a purely nitric fermentation under suitable conditions; but when nitrified solutions which have been long kept are employed as seed, the phenomena just mentioned may occur. Thus it is quite possible to seed two precisely similar solutions with two samples of ferment, and place the solutions under the same conditions as to temperature and aëration, and to obtain in one case a purely nitric, and in the other a purely nitrous fermentation. The altered ferment is capable of converting ammonia into nitrous acid, but not of converting nitrites into nitrates.

Actual experiments with a solution of potassium nitrite have shown it to be very permanent in the absence of a ferment, to be unaffected by the altered ferment just mentioned, but to be rapidly converted into nitrate by the addition of a few drops of a solution in which nitrites have lately changed into nitrates. The conversion of potassium nitrite into nitrate took place only in the dark.

The whole of the ammonia present in a solution has not been obtained as nitric acid, a small part of the nitrogen passing into organic combinations, or being otherwise lost. On an average of ten experiments, under different conditions of temperature, the nitrogen obtained as nitric acid was 93·7 per cent. of that taken as ammonia, but this result is probably somewhat too low.

Besides the papers already referred to, two papers by Schloesing (*Compt. rend.* lxxvii. 203, 353), treating of nitrification in soil with a limited supply of oxygen, and of the destruction of existing nitrates when oxygen is withheld, may be consulted with advantage.

R. W.

NITRILS, $R-C\equiv N$. *Normal Alcoholic Cyanides.*—These compounds are easily and completely converted into compound ethers by the action of gaseous hydrogen chloride on their solutions in absolute alcohol; still more readily by the action of sulphuric acid. In this manner the ethylic ethers of acetic, propionic, and benzoic acids are readily obtained (Beckurts a. Otto, *Ber.* ix. 1590).

Preparation of Aromatic Nitrils.—Experiments by K. Scheinberg (*Ber.* x. 746) on the preparation of these bodies have led to the following conclusions: (1). The haloïd compounds of aromatic hydrocarbons react directly with metallic cyanides. (2). Nitrils may be prepared from hydrocarbons and cyanogen gas by direct substitution. (3). Nitrils cannot be prepared from hydrocarbons and the cyanides of the halogen-elements, the reaction yielding nothing but haloïd compounds of the hydrocarbons and hydrogen cyanide.

The experiments were made by passing the vapours of the haloïd compounds in a slow stream over finely pulverised anhydrous *ferrocyanide of potassium*, mixed with a quantity of sand sufficient to prevent melting down, and heated to moderate redness. In this manner, *chloro-* and *bromo-benzene* yielded benzonitril, $C^6H^5.CN$ (at a higher temperature, however; and especially when a gun-barrel was used instead of a glass tube, ammonium cyanide and benzene were formed, with separation of carbon); *di-bromobenzene* yielded a small quantity of benzonitril, together with the nitril of terephthalic acid. A mixture of *ortho-* and *para-chloro-toluene* yielded the corresponding nitrils, convertible into *o-* and *p-*toluic acid; and *bromonaphthalene* at a high temperature yielded α -naphthyl cyanide. It was only in this last case that the yield of nitril was satisfactory; the smallest quantity was obtained in the case of the toluene compounds.

Aromatic nitrils were also produced by heating the corresponding halogen-compounds with excess of metallic cyanide, to 300°–400° in sealed glass tubes, small quantities of ammonia and hydrocyanic acid being also generally formed as secondary products, and in many cases cyanogen gas. Under these circumstances, *potassium ferrocyanide* acts but slowly on *chloro-* or *bromo-benzene*, only 20–22 per cent. of the theoretical amount of benzonitril being obtained after ten hours' heating. Crystallised *bromotoluene* is but very slowly attacked by potassium ferrocyanide; *bromobenzene* and *potassium cyanide* yield a smaller amount of nitril than bromobenzene and the ferrocyanide; *chlorobenzene* and *cyanide of lead* yielded only a small quantity of benzonitril (6·5 per cent. of the theoretical amount), a similar amount was obtained with lead cyanide and *bromo-benzene*, and still smaller amounts by the action of lead cyanide on *parabromotoluene* and *bromonaphthalene*. *Silver cyanide* (mixed with common salt to facilitate its pulverisation) acts on the halogen-compounds above mentioned in the same manner as lead cyanide. *Iodobenzene* and silver cyanide, heated together for ten hours, yielded a quantity of benzonitril from which 26·8 per cent. of the theoretical amount of benzoic acid was obtained; *paraiodotoluene* is less easily attacked; *orthoiodotoluene* behaves like iodobenzene. *Iodonaphthalene* (prepared by the action of iodine dissolved in carbon sulphide on mercury-dianaphthyl) yielded with silver cyanide at 350° large quantities of α -naphthonitril. *Benzene*, *toluene*, and *naphthalene*, heated with mercuric cyanide to 300°–400°, yielded small quantities of the corresponding nitrils.

Benzene-vapour, mixed with excess of cyanogen gas and slowly passed through a red-hot tube filled with fragments of pumice, yielded, with prussic acid, large quantities of benzonitril and small quantities of terephthalonitril; a small quantity of diphenyl, and apparently also of metadicyanobenzene, was formed at the same time (Scheinberg). *Naphthalene* similarly treated yielded large quantities of α -cyanonaphthalene; the α -naphthoic acid prepared therefrom melted at 160°. *Benzene* and cyanogen

bromide, heated together for five or six hours to 220°–240°, are converted partly into hydrogen cyanide and bromobenzene, partly into unctuous masses; *naphthalene* and *cyanogen bromide* yield in like manner bromonaphthalene, boiling at 276°. *Dimethylaniline* and *cyanogen iodide* act on one another at ordinary temperatures with evolution of heat, forming hydrocyanic acid and monoiododimethylaniline, melting at 79°.

Reaction of Nitrils with Aldehydes.—When *benzonitril* is added, with agitation, to strong *sulphuric acid* containing 1–1½ per cent. paraldehyde, ethylenedibenzamide, $\text{CH}_2\text{.CH(NHCOO}^{\text{C}_6\text{H}_5)_2}$, is produced; and in like manner benzonitril and *chloral* yield trichlorethylenedibenzamide, $\text{CCl}_3\text{.CH(NHCOO}^{\text{C}_6\text{H}_5)_2}$. When benzonitril (2 mols.) is diluted with an equal volume of *chloroform*, the mixture treated with strong sulphuric acid, and *methylal* (1 mol.) added, methylenedibenzamide, $\text{CH}_2\text{(NHCOO}^{\text{C}_6\text{H}_5)_2}$, is produced (Hepp a. Spiess, pp. 758, 1813).

Methylenediphenylacetamide, $\text{CH}_2\text{(NH.CO.CH}_2\text{.C}_6\text{H}_5)_2$, is obtained by heating 1 mol. methylal and 2 mols. *α*-tolunitril or benzyl cyanide, $\text{C}_6\text{H}_5\text{.CH}_2\text{.CN}$, first with a mixture of equal volumes of glacial acetic acid and strong sulphuric acid, afterwards with sulphuric acid alone, and pouring the product into water. It forms small needles which melt at 205°, distils almost without decomposition, is nearly insoluble in water, dissolves very sparingly in ether and in ligroin, more readily in carbon sulphide, somewhat abundantly in boiling alcohol and glacial acetic acid. By heating with hydrochloric acid or alcoholic potash, it is converted into phenylacetic acid; with dilute sulphuric acid and manganese dioxide into phenylacetamide (Hepp, *Ber.* x. 1649).

Trichlorethylenediphenylacetamide, $\text{CCl}_3\text{.CH(NH.CO.CH}_2\text{.C}_6\text{H}_5)_2$, obtained by similar treatment from benzyl cyanide and chloral, forms small white needles, which sublime before melting, and are as soluble as the preceding compound in the liquids above mentioned. In like manner are prepared trichlorethylenediacetamide from chloral and acetonitril, and trichlorethylenedibenzamide from chloral and benzonitril (p. 758, Hepp a. Spiess).

NITROBENZILE, $\text{C}_6\text{H}_5\text{(NO}_2\text{)O}_2$. This compound, treated with tin or zinc and hydrochloric or acetic acid, is reduced to amidobenzile, $\text{C}_6\text{H}_5\text{(NH}_2\text{)O}_2$, which crystallises in needles, melts at 94°, and dissolves in 300 pts. of boiling water, very easily in alcohol. The sulphate and oxalate are sparingly soluble and crystallise in needles; the hydrochloride, which is the most soluble of the salts, crystallises in rhombic laminae having a silvery lustre. The platinochloride is unstable.

NITROBENZONAPHTHYLAMIDE. See NAPHTHYLAMINES.

NITROBENZONITRIL. See BENZONITRIL (p. 306).

NITROBENZOYL, $\text{C}_6\text{H}_5\text{(NO}_2\text{)O}$. This name is given by Lippmann a. Hawliczek (*Deut. Chem. Ges. Ber.* ix. 146) to a substance having the composition of nitrobenzoic aldehyde, and occurring in the oil which is formed, together with solid metanitrobenzoic aldehyde (p. 303), by the action of a mixture of nitric and sulphuric acids on bitter almond oil. It is converted by oxidation into benzoic and nitric acids, and therefore probably contains the nitro-group in the side chain:

In accordance with this view of its constitution, it does not exhibit the characters of an aldehyde, and may be separated from admixed bitter almond oil by means of sodium sulphite. It is decomposed by distillation, even under a pressure of 6 lines.

NITROBROMACETANILIDES. See BROMANILINES, under PHENYLAMINES.

NITROBROMANILINES. See BENZENES (NITROBROMAMIDO-), p. 199.

NITROBUTANE. See NITROPARAFFINS, under PARAFFINS.

NITROCARBOL, *syn.* with NITROMETHANE. See PARAFFINS.

NITROCOLOPHTHALIN. See COLOPHTHALIN, under RESINS.

NITROCRESOLSULPHONIC ACID, $\text{C}_6\text{H}_2\text{(NO}_2\text{)(CH}_3\text{)(OH).SO}_3\text{H}$. See CRESOLSULPHONIC ACIDS (p. 583). An acid of this composition is formed, with evolution of nitrogen, by the action of a gentle heat on nitrodiazotoluenesulphonic acid. (See TOLUENESULPHONIC ACIDS.)

NITROETHANE. See PARAFFINS.

NITROGEN. On the Quantivalence of this Element, see AMMONIUM SALTS (p. 74).

Occurrence.—From H. Draper's observations on the solar spectrum (*Sill. Am. J.* [3], xiv. 89), it appears probable that nitrogen exists in the sun.

On the occurrence of Nitrogen in Volcanic Gases, see **VOLCANOS**.

Preparation.—In the preparation of nitrogen by the usual method from ammonium nitrite (iv. 63), W. Gibbs (*Deut. Chem. Ges. Ber.* x. 1387) recommends that the solution of sodium nitrite and ammonium sulphate be mixed with a strong solution of potassium dichromate and heated; the nitrogen is then given off with effervescence and quite free from oxygen-compounds.

On the effect of the *Silent Electric Discharge* on Nitrogen in presence of Water-vapour, see **ELECTRICITY** (p. 727); also on the oxides N^2O and NO (p. 728).

On the *Refractive and Dispersive Power* of Nitrogen and its Oxides, see **LIGHT** (p. 1183). On the *Spectrum* of Nitrogen, see **SPECTRAL ANALYSIS**.

On the *Friction-coefficient* of Nitrogen and its Oxides, see **GASES** (p. 851; compressibility, p. 853).

The *Expansion-coefficient* of Nitrogen, according to the experiments of Ph. Jolly (*Pogg. Ann.* 1874, *Jubelbd.* 82) is 0.0036677.

On the *Liquefaction* of Nitrogen, see **GASES** (p. 857).

Absorption.—Experiments on the absorption of nitrogen by the black decomposition-products of carbohydrates have been made by Déhérain (*Compt. rend.* lxxvi. 1390). The substances experimented on were mixtures of glucose and ammonia, glucose and caustic soda, moist sawdust mixed with lime, old vegetable soil, &c. A mixture of 10 grms. glucose and 40 g. caustic soda absorbed from the air 0.115 g. nitrogen, and from a stream of pure nitrogen 0.072 grm. In these experiments, the oxygen of the air was found to be converted into carbon dioxide, but the nitrogen had entered into combination in such a manner that the substances afterwards gave off ammonia when heated with soda-lime. This absorption of nitrogen takes place even at ordinary temperatures, and is probably of some importance in the nutrition of plants.

According to A. Pagel (*Dingl. pol. J.* ccxxv. 308) humus-substances do not absorb nitrogen from the air. Berthelot finds that under the prolonged influence of feeble electric tensions, such as may be produced by a voltaic battery with its poles unconnected, certain non-nitrogenous organic bodies are capable of absorbing nitrogen; and he thence infers as probable that the tissues and organs of plants under the influence of atmospheric electricity may take up nitrogen from the air and assimilate it as nutriment (*Compt. rend.* lxxv. 173). See also **ELECTRICITY** (p. 728).

On the *Absorption of Nitrogen by Iron*, see p. 1113.

Oxidation.—On the direct oxidation of nitrogen to *nitrous* and *nitric acids*, see Berthelot (*Compt. rend.* lxxxiv. 61).

On the *Heat of Oxidation of Nitrogen*, see **HEAT** (p. 952).

Estimation of Nitrogen in Organic Compounds.—Considerable discussion has taken place respecting the relative accuracy in the estimation of nitrogen attainable by Will a. Varrentrapp's method of combustion with soda-lime, and by the method of combustion with copper oxide and collection of the nitrogen as gas, in the manner recommended by Dumas (i. 242). According to the majority of chemists who have published their experience of the two methods, the soda-lime process, when applied to substances which are difficult to burn, such as albuminoids, meat and other animal matters, or to those in which the proportion of nitrogen is small, as in milk-residues, manures, &c., gives results lower than those which are obtained by the process of Dumas. (See Nowak, *Wien. Akad. Ber.* [2 Abth.], lxiv. 359–376; Seegen a. Nowak, *J. pr. Chem.* [2], vii. 200; *Zeitschr. anal. Chem.* 1874, 460; Kessler, *Pharm. J. Trans.* [3], iii. 328; Bobierre, *Compt. rend.* lxxx. 960; Musso, *Gazz. chim. ital.* 1876, 391, and *Zeitschr. anal. Chem.* 1877, 406; C. Liebermann, *Liebig's Annalen*, clxxxi. 103.) According to Märker, on the other hand (*Zeitschr. anal. Chem.* 1875, 325), the errors in the estimation of nitrogen in gluten and meat by the soda-lime method are insignificant, provided the analysis be conducted carefully and with soda-lime free from magnesia. Ritthausen also (*J. pr. Chem.* [2], viii. 10) finds that this process gives results quite equal in accuracy to those obtained by Dumas' method, provided the substance be finely pulverised and the ammonia be determined, not by titration, but by precipitation as platinumchloride. (See also Kreuzler, *Ber.* vi. 1407; *Jahresb. f. Chem.* 1873, 916.) In the estimation of nitrogen in horn, leather, and wool-refuse, E. A. Grete (*Ber.* xi. 1558) recommends that the substance be dissolved in warm concentrated sulphuric acid before heating with soda-lime, the results thus obtained being higher than those given by the ordinary process.

A modification of Dumas' method is described by A. Dupré (*Bull. Soc. Chim.* [2], xxv. 244), and a modification of Maxwell Simpson's apparatus (i. 243) by W. Hanko (*Ber.* xii. 451; *Chem. Soc. J.* xxxvi. 554).

Nitrogen Iodide is formed on adding iodine to white precipitate in presence of alcohol; but the reaction may be prevented by the addition of a small quantity of

phenol (C. Rice, *Pharm. J. Trans.* [3], vi. 765). According to Champion a. Pellet (*Bull. Soc. Chim.* [2], xxiv. 447), nitrogen iodide explodes in contact with chlorine or bromine.

NITROGEN OXIDES. *Formation.*—Elaborate experiments by Carius (*Liebig's Annalen*, clxxxiv. 1, 31; *Deut. Chem. Ges. Ber.* vii. 1481) have shown that, contrary to the generally received opinion, free nitrogen is not oxidised by ozone in presence of water, either at ordinary or at higher temperatures (120° – 210°), no acids of nitrogen being formed in any case. The alleged formation of aminonitrite by the evaporation of water or the condensation of aqueous vapour in air was tested by causing purified air to stream through water in a retort heated to temperatures ranging from 45° – 100° ; but not the least trace of a nitrogen-acid was formed, even though each experiment was continued for several days.

Schönbein found (1849) that lime-water through which a mixture of nitrogen and ozonised oxygen has been passed contained oxygen-acids of nitrogen. Berthelot, however, points out that lime-water prepared from ordinary lime contains appreciable quantities of calcium nitrate. To avoid this source of error, he passed the same gaseous mixture through pure baryta-water, and found that not a trace of nitrous or nitric acid was produced. On the other hand, he confirms the observation of Schönbein that nitrous acid is formed during the slow oxidation of phosphorus in the air (*Compt. rend.* lxxxiv. 61).

The experiments of Carius have rendered it probable that a principal source of the formation of nitrogen oxides is the oxidation of ammonia by ozone. Electrolytic oxygen containing from 2 to 3.5 v. p. c. of ozone passes through dilute aqueous ammonia for the most part unaltered, appearing, indeed, not to be absorbed by it more than by pure water. If, however, the solution be very dilute (1: 2500), a thick white cloud forms above the liquid, consisting of products of oxidation mixed with excess of ozone; this cloud is especially thick with somewhat stronger ammonia, and disappears only when the ammonia is extremely dilute. The best mode of proceeding is to pour a solution of 0.02 to 0.03 grm. ammonia in 50 c.c. of water into a narrow glass cylindrical vessel, the neck of which forms a narrow glass tube 0.6 met. long, so that the absorption may be promoted by the long column of liquid and the drops of water in the long neck; it is also favoured by cooling with ice. Nevertheless, such an experiment requires the continuation of a stream of richly ozonised oxygen (evolved by 12 to 16 Bunsen's cells) for twenty to thirty hours, inasmuch as the greater part of the ozone passes through unaltered. In this manner a solution is obtained which is mostly very faintly alkaline, but sometimes neutral or even slightly acid.

Numerous and exact experiments have shown that this solution contains nitrous acid, nitric acid, and hydrogen dioxide. The formation of the nitrous acid and hydrogen dioxide may be represented by the equation:

That of ammonium nitrate may be explained in various ways: (1). By a simultaneous further oxidation of the nitrite by the ozone. (2). By the action of hydrogen dioxide on the nitrite. (3). On the assumption that the oxidation of the ammonia partly takes place according to the equation:

The second explanation is perhaps the most probable. Carius was of opinion that the oxidation of ammonia by ozone is perhaps the most important natural source of nitrous and nitric acids. The modes of formation of these acids in nature established by experiment are, according to Carius' investigations, the following:

a. From Free Nitrogen.

- (1). By electric discharge in the air.
- (2). By oxidation of other bodies in the air.

b. Oxidation of Ammonia.

- (1). By electric discharge.
- (2). By the presence of so-called alkaline substances.
- (3). By ozone.

The efficacy of ozone as an oxidiser of ammonia (whereby nitrous acid, nitric acid, and water are produced) was also noticed by Goppelsroeder (*J. pr. Chem.* 1871, [2], iv. 139, 383). On the function of living organisms in promoting the oxidation of ammonia and organic nitrogen in the soil, see NITRIFICATION (p. 1400).

Reduction.—An elaborate research on the reduction of nitric acid and the oxides of nitrogen by various metals has been published by J. J. Acworth and H. E. Armstrong (*Chem. Soc. J.* 1877, xxxii. 54–90). The action of the metal on the nitric acid

Action of Metals on Nitric Acid.

is supposed to consist, in the first instance, in the replacement of the hydrogen of the acid by the metal, and formation of the corresponding nitrate :

the hydrogen, however, not being in any case evolved as gas, but acting on the free acid present, and reducing it more or less completely to nitrous acid, hyponitrous acid, hydroxylamine, and ammonia.

Lastly, the gaseous products which are given off in the solution of metals in nitric acid arise from the decomposition and mutual action of the reduction-products above mentioned. The nitrogen dioxide evolved results chiefly, if not wholly, from the decomposition of nitrous acid :

it is, however, likewise possible that the dioxide may be produced by oxidation of the hyponitrous acid and the hydroxylamine by the nitric acid. The monoxide, N^2O , is produced either by decomposition of the hyponitrous acid, HNO , or by the action of nitrous acid on hydroxylamine. Lastly, the nitrogen which is given off in the free state may be regarded as a product of the action of nitrous acid on ammonia.

The verification of these theoretical deductions requires an exact study of the mutual action of the various reduction-products under all possible conditions; and as a first stage in this extensive research, Acworth and Armstrong have made a special study of the gaseous products of the action of metals on nitric acid, the main results of which are embodied in the table on p. 1407.

Monoxide and Hyponitrous Acid. According to Favre (*Ann. Chim. Phys.* [5], i. 209), the heat evolved in the absorption of nitrogen monoxide by charcoal amounts to 3718 and its heat of liquefaction to 222.2 gram-degrees.

Hyponitrous acid, HNO , which Divers obtained by reducing a solution of potassium or sodium nitrate with sodium-amalgam (vii. 853), is, according to Zorn (*Deut. Chem. Ges. Ber.* x. 1306), more easily prepared by reduction of the nitrite. The resulting solution, after acidulation with acetic acid, gives, with silver nitrate, a greenish-yellow precipitate of silver hyponitrite which, by solution in dilute nitric acid and gradual precipitation with ammonia, is easily obtained of pure yellow colour. It may be dried over sulphuric acid, and may be heated for some time at 100° without alteration. When heated with acetic acid, it is resolved into silver acetate and nitrogen monoxide. It acts on alcoholic iodides, in some cases with violence. According to Van der Plaats (*ibid.* 235), this salt is not decomposed by diffused daylight; it is insoluble in water, and may be boiled therewith without decomposing. It decomposes when heated above 110° , and if it be quickly heated to 150° , the decomposition is accompanied by explosion and emission of brown vapours. It dissolves readily in dilute nitric or sulphuric acid, but is reprecipitated on neutralisation. It is not decomposed by carbonic acid, and caustic soda-ley does not attack it till heated to 70° . It is decomposed by phosphoric acid, acetic acid, hydrogen sulphide, and especially by hydrochloric acid, with liberation of hyponitrous acid, which is thus obtained in the form of a colourless solution having a strong acid reaction, and forming a yellow precipitate with silver nitrate. The solution is moderately stable, and may even be boiled with acetic or nitric acid without decomposing. It colours a mixture of potassium iodide and starch, and reduces permanganate. Strong sulphuric acid decomposes the acid and its silver salt, with evolution of nitrogen monoxide. The same decomposition takes place spontaneously when the aqueous solution is left to itself for a considerable time.

Sodium hyponitrite, $\text{NaNO} + 3\text{H}^2\text{O}$, crystallises in white needles. Its solution gives, with copper salts, a turquoise-blue precipitate; with magnesium, manganese, zinc, barium, strontium and calcium salts, white precipitates soluble in acetic acid; with bismuth, aluminium, lead, tin, and cerium salts, white precipitates insoluble in acetic acid; with cobalt chloride a red, with nickel sulphate a greenish-white, and with mercuric chloride a white precipitate easily changing to brown; with mercurous hydroxide a black, with ferrous sulphate an olive-green, with ferric chloride a yellow precipitate. From gold-solution it reduces the metal; with platonic chloride it forms a reddish-white precipitate. By heating the silver salt with ethyl iodide, an ethyl hyponitrite is obtained (Menke, *Chem. Soc. J.* xxxiii. 401).

Dioxide, NO or N^2O^2 . On the *liquefaction* of this gas, see GASES (p. 857).

A lecture experiment to demonstrate the direct combination of nitrogen dioxide with oxygen, and the reaction of the resulting tri- and tetroxide with water, is described by G. Brühlants (*Deut. Chem. Ges. Ber.* ix. 7; *Chem. Soc. J.* xxxix. 878).

Nitrogen dioxide may be utilised for the regeneration of manganese residues. Manganous nitrate, heated to 200°, leaves a residue of pure manganese dioxide, and if the evolved gases, mixed with a sufficient quantity of air, be passed into precipitated manganous hydroxide, a fresh quantity of nitrate will be produced, which may be decomposed by heat as before, and so on. Nitrogen dioxide is never reduced by manganous hydroxide to the monoxide or to free nitrogen (Kuhlmann, *Dingl. pol. J.* cxxi. 25).

Reaction with Pyrogallol.—Nitrogen dioxide is decomposed by an alkaline solution of pyrogallol, more than 50 per cent. of it disappearing and being replaced by monoxide and free nitrogen. As, however, the same reaction is produced after some time by an alkaline solution of pyrogallol which has become completely saturated with oxygen by prolonged contact with the air, and likewise with potash-ley, as observed by Gay-Lussac,—and, moreover, as even pure water, when heated for a long time with nitrogen dioxide in sealed tubes, effects its conversion into nitrous acid, nitrogen monoxide, and free nitrogen,—and as, on the other hand, pure pyrogallol exerts no action on nitrogen dioxide, it seems probable that the change under consideration is due, not to the alkaline pyrogallate, but to the gradual action of the excess of alkaline hydrate present, or perhaps to that of products formed by the action of oxygen on pyrogallol. For gas analysis, these observations have a practical value, inasmuch as they show that a contraction of volume ensuing on the introduction of alkaline pyrogallol into a measured quantity of air is not necessarily due to the presence of oxygen (Russell a. Lapraik, *Chem. Soc. J.* xxxii. 35).

Trioxide, N²O³. On the formation of this Oxide and of Nitrous Acid and Ammonium Nitrate in the soil, &c. see p. 1406.

On the constitutional formulæ of Nitrogen Trioxide and of the Nitrites, see Günsberg (*Wien. Akad. Ber.* lxxviii. 498; *Jahresb. f. Chem.* 1873, 218).

On the Colouring Matters produced by the action of Nitrous Acid upon Phenol, and on Liebermann's reaction, see vii. 901; viii. 697.

Detection and Estimation of Nitrous Acid.—E. Kopp (*Deut. Chem. Ges. Ber.* v. 284; *Chem. Soc. J.* xxvi. 91) recommends diphenylamine as a test for nitrous acid. To prepare the reagent, pure sulphuric acid is poured over a few crystals of diphenylamine, and a little water is added, whereby a clear solution is obtained which produces with nitrous acid a very fine and permanent blue colour. The reaction is at least as delicate as that with ferrous sulphate.

To detect the presence of nitrous acid in waters, H. Kämmerer (*Jahresb. f. Chem.* 1874, 964) adds to 500 c.c. of the water 1 c.c. of thick starch-paste, a granule of potassium iodide, a pinch of zinc-dust, and finally a quantity of dilute acetic acid (sp. gr. 1·04) sufficient to produce a strong acid reaction. The production of a blue colour indicates the presence of nitrous acid. Sulphuric acid must not be used in place of acetic acid, since it would decompose any nitrates present in the liquid, and the nitric acid thereby set free might be reduced to nitrous acid by organic matter. If, however, nitrous acid is known to be absent, the starch-paste mixture above described may serve for detection of nitric acid by the simple addition of sulphuric acid. According to Fresenius, this method is not sufficiently delicate for the detection of small quantities of nitrous acid in waters; but satisfactory results may be obtained by acidifying the liquid with acetic acid and distilling. The nitrous acid then passes over undecomposed in the first portions of the distillate, and may be determined by permanganate solution. This method has the advantage of insuring the absence of non-volatile compounds, which might decompose the iodised starch.

F. Fischer (*Dingl. pol. J.* ccxii. 404) considers this last method as the most delicate and exact of any that have been proposed for the estimation of nitrous acid in potable waters.

METALLIC NITRITES. Observations on the occurrence of these salts in plants have been made by P. Genadius (*Amer. Chem.* v. 7). The characteristic blue colour with potassium iodide, starch-paste, and sulphuric acid was immediately exhibited by the juice of *Lactuca sativa*, *Lycoperdon esculentum*, *Taraxacum Dens Leonis*, *Dahlia variabilis*, *Batata edulis*; gradually and faintly by that of *Solanum pseudo-capsicum*, *Plantago major*, *Daucus Carota*, *Solanum tuberosum*; not at all by that of *Asparagus officinalis*, *Rheum raphaniticum*, *Vitis labrusca*, *Cannabis sativa*, or *Zea Mays*. The bluing is for the most part produced only by the fresh juice, not by juice a few minutes old; sometimes, however, by juice twenty-four hours old.

Ammonium Nitrite, NH⁴.NO².—Weith a. Weber (*Deut. Chem. Ges. Ber.* vii. Vol. VIII. 4 Y

1745) confirm the statement of Carius that ammonium nitrite is never formed by the direct combination of water and nitrogen. Berthelot finds, however, that this salt is produced when perfectly pure nitrogen gas and water are enclosed between two concentric tubes and subjected to the action of a very powerful Ruhmkorff's coil, but that this effect is not produced by weak electric currents (*Bull. Soc. Chim.* [2], xxvii. 338). Zöller a. Grete (*Deut. Chem. Ges. Ber.* x. 2145) confirm the statement of Schönbein (*Jahresb. f. Chem.* 1862, 94), which was doubted by Bohlrig (*ibid.* 1863, 167) that ammonium nitrite is formed during the combustion of perfectly pure hydrogen in perfectly pure atmospheric air.

On the formation of this salt by oxidation of ammonia, see p. 1406; on its production, together with hydrogen dioxide, when a dilute solution of pyrogallol is exposed to the air, see p. 1071.

Potassium and Sodium Nitrites may be prepared by fusing the corresponding nitrates with equivalent quantities of dried potassium or sodium sulphite:

The cooled mass is pulverised, and the nitrite is purified by extraction with alcohol or by crystallising out the sulphate (Etard, *Bull. Soc. Chim.* [2], xxvii. 434). The sodium salt is recommended by C. Lieber (*Dingl. pol. J.* cxxix. 245) as an antichlor, instead of the thiosulphate, as it has the advantage of not depositing sulphur in the pores of the tissues. 100 parts of it are capable of counteracting the action of 103 pts. of chlorine; 100 pts. of the thiosulphate neutralise 114.4 chlorine.

Lead Nitrites.—The basic nitrites of lead have been examined by F. Meissner (*Jenaische Zeitschrift*, [2], iii. 26). The red salt obtained by boiling 1 pt. normal lead nitrate with 1½ pt. granulated lead and 50 pts. water was regarded by Berzelius as $\text{NO}^{\circ}\text{HPb}^2$ or $4\text{PbO}.\text{N}^{\circ}\text{O}^3.\text{H}^2\text{O}$ (iv. 73). Meissner finds that, after repeated crystallisation from water perfectly freed by boiling from air and carbonic acid, it has the composition $\text{N}^{\circ}\text{O}^2\text{Pb}^2.\text{H}^2\text{O}$ or $3\text{PbO}.\text{N}^{\circ}\text{O}^3.\text{H}^2\text{O}$ or $2\text{PbO}.(\text{NO}^{\circ})^2\text{Pb}.\text{H}^2\text{O}$. The yellow basic nitrite, obtained by digesting 100 pts. lead nitrate with 78 lead, and water at 70° – 75° , has, according to Meissner, the composition $\text{NO}^{\circ}\text{PbH}^3$ or $\text{PbO}.(\text{NO}^{\circ})^2\text{Pb}.\text{H}^3\text{O}$.

Platinum Nitrites.—See PLATONITRITES, under PLATINUM.

ALCOHOLIC NITRITES. NITROUS ETHERS. *Amyl Nitrite*, $\text{NO}^{\circ}(\text{C}^5\text{H}^{11})$.—For the preparation of this ether, A. Hilger (*Arch. Pharm.* [3], iv. 485) recommends passing nitrogen trioxide (from As^2O^3) into amyl alcohol heated to 60° – 70° . The distillate is shaken with weak aqueous potash, then dehydrated and rectified. The pure ether has a pale yellow colour, sp. gr. = 0.902, and boils at 94° – 95° . In contact with the air it easily decomposes, yielding nitrous acid, valeric acid, amyl alcohol, and amyl valerate. According to E. Rennard (*Russ. Zeitschr. Pharm.* 1874, 1), a good yield is obtained by distilling 30 pts. amyl alcohol with 26 pts. potassium nitrite dissolved in 15 pts. water and 30 pts. sulphuric acid.

Propyl Nitrite, $\text{NO}^{\circ}(\text{C}^3\text{H}^7)$, prepared by passing nitrogen trioxide into propyl alcohol, has a fragrant odour, sp. gr. = 0.935 at 21° , and boils at 43° – 46° (Cahours, *Compt. rend.* lxxvii. 749).

Tertiary Butyl Nitrite, $\text{NO}^{\circ}\text{C}(\text{CH}^3)^3$, is formed, together with a small quantity of its isomeride, tertiary nitrobutane, $\text{C}(\text{NO}^{\circ})(\text{CH}^3)^3$, by treating the corresponding butyl iodide with silver nitrite. It is a liquid boiling between 76° and 78° , and slightly soluble in water (Tschemniak, *Deut. Chem. Ges. Ber.* ix. 155).

Tetroxide, NO^2 or N^2O^4 . *Compound with Magnesium Phosphate*, $2\text{PO}^4\text{MgH} + \text{NO}^2$. This compound is prepared by dissolving magnesium pyrophosphate in nitric acid of sp. gr. 1.25; keeping the solution for some time near the boiling heat to convert the pyrophosphoric acid into orthophosphoric acid; then evaporating the liquid on the water-bath; reducing the white gummy fissured acid residue to coarse powder; and heating it for some time to a somewhat higher temperature, best on a paraffin bath, till it has become red-brown and no longer gives off acid vapours. As thus prepared, it is a crystalline powder, whitish-yellow at ordinary temperatures, turning rusty brown when heated, and recovering its whitish-yellow colour on cooling. At a higher temperature it gives off water and nitrogen tetroxide, and leaves magnesium pyrophosphate (E. Luck, *Zeitschr. anal. Chem.* 1874, 255).

Reactions.—Alcoholic iodides are converted by nitrogen tetroxide, with separation of iodine, into the corresponding nitrates, e.g. amyl iodide at 147° – 150° into amyl nitrate, ethyl iodide at 83° – 85° into ethyl nitrate. This reaction tends to confirm the view that liquid nitrogen tetroxide has the constitution $\text{NO}^2.\text{O}.\text{NO}$, and is not easy to reconcile with the formula $\text{NO}^2.\text{NO}^2$:

(L. Henry, *Bull. Acad. Belg.* [2], xxxviii. 1). This view is also in accordance with Exner's observations on the reaction of nitryl chloride with silver nitrite (vii. 855). See, on the other hand, Günsberg (*Wien. Akad. Ber.* [2 Abth.], lxviii. 498; *Jahresb. f. Chem.* 1873, 218).

On the reaction of Nitrogen Tetroxide with *Boron Chloride*, see BORON (p. 342).

On the *Heat of Solution* of Nitrogen Tetroxide, see HEAT (p. 989).

Pentoxide, N_2O_5 . The following modification of R. Weber's method of preparing the pentoxide by the action of phosphoric anhydride on nitric acid (vii. 856) has been proposed by Berthelot (*Bull. Soc. Chim.* [2], xxi. 53). Phosphoric anhydride is added continuously and by small portions to somewhat less than an equal weight of hydrogen nitrate, NO^2H , cooled with ice and salt, care being taken that the temperature of the liquid never rises above 0° ; the thick mass is then introduced into a wide retort through the tubulus, and very slowly distilled, the retort being immediately cooled if the mass shows any tendency to froth over. The nitrogen pentoxide then passes over quite pure, and condenses in the receiver to large perfectly white crystals. Towards the end of the distillation, a small quantity of Weber's hemihydrate, $2\text{N}^2\text{O}_5 \cdot \text{H}_2\text{O}$, passes over. 150 grams of hydrogen nitrate thus treated yielded 80 grams of crystallised pentoxide. The latter may be kept in stoppered glass bottles placed under a bell-jar with sulphuric acid. When exposed to light, it is very quickly resolved into oxygen and the tetroxide.

Nitric Acid, NO^2H . *Occurrence in Rain-water*.—Observations on the quantities of nitric acid and ammonia in the rain-water which fell during the years 1870–71–72 at Florence and at a station on Vallombrosa, a spur of the Tuscan Apennines, 957 meters above the sea-level, have been published by E. Bechi (*Ber.* vi. 1203). The following are the results per hectare of surface :

	Florence			Vallombrosa
	1870	1871	1872	
Quantity of Rain in cubic meters . . .	9284	10789	12909	20278

„ Nitric Acid „ . . .	15728	9153	13057	11726

On the formation of Nitric Acid in nature by the oxidation of Ammonia and its non-formation by the oxidation of free Nitrogen, see p. 1406.

A process for the continuous formation of Nitric Acid from Ammonia by means of oxygen evolved from a mixture of Manganese Dioxide and Caustic Soda, is described by Schwarz (*Dingl. pol. J.* ccxviii. 219; *Chem. Soc. J.* xxix. 878).

On recent Improvements in the Manufacture of Nitric Acid, see H. Göbel (*Dingl. pol. J.* ccxx. 238; *Chem. Soc. J.* xxx. 238).

On the Thermal relations of Nitric Acid and the Nitrates, see HEAT (pp. 952–959, 965, 973, 981, 984, 987, 993, 995).

On the action of Nitric Acid upon *Metals*, see p. 406; on *Lead Chromate*, p. 461.

Detection. 1. With *Ferrous Sulphate*.—F. Bolas (*Chem. News*, xxviii. 248) recommends for the detection of nitric acid and nitrates, the use of a solution of *ferrous sulphate* in strong sulphuric acid, the liquid to be tested being carefully poured upon this solution by means of a pipette. The solution of ferrous sulphate is prepared by mixing the sulphuric acid with 10 v. p. c. of a cold-saturated aqueous solution of ferrous sulphate, and heating it to boiling, in order to decompose any nitrogen-acids that may be present in the sulphuric acid.

2. With *Brucine*.—According to E. Reichardt (*Arch. Pharm.* cxlv. 108), the red colour which brucine produces with nitric acid is distinctly perceptible in a solution of 1 pt. potassium nitrate in 100,000 pts. of water, if to half a drop of the liquid to be tested there be added 1 or 2 drops of brucine-solution, and then gradually from a pipette a few drops of strong sulphuric acid. Böttger (*N. Rep. Pharm.* xxiii. 120) recommends this method for the detection of nitric acid or nitrates in potable waters, &c.

Testing of Nitric Acid for Iodine.—According to A. Hilger (*Arch. Pharm.* [3], vi. 391), the best method of detecting iodine (i.e. iodic acid) in nitric acid, is to dilute the acid with an equal volume of water, agitate it with carbon sulphide, and then add a small quantity of metallic tin. The tin then reduces the nitric acid to nitrogen dioxide and nitrous acid, both of which exert a strong reducing action on the iodic acid.

Estimation. (1). With *Indigo*.—The method given by Marx (vii. 858) for estimating nitric acid in well-water by means of indigo-solution has been modified by F. Fischer (*J. pr. Chem.* [2], vii. 57), in so far that the sulphuric acid is mixed with the indigo-solution and added by drops to the water, till a faint greenish tint is pro-

duced. By this mode of proceeding, the nitric acid is not set free to act on the organic matter in the water before the indigo-solution is added. Fischer also recommends that the standard indigo-solution should be prepared with indigo purified by precipitation or sublimation, as the impurities in commercial indigo interfere with the accuracy of the determination (*Dingl. pol. J.* cxxii. 404; cxxiii. 423).

The following observations on this method have been made by R. Warington (*Chem. News*, xxxv. 45, 57; xxxix. 285).

(1). The maximum amount of indigo is consumed only when a sufficiency of indigo is present with the nitrate before the addition of oil of vitriol. The plan adopted by Marx of mixing the nitrate-solution with twice its volume of oil of vitriol, and then immediately running in the indigo, always consumes less indigo than the nitrate is capable of oxidising. The full amount of indigo can be ascertained only by a series of approximating experiments, in which the oil of vitriol is suddenly added to the previously mixed nitrate and indigo. (2). The amount of indigo required depends greatly on the proportion of sulphuric acid present, and within certain wide limits the amount of indigo is less as the proportion of sulphuric acid is greater. With 10 c.c. of nitre solution 11.3 c.c. of indigo were required, when the indigo and nitre were mixed with their own volume of oil of vitriol; but 8.9 c.c. of indigo were sufficient when two volumes of oil of vitriol were employed. (3). The full amount of indigo is consumed only when the temperature of the mixture remains sufficiently high during the reaction; 100°, 110°, and 120° are given by various writers as the minimum temperature. When the reaction is immediate, artificial heat is unnecessary; but when, through dilution of the nitrate, small volume of the liquid, weakness of the vitriol, &c., the reaction is tardy, the temperature of the flask containing the mixture must be maintained by a paraffin or chloride of calcium bath, or the results will be too low. (4). The true tint of final reaction is a dull brown, which precedes the commencement of green; the brown tint becomes green when suddenly diluted with water. If a solution of sublimed indigotin in sulphuric acid is employed, the tint passes at once from gold to green without an intermediate brown stage. (5). When a nitrate solution is diluted, it apparently requires distinctly less indigo per unit of nitrate if a double volume of oil of vitriol be employed; but if a single volume is used, the difference is very slight, and in the contrary direction. If two volumes of sulphuric acid are employed, the indigo must, therefore, be standardised with nitre solutions of several dilutions to ascertain the value of different parts of the scale. (6). The influence of chlorides is slightly to diminish the indigo required. With .03 to .10 gram of chloride of sodium in 10 c.c. of nitre solution, the reducing effect of 100 chloride of sodium was equal to 1.16 nitre. With much chloride the final tint is a bright green. (7). Some kinds of organic matter have a powerful reducing action. Cane-sugar had a greater effect the larger the proportion of sulphuric acid and the more dilute the nitrate; with a $\frac{1}{10}$ th nitre solution, and a double volume of oil of vitriol, 100 of sugar had a reducing effect equal to 62.3 nitre. The soluble humic matter of soils was apparently without influence, determinations of nitrate in a kitchen garden soil by the mercury method and by the indigo method giving accordant results: only 1 vol. of sulphuric acid was used in this experiment. (8). Nitrites cannot be determined by indigo: they oxidise less indigo than nitrates, and do not give a sharp reaction; they must be converted into nitrates by permanganate before employing the indigo. For details of the experiments on which these conclusions are founded, see *Chem. Soc. J.* xxxv. 578-589.

(2). *Estimation of Nitric Acid as Nitrogen Dioxide by means of its action on Mercury.*—This method, introduced by W. Crum (iv. 88) and improved by Frankland, has also been tested by Warington (*Chem. Soc. J.* xxxv. 375), who finds that, in the absence of organic matter, and with proper manipulation, it is susceptible of great accuracy, and is capable of determining extremely small quantities of nitrates and nitrites. The natural error of the process is one of deficiency. The presence of chlorides in moderate quantity is no hindrance: quantities of organic matter, small in relation to the nitrates present, have little or no effect on the results; larger quantities, especially of cane-sugar, may cause a considerable deficiency, which is reduced, but not entirely removed, by the presence of chlorides.

(3). *By Conversion into Ammonia.*—a. A mode of estimation founded on the conversion of nitric acid into ammonia through the agency of the copper-zinc couple (vii. 454; viii. 568), is given by T. E. Thorpe (*Chem. Soc. J.* xxvi. 541). When a strip of zinc, coated with finely divided copper (p. 568), is immersed in water containing potassium nitrate, no evolution of hydrogen takes place, but a smell of ammonia becomes perceptible and free alkali is produced. The conversion of nitric acid into ammonia thus effected is complete with the nitrates of potassium, sodium, calcium, lead, and probably also with those of silver, mercury, copper, thallium and

all other metals which are reduced by zinc, so that in these cases it may be made the foundation of a quantitative estimation of nitric acid in well-waters, &c. The reduction appears to be most difficult in the case of ammonium nitrate. The result may also be affected by the concentration of the solution and the quantities of zinc and copper employed. If the solution is too strong, nitrogen tetroxide will be evolved, and if the quantities of zinc and copper present are insufficient, the reduction will be imperfect. β . Piuggari (*Compt. rend.* lxxvii. 481) digests the substance under examination (waters, soils, manures) for two or three hours at 50° – 60° with a mixture of silver chloride and potash, whereby the whole of the nitrogen present is converted into ammonia, nitric acid, and nitrous acid, and reduces the two latter completely to ammonia with aluminium-foil and potash. The ammonia is then determined colorimetrically by Nessler's test, or with phenol and sodium hypochlorite. γ . Fr. Gramp (*J. pr. Chem.* [2], xi. 72), from a comparison of the various methods which have been proposed for the estimation of nitric acid, concludes that the conversion of the acid into ammonia by means of sodium-amalgam is the quickest and most exact.

A comparison of the various methods which have been proposed for the estimation of nitric acid, with suggestions for ensuring greater accuracy, is given by J. M. Eder (*Zeitschr. anal. Chem.* 1877, 267–314; *abstr. Chem. Soc. J.* xxxii. 643); also by G. Lunge (*Ber. x.* 1073; *Chem. Soc. J.* xxxii. 642).

On the estimation of Nitric Acid in Chili Saltpetre and commercial Nitrates in general, see F. Jean (*Bull. Soc. Chim.* [2], xxvi. 10; *Jahresb. f. Chem.* 1876, 979).

Valuation of Alkaline Nitrates.—H. Joulie (*Compt. rend.* lxxvi. 230) converts these salts into chlorides by ignition with sal-ammoniac, and determines the chlorine before and after this operation by titration with silver nitrate and potassium chromate. The difference between the two determinations gives the quantity of chlorine which has taken the place of the nitric acid, and this number multiplied by 1.62 gives the amount of nitric acid in the nitrate under examination. In the valuation of sodium nitrate, the weight of the mass after ignition should come very near to that which is obtained by converting the total quantity of chlorine found into sodium chloride. If it comes out more than 0.5 or 0.75 times as great as this number, the foreign ingredients must be determined quantitatively. In the case of potassium nitrate, the quantity of chlorine originally present, reckoned as sodium chloride, and the quantity of chlorine equivalent to the nitric acid reckoned as potassium chloride, should together give a number somewhat smaller than the weight of the ignited mass. Should it be equal to or greater than the latter, the presence of sodium nitrate must be assumed, and a quantitative estimation of the potash must be made.

METALLIC NITRATES.

Ammonium Nitrate, NH_4NO_3 .—G. Tissandier (*Compt. rend.* lxxxii. 388) has described and figured the microscopic appearance of the crystals which remain on leaving rain-water to evaporate. These crystals, which Tissandier regards as ammonium nitrate, exhibit an extraordinary diversity of shape, which he attributes to the simultaneous presence of organic substances, since very dilute solutions of ammonium nitrate artificially prepared leave, on spontaneous evaporation, crystals of only one kind.

Observations on the decomposition of ammonium nitrate by heat have been made by Berthelot (*Compt. rend.* lxxxii. 932). The salt melts at about 152° , but does not begin to decompose rapidly till heated to about 210° . Above this point, the decomposition goes on with increasing rapidity as the temperature rises, and above 300° it becomes explosive. The quantity of nitrogen monoxide evolved in this decomposition is always below that indicated by theory, because a considerable proportion of the salt volatilises undecomposed. Ammonium nitrate may indeed be volatilised without appreciable decomposition by introducing the previously fused salt into a basin covered with filter-paper, and placing above this cover a cylinder of stouter paper filled with coarse fragments of glass. On slowly heating the basin on a sand-bath, not above 190° – 200° , the salt sublimes in beautiful shining crystals, which collect on the sides of the basin or on the lower surface of the paper. Part of it also passes through the filter-paper and condenses in the form of a white deposit. As the temperature of the paper traversed by the salt may rise above 180° without any sign of alteration in the paper, Berthelot infers that the ammonium nitrate in this experiment volatilises as a whole, and is not resolved into nitric acid and ammonia, since the paper could scarcely remain in contact with free nitric acid at so high a temperature without immediate destruction.

The action of ammonia on ammonium nitrate, and the properties of the resulting ammoniated ammonium nitrate have been studied by F. Raoult (*Compt. rend.* lxxvii.

788) with results nearly the same as those obtained by Divers (vii. 859). Ammonia-gas is rapidly absorbed by the nitrate at all temperatures between -15° and $+25^{\circ}$, forming a colourless liquid, the composition of which varies with the temperature; when heated above 25° , it gives off ammonia and solidifies. 100 pts. ammonium nitrate under a pressure of 760 mm. absorb the following quantities of ammonia-gas:

Temperature	NH ³ absorbed	State of Aggregation
-10°	42.56	Liquid
0	35.00	"
+12	33.00	"
18	31.50	"
28	23.25	"
29	20.90	Solid
30.5	17.50	"
40.5	6.00	"
79	0.50	"

At -10° the liquid has the composition $\text{NH}_4\text{NO}_3.2\text{NH}_3$. It does not solidify in a mixture of ice and salt. Sp. gr. = 1.05. It easily gives off ammonia when heated, and the solid compound, obtained by heating it to 28.5° , has the composition $\text{NH}_4\text{NO}_3.\text{NH}_3$. By heating the liquid compound in a sealed bent tube, it is easy to obtain large quantities of liquid ammonia, 1 vol. of the liquid yielding about $\frac{1}{3}$ vol. of the liquefied gas, and leaving a residue of $\text{NH}_4\text{NO}_3.\text{NH}_3$.

Barium Nitrate, $\text{Ba}(\text{NO}_3)_2$.—This salt, as first observed by Scacchi (*Jahresb. f. Chem.* 1860, 13), crystallises in tetartohedral forms, the octohedral faces which occur on it easily splitting up into a predominant and a subordinate octohedron. The stripe-like elevations and corrosion-figures on the cubic faces of the crystals likewise indicate their tetartohedral development (H. Baumhauer, *Zeitschr. Kryst.* i. 51; W. J. Lewis, *Phil. Mag.* [5], iii. 453).

The product of decomposition of this salt by heat consists, according to Rammelsberg, not of barium monoxide, as hitherto supposed, but of a higher oxide, $\text{Ba}^2\text{O}^4 = 2\text{BaO} + \text{BaO}^2$ (p. 143).

Bismuth Nitrates.—The decomposition of these salts by water has been examined by Yvon (*Compt. rend.* lxxxiv. 1164). The crystallised nitrate, formed either with or without excess of acid, or by evaporating the wash-water which has served for the preparation of the basic nitrates, has always the same composition, viz. $\text{Bi}(\text{NO}_3)_3 + 5\frac{1}{2}\text{H}_2\text{O}$. When dried at temperatures above 100° , it gives off nitric acid as well as water, whence probably arise the discordant statements that have been made respecting the amount of water contained in it. When heated for some time in an oil-bath to 120° , it gives off water and acid and leaves a white pulverulent basic salt, $\text{Bi}^2\text{N}^2\text{O}^8 + 1\frac{1}{2}\text{H}_2\text{O}$. The same composition belongs also to the basic salts produced by the action of water or of the carbonates of the alkaline earths on the normal nitrate. The basic salt thus separated dissolves, as is well known, in a very large quantity of water; and Yvon finds that the solution thus formed deposits, in the course of several weeks, small prismatic crystals having the composition $\text{Bi}^2\text{N}^2\text{O}^8 + \frac{1}{2}\text{H}_2\text{O}$. These crystals, according to measurements by Des Cloizeaux (*Compt. rend.* lxxxiv. 1162), belong to the asymmetric or triclinic system. Their principal angles are:

$$\begin{aligned} (110)(1\bar{1}0) \text{ or } \angle P &: \angle P = 57^{\circ} 20'; (001)(110) \text{ or } \angle P &: \angle P = 56^{\circ} 25'; \\ (001)(1\bar{1}0) \text{ or } \angle P &: \angle P = 67^{\circ} 8'. \end{aligned}$$

The plane of the optic axes is exactly parallel to the edge $(110)(100)$ or $\infty P : \infty \bar{P} \infty$. When the basic salt separated by water is repeatedly washed with water or with an alkaline carbonate, the compound $5\text{BiONO}_3.3\text{Bi}^2\text{O}^8 + 5\frac{1}{2}\text{H}_2\text{O}$ is obtained (Yvon). Similar results with regard to the decomposition of normal bismuth nitrate have been obtained by A. Ditte (see CHEMICAL ACTION, p. 427).

Cadmium Nitrate, $\text{Cd}(\text{NO}_3)_2 + 4\text{H}_2\text{O}$.—The sp. gr. of this salt is 2.450 at 14° , and 2.460 at 20° (H. Laws, *Sill. Am. J.* [3], xiv. 281).

Copper Nitrate, $\text{Cu}(\text{NO}_3)_2$.—When a saturated solution of this salt is separated by a diaphragm of parchment-paper from a solution of potassium oxalate, there is formed, on the side of the paper in contact with the latter, a crystalline deposit of potassio-cupric oxalate, while potassium nitrate enters into the copper solution (Becquerel, *Compt. rend.* lxxvi. 245).

Didymium Nitrate, $\text{Di}(\text{NO}_3)_3 + 6\text{H}_2\text{O}$. See DIDYMIUM (p. 643).

Lanthanum Nitrate, $\text{La}(\text{NO}_3)_3 + 6\text{H}_2\text{O}$. See LANTHANUM (pp. 423, 1164).

Lead Nitrates.—The hexplumbic nitrate, $5\text{PbO}.\text{PbN}^2\text{O}^6.\text{H}_2\text{O}$ or Pb^5HNO^6 ,

which Berzelius obtained by precipitating the normal salt with excess of ammonia (iv. 95), may be regarded as a derivative of orthonitric acid, $N(OH)^3$, and represented by the formula :

or in the anhydrous state :

Heated to 170° in a sealed tube with ethyl iodide, it does not yield the corresponding pentethylic nitrate, but is converted, with formation of ethyl oxide and lead iodide, into normal lead nitrate, together with a small quantity of tetraplumbic nitrate (Meissner, *Jenaische Zeitschrift*, [2], iii. zweites Suppl.-Heft. 26).

Mercurous Nitrate is decomposed by hydrogen-potassium sulphide, with precipitation of metallic mercury, the supernatant liquid acquiring a yellow colour from formation of a polysulphide of potassium (J. Myers, *Deut. Chem. Ges. Ber.* vi. 440).

Nickel Nitrate.—A solution of this salt is recommended by H. Emsmann (*Pogg. Ann. Ergänzbd.* vi. 334) as an absorption-preparation. Its spectrum is entirely destitute of the extreme colours, red and violet.

Potassium Nitrate, KNO^3 .—This salt is contained in considerable quantity in the leaves of the castor-oil plant.

On its formation in the soil by the influence of organised ferments, see NITRIFICATION.

Experiments on the function of ferric oxide in the formation of saltpetre have been made by L. Pesci (*Gazz. chim. ital.* 1875, 307). The observation that saltpetre very generally effloresces from walls of ochreous bricks, led to the inquiry whether its formation arose from the oxidation of ammonia by the ferric oxide to which the colour of these bricks is due. It was found that ferric oxide, after being exposed to ammoniacal vapours for about six days, at 20° – 30° , and then exhausted with water, yielded a solution containing both nitric and nitrous acids. That this effect was not due merely to the porosity of the oxide, was shown by the same effect being produced in an atmosphere of carbonic anhydride containing ammonia, with partial reduction of the oxide. The reduction was more abundant when the action took place under a layer of water. The peculiar fertilising effects of composts containing ferric oxide is due to this property of ferric oxide, and for a similar reason ochreous chalk is preferable in forming an artificial nitre bed. Several samples of nitre have been found by Pesci to contain nitrites. The same observation was made by Böttger in 1869, in purified as well as in crude saltpetre.

Silver Nitrate, $AgNO^3$.—Uranous oxide, added to a solution of this salt, throws down metallic silver, the reaction taking place by two stages : first a salt of uranous oxide and argentous oxide is formed, and then the uranous salt is converted into uranyl salt, the colour of the solution changing from green to yellow, and at the same time the argentous oxide is reduced to metallic silver :

Silver is also precipitated from the nitrate, though very slowly, by the oxide U^2O^3 (Isambert, *Compt. rend.* lxxx. 1087).

On the reaction of silver nitrate with *hydrogen*, see vii. 660.

Double Salts.—When a solution of the nitrates of silver and potassium, containing more than an equivalent of silver nitrate, is evaporated, a double salt separates out, having the composition $AgNO^3.KNO^3$. With ammonium nitrate a similar compound is formed, an excess of silver nitrate, however, being unnecessary. With sodium, lithium, and lead nitrates no double salts are formed. On evaporating solutions containing equivalent quantities of silver nitrate and of sodium or lithium nitrate, no double salt is formed, but the silver salt separates out first, though it is much more soluble than the nitrate of the alkali-metal. With lead nitrate, also, no double salt is formed, but the lead salt, which is less soluble than the silver nitrate, is the first to crystallise out.

The crystals of the potassium and ammonium double salts are monoclinic. Axial ratio $a : b : c = 1.405 : 1 : 1.646$. Acute angle of axes = $82^\circ 22'$. Double refraction negative. The optic axes lie in a plane perpendicular to the plane of symmetry, their divergence for red light being about $4^\circ 25'$; for blue light $13^\circ 11'$. Strontium nitrate containing silver nitrate crystallises in cubo-octohedrons (Russell a. Maskelyne, *Proc. Roy. Soc.* xxvi. 357).

Vanadium Nitrate. See VANADIUM.

Zinc Nitrate, $\text{Zn}(\text{NO}_3)_2$.—When nitric acid is treated with a considerable excess of pure zinc, a basic salt is formed having the composition $\text{Zn}^6\text{H}^{16}\text{N}^2\text{O}^{19} = \text{Zn}(\text{NO}_3)_2 \cdot 5\text{Zn}(\text{OH})_2 + 3\text{H}_2\text{O}$. When a neutral solution of zinc nitrate is evaporated to a syrup, the whole solidifies to a vitreous mass, which, when treated with water, is converted, with rise of temperature, into a vitreous basic salt. The vitreous mass has, according to Ordway, the composition $4\text{ZnO} \cdot 3\text{N}^2\text{O}^5 \cdot 3\text{H}_2\text{O}$ or $\text{ZnO} \cdot 3\text{Zn}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$ (iv. 107); according to Bertels, however, it is not of constant composition. The basic salt obtained by treating it with water was found by Bertels to consist of $\text{Zn}^7\text{H}^8\text{N}^3\text{O}^{11} = 4\text{Zn}(\text{NO}_3)_2 \cdot 3\text{Zn}(\text{OH})_2 + 11\text{H}_2\text{O}$ (*Jahresb. f. Chem.* 1874, 274).

NITRIC ETHERS. According to J. Champion (*Compt. rend.* lxxiii. 571, 573; lxxviii. 1150), the nitric ethers of the fatty series may be prepared by the action of a mixture of nitric and sulphuric acids on the corresponding alcohols (vii. 860) or their acid sulphates, the proportions of the acid mixture being varied for the several alcohols. Methyl and ethyl alcohol react best with a mixture of 1 pt. nitric and 2 pts. sulphuric acid; the higher alcohols of the series with 1 nitric to 3 sulphuric acid.

Dichlorhydrin Nitrate, $\text{C}^2\text{H}^3\text{Cl}^2\text{NO}_3$, is formed as an intermediate product of the action of nitric acid on L. Henry's dichlorhydrin, the final product being dichloropropionic acid (p. 876). It is a colourless liquid having a peculiar aromatic odour and sweet taste. Sp. gr. 1.3 at 7°; boiling point 180° (L. Henry, *Deut. Chem. Ges. Ber.* vii. 409).

Ethyl Nitrate, $\text{C}^2\text{H}^5\text{NO}_3$.—G. Berton (*Gazz. chim. ital.* 1876, 406) prepares this ether by a modification of the ordinary process, whereby large quantities of it may be obtained in a short time. 150 c.c. nitric acid of sp. gr. 1.36 are poured upon 10 grams of urea contained in a retort—the acid having been previously heated with a small quantity of urea—and heat is applied till the whole of the urea is dissolved. 150 c.c. alcohol of 92 per cent. are then poured to the bottom of the retort through a long-necked funnel, so that the two liquids may immediately mix. The liquid is then distilled till the greater part has passed over, and the residue is again treated with 150 c.c. of alcohol and acid and distilled. After this second distillation, a further quantity of ethyl nitrate may be obtained by adding 50 c.c. of alcohol and acid, and distilling a third time.

NITROGLYCERIN. See GLYCERIN (p. 875). A comprehensive memoir on this compound has been published by A. Brull in the *Bulletin de la Société d'Encouragement*, 1877, iv. 493, 562.

NITROLIC ACIDS. See NITROPARAFFINS, under PARAFFINS.

NITROMETHYLBENZOPHENONE, $\text{C}^1\text{H}^{11}(\text{NO}_2)\text{O}$. See vii. 861; also TOLYL-PHENYL KETONES in this volume.

NITROPARAFFINS. See PARAFFINS.

NITROPHOSPHENYLIC ACID. See PHOSPHENYLIC ACID.

NITROPROIOPHENONE, $\text{C}^6\text{H}^4(\text{NO}_2)\text{CO} \cdot \text{C}^2\text{H}_5$. See KETONES (p. 1152).

NITROPRUSSIDES. It is commonly stated that these compounds are not attacked by chlorine. According to E. W. Davy, however (*Chem. News*, xxxviii. 105), chlorine does act on them, very slowly under ordinary circumstances, but much more quickly in bright sunshine, under the influence of which it soon decomposes them completely. *Sodium nitroprusside* thus treated is resolved into ferric chloride, sodium chloride, hydrochloric acid, and the compound $\text{C}^2\text{N}^4\text{Cl}^{14}$, known as chlorocyanic oil. The nitroprussides of *potassium, barium, calcium, zinc, iron, manganese, and silver* are attacked in a similar manner, the *copper salt* being the only one which resists the combined action of chlorine and light. Heat, like light, appears to aid the decomposing action.

Sodium Nitroprusside has, according to Clarke (*Sill. Am. J.* [3], xiv. 281), a sp. gr. of 1.6896 at 25°. Schröder found 1.710 and 1.716.

According to Filhol (*N. Rep. Pharm.* xxiv. 242), a solution of this salt, mixed with hydrogen sulphide, is an extremely delicate test for the alkalinity of a liquid, producing a blue-violet colour, not only with free alkalis, but also with alkaline carbonates, borates, phosphates and silicates.

NITROSACETANILIDE, or *Acetylphenylnitrosamine*, $\text{CH}^3\text{CO} \cdot \text{N}(\text{NO})(\text{C}^6\text{H}_5)$, is formed by the action of nitrous acid on acetanilide dissolved in cooled glacial acetic acid:

The reaction, which takes place very nearly in the proportions thus indicated, is com-

plete when the solution exhibits a green colour arising from excess of nitrous acid. The nitrosacetanilide may be purified by solution in glacial acetic acid and precipitation by water. It is a very unstable compound, decomposing, when kept, with evolution of nitrous acid; when boiled with water, it melts and is converted into a greasy mass. It dissolves readily in glacial acetic acid, and the solution, when left to evaporate, deposits crystals which change into a black substance. By quick evaporation of the ethereal solution, slender needles are obtained. With phenol and sulphuric acid, nitrosacetanilide gives Liebermann's colour reactions (vii. 901). It melts at 40° – 41° , and detonates at a higher temperature. Its dust excites sneezing. By reducing agents it is reconverted into acetanilide (O. Fischer, *Ber.* ix. 463; comp. W. Heintz, *ibid.* 1573).

Nitrosacetoparatoluide, $\text{CH}^3\text{C}^6\text{H}^4\text{N}(\text{NO})\text{C}^2\text{H}^3\text{O}$, obtained in like manner, melts with decomposition at 80° , and detonates at a higher temperature (Fischer, *ibid.* x. 959).

NITROSAETOACETATE (ETHYLIC),

formed by the action of nitrous acid upon ethyl acetoacetate, was originally obtained as a heavy yellowish oil, which did not solidify at -25° , but after it had remained liquid for some months, a small quantity of it suddenly crystallised, and, by introducing the crystals thus formed into the liquid acid, a large quantity of it was obtained in the crystalline state. The crystals are hard colourless shining prisms, melting at 52° – 54° to a transparent liquid which is completely decomposed by distillation (Meyer a. Züblin, *Ber.* xi. 320).

NITROSAMARINE, $\text{C}^{21}\text{H}^{17}(\text{NO})\text{N}^2$. See AMARINE (p. 70).

NITROSAUSTRALENE. See NITROSOTERPENES (*infra*).

NITROSETHYLANILINE, $\text{C}^6\text{H}^5\text{N}(\text{NO})(\text{C}^2\text{H}^5)$. See ETHYLANILINES, under BENZENES, AMIDO- (p. 206).

NITROSETHYLPHENYLSEMICARBAZIDE,

See HYDRAZINES (p. 1055).

NITROSINDOL, $\text{C}^{16}\text{H}^{12}(\text{NO})\text{N}^2$. See INDOLE (p. 1090).

NITROSOCHLORIDHESPERIDENE. See NITROSOTERPENES.

NITROSODIETHYLANILINE, $\text{C}^6\text{H}^4(\text{NO})\text{N}(\text{C}^2\text{H}^5)^2$, obtained by the action of amyl nitrite, alcohol, and hydrochloric acid on diethylaniline, crystallises in large prisms melting at 84° , and decomposes at a higher temperature. It dissolves in alcohol and in ether, less easily in water. Its salts are yellow, and dissolve readily in water and in alcohol. It yields addition-products (A. Kopp, *Ber.* viii. 621).

NITROSODIETHYL-CARBAMIDE,

(E. Fischer, *Ber.* ix. 111). This compound, which v. Zotta obtained by treating diethyl-carbamide with alkaline nitrites (*Liebig's Annalen*, clxxix. 101), is more readily obtained in the pure state by passing nitrous acid in excess into an ethereal solution of the carbamide. On leaving the ether to evaporate at a very low temperature, washing the residual oil with water, redissolving it in ether, drying the solution with calcium chloride, and again leaving it to evaporate, an oily residue is left, from which, after long standing in the cold and in a vacuum, nitrosodiethyl-carbamide is deposited in well-defined transparent plates melting at 5° . It is indifferent to acids and alkalis. In contact with phenol and sulphuric acid, it produces Liebermann's dyes (p. 697). By reduction with zinc-dust and acetic acid it is converted into diethylhydrazine-carbamide, $(\text{C}^2\text{H}^5)(\text{NH}^2)\text{N}\cdot\text{CO}\cdot\text{NH}(\text{C}^2\text{H}^5)$. The reduction, which should take place at a temperature not exceeding 20° – 25° , is complete when the liquid no longer becomes turbid on addition of hydrochloric acid and water. On evaporating the filtered solution, mixing it with potash-ley in a cooled vessel, agitating the liquid several times with ether, and evaporating the ethereal extract, diethylhydrazine-carbamide remains in the form of a colourless syrup, easily soluble in water, alcohol, and ether, not altered by boiling with water, decomposing without carbonisation when strongly heated. It has an alkaline reaction, and when dissolved in potash reduces Fehling's solution and platinic chloride. By alkalis, and more easily by heating it in a sealed tube on the water-bath with 3 or 4 pts. hydrochloric acid of

sp. gr. 1.19, it is resolved, with assumption of water, into carbon dioxide, ethylamine, and ethylhydrazine (p. 1061). The *hydrochloride*, $C^6H^{13}N^3O.HCl$, obtained by acidulating its alcoholic solution with fuming hydrochloric acid, and adding ether, crystallises in white slender needles easily soluble in water and in alcohol, less easily in strong hydrochloric acid, and decomposing when heated. The *platinochloride*, $(C^6H^{11}N^3OCl)^2PtCl_4$, crystallises in fine yellow needles.

NITROSODIMETHYLAMINE, $C^2H^6N^2O = (CH^3)^2N=N=O$, also called *Dimethylnitrosamine* and *Nitrosodimethyline*. The hydrochloride of this base is formed by heating a concentrated, acidulated, aqueous solution of dimethylamine hydrochloride with potassium nitrite to $60^\circ-70^\circ$. It is a yellow oil having a peculiar pungent odour, and reduced by zinc-dust and acetic acid to hydrochloride of dimethylhydrazine, $(CH^3)^2N-NH^2$ (p. 1063), (E. Fischer, *Ber.* viii. 1587).

NITROSODIMETHYLANILINE, $C^6H^4(NO).N(CH^3)^2$, also called *Dimethylnitrosaniline*. The preparation of the hydrochloride of this base by the action of nitrous acid on dimethylaniline hydrochloride, as practised by Baeyer & Caro, has already been described (p. 205). C. Schraube (*Ber.* ix. 716) adds 75 pts. amyl nitrite cooled to 0° to an ice-cold mixture of 50 pts. dimethylaniline, 100 strong hydrochloric acid and 600 of a mixture of 1 vol. hydrochloric acid and 2 vols. alcohol.

Nitrosodimethylaniline melts at 85° . Its salts, formed by adding dilute aqueous or ethereal solutions of the respective acids to an ethereal solution of the base, crystallise well for the most part. Especially characteristic is the *neutral oxalate*, which, when recrystallised from wood-spirit, forms brown-red monoclinic crystals containing 2 mols. water.

Addition-products, in large splendid steel-blue crystals, are formed on heating a solution of this nitroso-base in alcohol or benzene with aniline or paratoluidine. The addition-product of *dimethylaniline* and nitrosodimethylaniline crystallises from benzene in dark-green shining crystals which effloresce quickly on exposure to the air. The *phenol-addition-product*, formed by mixing 2 mols. nitrosodimethylaniline and 1 mol. phenol, with addition of water, crystallises in brown slender needles which give off all their phenol at 70° . Nitrosodimethylaniline also unites with *silver nitrate*, forming an addition-product which may be recrystallised from water at 25° , and then forms small dark-blue shining crystals, violet by transmitted light.

Nitrosodimethylaniline is reduced by *tin* and *hydrochloric acid* to phenylene-dimethyldiamine, $N^2H^4(C^6H^4)(CH^3)^2$ (see PHENYLENE-DIAMINES). By *potassium ferricyanide*, or better by *permanganate*, it is oxidised to nitrodimethylaniline, which is a base forming large sulphur-yellow crystals melting at 169° . *Nitric acid* oxidises nitrosodimethylaniline with great violence; nevertheless, it is possible, by careful treatment with dilute nitric acid, to carry the action as far as the formation of dinitrodimethylaniline, which forms large yellow crystals melting at 73.5° , and may be recrystallised from ether-alcohol. With *aniline acetate*, nitrosodimethylaniline forms azophenine, $C^{10}H^{10}N^2O$, together with other products (Kimich, p. 138).

NITROSOFORMANILIDE, $C^6H^3.N(NO)(CHO)$, prepared by the action of nitrous acid on formanilide, melts at 39° (Fischer, *Ber.* x. 959).

NITROSOFURFURINE, $C^{15}H^{11}(NO)N^2O^3$. See FURFURINE (p. 837).

NITROSOGUANIDINE, $CH^4(NO)N^3$. See GUANIDINE (p. 904).

NITROSKETONES (V. Meyer & J. Zübelin, *Ber.* xi. 320, 692). 1. *Methylnitrosomethylketone* or *Nitrosacetone*, $C^3H^5NO^2 = CH^3.CO.CH^2(NO)$, is formed by the action of nitrous acid on the ethylic ether of acetoacetic acid:

To prepare it, ethyl acetoacetate (1 mol.) is added by successive portions to a solution of alcoholic potash (1 mol.); the mixture is diluted with water; a solution of potassium nitrite (1 mol.) is added; the liquid is acidulated with dilute sulphuric acid and again supersaturated with potash; the unattacked ethyl acetoacetate is dissolved out by ether; the alkaline liquid left at rest for three or four days, then again acidulated with sulphuric acid, and several times exhausted with ether; and the greater part of the ether is removed by distillation, the remainder by leaving the solution for several days over sulphuric acid. The product thus obtained is a light yellow oil, which may be made to crystallise by spreading it out on a number of flat-bottomed dishes, and leaving these over sulphuric acid.

Nitrosacetone consists of silvery plates or prisms melting at 65° , easily soluble in ether, and in cold or hot water. It passes over readily with steam, but cannot be distilled alone without decomposition. It has acid properties, and its alkaline solution is intensely yellow; it gives a yellow solution with phenol and sulphuric acid.

2. *Methyl-nitrosoethyl Ketone* or *Nitrosomethylacetone*, $C^4H^7NO^2 =$

$\text{CH}_3\text{CO.CH(ONO)CH}_3$, is formed by the action of nitrous acid on the ethylic ether of methylacetacetic acid :

It crystallises from water in pearly scales, and from its solutions in ether, alcohol, and chloroform in colourless prisms, which melt at 74° . It boils without decomposition at 185° ; and has a vapour-density of 3.51, exactly coinciding with that required by the formula $\text{C}^4\text{H}_7\text{NO}^2$.

3. *Methylnitrosopropyl Ketone* or *Nitroethylacetone*, $\text{C}^6\text{H}^9\text{NO}^2 = \text{CH}_3\text{CO.CH(ONO)(C}^2\text{H}_5\text{)}$, obtained like the preceding, forms colourless crystals easily soluble in alcohol, ether, and chloroform, melting at $53^\circ-55^\circ$.

Both these nitrosoketones give deep red solutions with phenol and sulphuric acid, and a fiery saffranine-red colour when they are dissolved in aniline, and glacial acetic acid is added to the solution.

NITROSOTRIACETONAMINE, $\text{C}^9\text{H}^{16}\text{N}^2\text{O}^2 = \text{C}^9\text{H}^{16}(\text{NO})\text{NO}$ (Heintz, *Liebig's Annalen*, clxxxv. 1; clxxxvii. 233). This compound is formed on mixing the neutral solutions of triacetoneamine hydrochloride and potassium nitrite, and separates after a while in long faintly yellowish crystals, a further quantity of which may be obtained by gently warming the decanted liquid, and then leaving it to cool. Nitrosotriacetoneamine cannot be recrystallised from hot water without loss, as it volatilises with the vapour; but it may be purified by dissolving it in very slightly warmed alcohol, and precipitating it at 50° by gradual addition of water.

Nitrosotriacetoneamine has a specific gravity of 1.14; melts at $72^\circ-73^\circ$; sublimes, though very slowly, below its melting-point; dissolves readily in alcohol and ether, and crystallises therefrom in long needles; is neutral to litmus-paper. By the action of potash, or by prolonged boiling of its aqueous solution, it is resolved into nitrogen, water, and phorone:

When nitrosotriacetoneamine is heated with hydrochloric or strong sulphuric acid, the greater part of it is converted into triacetoneamine; but at the same time four other bodies are formed, viz., two bases—one having the composition $\text{C}^9\text{H}^{16}\text{N}^2\text{O}$ —whose hydrochlorides are sparingly soluble in water, and two substances which exhibit the characters of amido-acids. Nitrous acid does not reduce nitrosotriacetoneamine to amidonitrosamine.

The constitution of nitrosotriacetoneamine may be represented by one of the following formulæ :

NITROSYL-COMPOUNDS. The *Sulphate*, H(NO)SO^4 , or $\text{SO}^2\begin{Bmatrix} \text{OH} \\ \text{ONO} \end{Bmatrix}$ identical with the 'lead-chamber crystals,' is easily prepared by saturating cold strong sulphuric acid with nitrogen trioxide, or by passing sulphur dioxide into nitric acid; most advantageously however by burning a mixture of 1 pt. sulphur with 2.5 to 3 pts. potassium nitrate in moist air (Girard a. Pabst, *Bull. Soc. Chim.* [2], xxx. 531). Tilden prepares it by passing the gases evolved from aqua regia and dried by calcium chloride into cold strong sulphuric acid. It forms long thin prismatic crystals melting at $85^\circ-87^\circ$. When gently heated with dried chloride or bromide of sodium, it yields the corresponding chloride or bromide, NOCl or NOBr ; and with potassium nitrate in like manner it yields nitrogen tetroxide, N^2O^4 , which may therefore be regarded as nitrosyl nitrate, NO.NO^3 (Girard a. Pabst). Compare p. 410.

Nitrosyl Chloride, NOCl , is an orange-yellow gas which condenses in a freezing mixture to a deep yellow liquid boiling at -8° . The density of its vapour was found to be 2.33-2.29 at 10° (air=1), or 33.5-33.0 ($\text{H}=1$); calc. 32.75. The *dichloride*, NOCl_2 , said by Gay-Lussac to be formed, together with other products, by the distillation of aqua regia, was probably a solution of the monochloride in chlorine gas. The reaction between hydrochloric and nitric acids may be represented by the equation

(Tilden, *Chem. Soc. J.* xxviii. 630).

Nitrosyl Bromides.—The *monobromide*, NOBr, prepared like the chloride by distilling nitrosyl sulphate with sodium bromide, is described by Girard a. Pabst as an easily decomposable liquid boiling at 19°. According to Landolt, on the other hand, who prepared it by passing nitrogen dioxide into bromine cooled below -4°, it is a blackish-brown liquid which begins to boil and give off brown-red vapours at -2°, sinks unaltered in very cold water, begins to form bubbles of nitrogen dioxide if heated therein to 14°, and if then stirred with a sharp-edged glass rod or a wire, gives off torrents of gas, being decomposed in the manner represented by the equation

The *tribromide*, NOBr₃, is formed by decomposition of the monobromide, and remains as a dark brownish-red liquid when the temperature is allowed to rise to about 23°. It is also formed by saturating bromine with nitrogen dioxide at ordinary temperatures, and Muir has shown (*Chem. Soc. J.* xxviii. 844) that the compound thus formed has the same composition whether the absorption takes place under the ordinary atmospheric pressure or at any lower pressures down to 250 mm. It has a specific gravity of 2.628 at 22.6°, volatilises almost without decomposition when quickly heated, but is resolved by slow distillation into nitrogen dioxide and bromine (Landolt, *loc. cit.*)

NITROTOLYL-PHENYL KETONES. The *mononitro-derivative*, C¹⁴H¹¹(NO²)O, (*Nitromethylbenzophenone*), obtained by the action of fuming nitric acid on solid paratolyl-phenyl ketone (p. 1154), is identical with that which Milne obtained (*Ber.* v. 683) by heating benzyl-toluene with nitric acid of sp. gr. 1.4. It crystallises from hot alcohol in broad shining laminae or in needles, melts at 126°-127°, and sublimes easily in shining laminae; dissolves readily in chloroform, benzene, and hot acetic acid. When its solution in glacial acetic acid is boiled with *chromic acid*, benzoic and nitrobenzoic acids are produced, the latter melting at 140°, and yielding a barium salt which crystallises with 4H²O. The greater part of the nitro-ketone is however completely burnt, and it has not been found possible to obtain the first product of the oxidation, viz., mononitrobenzoylbenzoic acid (Plascuda a. Zincke, *Ber.* vii. 982). By *tin* and *hydrochloric acid*, the nitroketone is converted into the corresponding amido-compound, which is precipitated from its solution in hydrochloric acid by soda-ley, in the form of a loose white powder. It dissolves readily in alcohol and ether, and forms with acids uncrystallisable salts which dry up to gummy masses (Milne).

Dinitro-tolyl-phenyl Ketone, C¹⁴H¹⁰(NO²)₂O, is formed by boiling dinitrobenzyl-toluene (vii. 183) for a considerable time with nitric acid of sp. gr. 1.4, or by heating its solution in glacial acetic acid with chromic acid. It crystallises from acetic acid in thick yellowish needles, from alcohol in silky laminae; melts at 126°-127°; decomposes without subliming at a higher temperature; and dissolves with moderate facility in benzene and in chloroform, less easily in ether. By oxidation it is converted into paranitrobenzoic acid and dinitrobenzoylbenzoic acid, C¹⁴H⁸(NO²)₂O³, melting at 211°-212° (Plascuda a. Zincke).

Trinitro-tolyl-phenyl Ketone, C¹⁴H⁹(NO²)₃O, obtained by adding solid tolyl-phenyl ketone, or its mono- or dinitro-derivative, to a mixture of nitric and sulphuric acids, crystallises from acetic acid or alcohol in small, yellowish, well-defined prisms; melts at 165°, and decomposes at a higher temperature without subliming (Plascuda a. Zincke).

NOMENCLATURE. Suggestions with regard to Chemical Nomenclature, chiefly with the view of securing uniformity of termination in the names assigned to different classes of compounds, have lately been drawn up by the Council of the Chemical Society, and published in the Journal of that Society (1879, vol. xxxv. pp. 277-280).

The terminations recommended are for the most part the same as those which have been used in this Dictionary (see vol. iv. p. 133); but attention may be especially directed to the recommendation respecting the use of the terminal '*ol*' for all hydroxyl-derivatives of hydrocarbons, in other words for all compounds of alcoholic character, and its absolute restriction thereto. Thus glycerin, erythrite, mannite, hydroquinone, resorcin, pyrocatechin, saligenin, are in future to be called glycerol, erythritol, mannitol, quinol, resorcinol, catechol, saligenol; and, on the other hand, the ethers of the phenols, *e.g.* C⁶H⁵.OCH³, C⁶H⁵.OC²H⁵, &c., hitherto called anisol, phenetol, &c., are to be designated as anisoil, phenetoil, &c.; and certain aldehydes, hitherto denoted by names ending in *ol*, are to be designated, like aldehydes in general, *e.g.* the so-called furfural as furfuraldehyde or furfural. Other compounds which are

not alcohols, but have hitherto been known by names ending in *ol*, may be represented by names ending in *ole*—*e.g.* indole instead of indol. The hydrocarbon C^6H^6 and its homologues, sometimes called benzol, toluol, &c., are to be called benzene, toluene, &c.

Another point deserving of special remark is the use of the terminations *ine* and *in*, the former for organic bases, ethylamine, aniline, toluidine, quinine, morphine, &c., the latter for certain neutral compounds. *viz.* glycerides, glucosides, bitter principles, and proteids, *e.g.* palmitin, amygdalin, albumin, casein,* &c.

NONTRONITE. A mineral resembling nontronite (iv. 134) has been found by A. Schrauf (*Jahrb. f. Min.* 1877, 255) in the Wenzel shaft at Mugrau in Bohemia, forming layers of lenticular nodules alternating with graphite. Under the microscope it appears to be made up of irregular, semitransparent laminae, exhibiting slight double refraction. The amount of water varies considerably. The following analyses relate to material well dried in the air; the powder, after drying over sulphuric acid, gave 13.59 per cent. water; after exposure to moist air, 22.02 per cent.

SiO ²	Fe ² O ³	Al ² O ³	CaO	MgO	H ² O
43.98	27.50	4.16	2.97	1.77	19.62 = 100
42.93	28.91	3.19	3.35	2.84	18.32 = 99.54

These analyses may be represented by the formula:

NONYLACETYLENE, or *Rutylidene*, $C^{11}H^{20} = (C^9H^{19})C \equiv CH$, is formed from the methyl-nonyl ketone which is the chief constituent of rue-oil (vii. 808), by treating this ketone with PCl^3 , and abstracting 2 mols. HCl from the resulting chloride, $CH^3.CCl^2.C^9H^{19}$, by the action of potash. It is an oily liquid, boiling at 215° – 220° , and forming with ammoniacal silver-solution a white precipitate, $C^{11}H^{19}Ag$, with copper-solution a yellow-brown precipitate (Bruylants, *Ber.* viii. 406, 410).

NORTON'S SALT, $PtCl^4OH^2$. See PLATINUM CHLORIDES.

NOSEAN-ANDESITE. See ISENITE (p. 1125).

NOSEAN-PHONOLITE. A specimen of this rock from Hohentwiel in Högau has been analysed by J. Bernath (*Jahrb. f. Min.* 1877, 740):

A. Fresh rock; 55.9 per cent. soluble, 44.1 per cent. insoluble. B. Weathered; 39 per cent. soluble, 61 per cent. insoluble.

SiO ²	Al ² O ³	Na ² O	K ² O	CaO	H ² O	Fe ² O ³	FeO	MgO
55.214	21.782	10.637	3.475	2.097	2.069	2.061	2.006	0.127 = 99.468
55.842	19.871	8.058	6.231	—	3.874	2.583	1.549	1.810 = 99.818

Moreover, in A, 0.546 per cent. SO^2 , 0.074 Cl. In both, traces of manganese, titanium, and lithium. Sp. gr. of A = 2.54; of B, 2.41.

NOVACULITE. An analysis, by C. E. Wait, of this material, also called *Ouachita Whetstone*, from Hot Springs, Arkansas, has been published by J. W. Mallet (*Chem. News*, xxviii. 272):

SiO ²	Al ² O ³	MgO	Na ² O	Sp. gr.
99.635†	0.113	0.087	0.165 = 100	2.649

The mass, of which a small proportion is soluble in caustic soda, is essentially a cryptocrystalline quartz containing, in addition to the above constituents, traces of potassium and iron.

NUCIN. This substance, also called *Juglone*, which Vogel a. Reischauer obtained from the green shells of walnuts (iv. 143), has been analysed, together with the copper-compound obtained by precipitating its alcoholic solution with cupric acetate, by Reischauer (*Deut. Chem. Ges. Ber.* x. 1542), who finds it to have the composition $C^{26}H^{12}O^{10}$.

NUCITE. A variety of glucose, obtained from the leaves of the nut-tree.

NUCLEIN (iv. 143; vii. 862). This substance has been found in the human brain to the amount of 1.4 pts. in a thousand (Geoghegan, *Zeitschr. physiol. Chem.* i. 330); in the spermatie chords of the salmon, to the amount of 48.7 per cent., united with an organic base called *protamine* (Miescher, *Ber.* vii. 376); and in the casein of cows' milk (Lubavin, *ibid.* x. 917). Pure nuclein from this last mentioned

* This distinction was suggested many years ago, by Dr. Hofmann, and has been uniformly observed in this Dictionary; but many writers unfortunately neglect it, and use the two terminations indiscriminately.

† Determined by difference.

source may be obtained by digesting commercial casein (previously freed from fat in an extraction-apparatus) with artificial gastric juice at 40°; washing the undissolved residue with hot and cold water; then dissolving it in a 1 per cent. solution of sodium carbonate; precipitating the filtered solution with weak hydrochloric acid; and washing the precipitate with water, alcohol, and ether in succession. That nuclein is not a phosphate of casein is inferred by Lubavin from the following facts: When a solution of nuclein in excess of sodium carbonate is dialysed, the diffusate does not exhibit a trace of phosphoric acid till decomposition has set in. Nuclein cannot be prepared synthetically from casein and sodium phosphate; from a solution of casein in that salt, magnesia-mixture throws down the whole of the phosphoric acid, whereas the phosphoric acid of nuclein is not precipitated by similar treatment. When a solution of casein in aqueous sodium phosphate is mixed with 1 per cent. hydrochloric acid, the precipitate formed by the first drops of acid disappears on further addition, and the resulting solution gives a precipitate when cautiously neutralised with ammonia or mixed with solution of common salt or sal-ammoniac. Lubavin regards nuclein as a mixture of at least two distinct compounds, inasmuch as the partial precipitates obtained from its solution in sodium carbonate by successive addition of equal amounts of hydrochloric acid differ from one another in composition, and the precipitates formed by successive addition of equal amounts of hydrochloric acid, likewise differ in quantity. The isolation of the chemically distinct individuals existing in nuclein has not yet been accomplished. Nuclein has a marked acid character; it reddens litmus and decomposes carbonate and even acetate of sodium. The solution of nuclein in sodium acetate gives precipitates with zinc, copper, and lead salts; the lead precipitate is white, granular, and easy to wash. The precipitation of nuclein by lead acetate is not complete, and fractional precipitation yields precipitates containing different quantities of lead (Lubavin).

Digestibility.—From experiments by A. Bókay (*Zeitschr. physiol. Chem.* i. 157), it appears that nuclein is not attacked by any of the digestive ferments, and that it is probably a constant constituent of fecal matters, since it is present in nearly all kinds of food.

NUX VOMICA. According to C. Bullock (*Pharm J. Trans.* [3], v. 326), the oil of *Nux vomica*, separated in the preparation of the extract, contains both strychnine and brucine.

O.

OBSIDIAN. Obsidian from Antisana has been found by G. vom Rath (*Zeitschr. geol. Ges.* xxvii. 295) to contain:

SiO ²	Al ² O ³	Fe ² O ³	CaO	K ² O Na ² O	H ² O	Sp. gr.
77.76	13.14	1.47	0.63	7.00	0.24 = 100.24	2.320 at 10°

An analysis by J. A. Cabell of the outer crust of a mass of obsidian from Lipari, which had been exposed to the action of volcanic vapours, has been published by J. W. Mallet (*Chem. News*, xxviii. 272):

SiO ²	Al ² O ³	CaO	Fe ² O ³	Fe ² Cl*	H ² O*	H ² O†	Sp. gr.
93.46	0.37	0.74	0.37	0.15	4.55	0.08 = 99.72	2.062

Tumefaction of Obsidian by Heat.—Obsidian when strongly heated swells up suddenly, and is converted into pumice. This result is attributed by Boussingault a. Damour (*Compt. rend.* lxxvi. 1158; *Ann. Chim. Phys.* [4], xxix. 543; *Chem. Soc. J.* xxvi. 856) to a sudden disengagement of vapours of water and hydrochloric acid, the latter resulting from the action of the silicates on the chlorides contained in the mineral. The following are some of the analytical data on which this conclusion is founded:

A. Loss on ignition. B. Direct estimation of the water. C. Of the hydrochloric acid. D. Amount of chlorine reckoned as HCl. E. After fusion. The whole of the values are calculated in percentages of the substance experimented on.

* Above 100°.

OCTAMINE COBALT-COMPOUNDS. See COBALT (p. 546).

OCTANE, C^8H^{18} . The octane obtained by the action of zinc and hydrochloric acid on methyl-hexyl-carbinyl iodide, $(CH^3)CHI(C^6H^{13})$ (from castor-oil alcohol, vi. 877), has the same boiling point (124°) and sp. gr. (0.7083 at 12.5°) as that which is produced by the action of sodium on normal butyl iodide (vii. 867); it is, therefore, normal octane, $CH^3(CH^2)^6CH^3$; and this conclusion is in accordance with the fact that the methyl-hexyl carbinol from castor-oil is converted by oxidation into normal caproic acid (Schorlemmer, *Chem. Soc. J.* [2], xii. 1029).

An octane, perhaps identical with the preceding, is obtained, together with other paraffins, among the products of the distillation of fatty acids with overheated steam (Cahours a. Demarçay, *Compt. rend.* lxxx. 1568).

Di-isobutyl, $(CH^3)_2CH.CH^2.CH^2.CH(CH^3)_2$. This is the octane which Kolbe obtained by the electrolysis of potassium valerate, and Wurtz by the action of potassium or sodium on isobutyl iodide (v. 731). Schorlemmer (*Proc. Roy. Soc.* 1876, 34) obtained it by the action of sodium on a mixture of the iodides of isopropyl and isopentyl (amyl); and it has lately been further investigated by W. Carleton-Williams (*Chem. Soc. J.* 1877, xxxi. 541; 1879, xxxv. 125), who prepares it by the action of sodium on isobutyl bromide, and purifies it by leaving it in contact for several hours with strong sulphuric acid, then washing it with water, leaving it over solid caustic potash for two or three days, and finally subjecting it to fractional distillation.

Pure di-isobutyl thus obtained boils, under a pressure of 745 mm. (reduced to 0°), at 108° – 108.3° (mercury-column wholly in the vapour), remains liquid at -17° , and exhibits the following densities at different temperatures:

t .	Sp. gr.	t .	Sp. gr.
0°	0.7091	30°	0.686
0°	0.7085	40°	0.677
10°	0.7015	50°	0.669
20°	0.6931	100°	0.626

These results agree closely with those obtained by Kopp (v. 731). The vapour-density, determined by Victor-Meyer's process (*Ber. x.* 2068), was found in two experiments to be 57.64 and 58.51; calc. 57 ($H = 1$).

An examination of the refractive power gave the following results:

	Potassium (red line)	Lithium	Sodium	Thallium	Strontium (blue line)
Refractive indices at $16^\circ = \mu$	1.3901	1.3917	1.3943	1.396	1.4008
Refractive energy $\frac{\mu-1}{d}$	0.5591	0.5618	0.5655	0.568	0.5748
$d = 0.6972$ at 16°					
Refraction equivalent, $P \frac{\mu-1}{d}$ (vi. 783.)	63.78	64.04	64.47	64.75	65.55

On the assumption that $C = 5$ and $H = 1.3$, the calculated refractive equivalent for di-isobutyl is 63.4.

Di-isobutyl has no action on polarised light.

On the action of *chlorine* on di-isobutyl, see p. 1425.

OCTOBROMOMETHYL OXIDE, $(C^8HBr)^2O$, is formed, together with other products, by heating ethylidene oxychloride (p. 757) with bromine for ten hours at 100° , 150° – 190° , and 190° – 210° , till it begins to carbonise. The syrupy product, when redistilled, separates into three portions, the first of which (b. p. 130° – 190°) contains the octo-brominated ether. This compound is a thickish liquid having an odour of perspiration, fuming very slightly in the air, insoluble in water, but decomposing when left in contact therewith at ordinary temperatures, more quickly on boiling (F. Kessel, *Ber.* x. 1667).

OCTOIC ACIDS, $C^8H^{16}O^2 = C^8H^{15}.COOH$. (1). The identity of the iso-octoic acid, $(CH^3)^2CH.(CH^2)^4.COOH$, obtained by oxidation of isoprimary octyl alcohol, with caprylic acid prepared by saponification of cocoa-nut oil, has been already noticed (p. 379).

(2). Another iso-octoic acid, $(CH^3)^2CH.CH^2.CH^2.CH < \begin{smallmatrix} CH^3 \\ COOH \end{smallmatrix}$, formed by oxidising the corresponding alcohol from di-isobutyl with chromic acid mixture, is an oily liquid, which boils at 218° – 220° under 767 mm. pressure (reduced), and does not solidify at -17° . It is soluble in alcohol and in ether, and sparingly soluble in water, 100 c.c. of water at 15° dissolving 0.15 gram of the acid. At the ordinary temperatures it has an unpleasant odour, which becomes much more powerful at higher temperatures, when it somewhat resembles that of rotten cheese. The sp. gr. of the acid compared with water at 4° is:

At 0°	0.926	40°	0.893
„ 20°	0.911	50°	0.885
„ 30°	0.903	100°	0.846

The *sodium salt*, prepared by neutralisation, remains, after evaporation over sulphuric acid, as a deliquescent gummy mass, which begins to crystallise after standing for several days over sulphuric acid in a vacuum. The *potassium salt* is a semi-crystalline deliquescent mass. The *silver salt*, $C^8H^{15}AgO^2$, is a white curdy precipitate, slightly soluble in boiling water, and separating on cooling in silky threads or small tooth-shaped crystals. The *calcium salt*, $(C^8H^{15}O^2)_2Ca + H^2O$, prepared by neutralising the acid with milk of lime, may be obtained by spontaneous evaporation in radiate groups of well-formed crystalline plates. It is more soluble in cold than in warm water, a solution saturated at 15° becoming turbid at 37° ; the density of the precipitate increases with the temperature, and the salt redissolves on cooling. The *barium salt*, prepared by boiling barium carbonate in the acid, is uncrystallisable and remains as an amorphous pellicle on leaving the solution to evaporate in a vacuum. The *strontium salt* may be prepared by neutralisation, and is precipitated on mixing the concentrated solutions of strontium nitrate and potassium iso-octoate. It dissolves freely in absolute alcohol, and is deposited from the alcoholic solution in transparent six-sided plates, which appear to belong to the monoclinic system, and to consist of a combination of the basal terminal plane with the clinodagonal and orthodagonal domes. The salt is slightly less soluble in hot than in cold water, a solution saturated at the ordinary temperature becoming slightly turbid when heated. From an aqueous solution it is deposited in transparent needle-shaped crystals, which effloresce and grow opaque on exposure to the air. The *magnesium salt*, $(C^8H^{15}O^2)_2Mg + 2H^2O$, prepared by neutralisation, is a transparent, deliquescent, non-crystalline mass, which slowly becomes opaque and crystalline when left in a vacuum over sulphuric acid. The *zinc-salt* is a white pearly mass, which is decomposed by water, but dissolves in the dilute acid.

The concentrated solution of the potassium salt produces in a solution of *mercuric chloride* a faint turbidity; with *mercuric nitrate* no precipitate; with *mercurous nitrate* a dense white precipitate, which is soluble in hot water and crystallises out again on cooling. *Lead acetate* and *manganese nitrate* form amorphous precipitates insoluble in water. *Cupric acetate* throws down a green precipitate, insoluble in water, but soluble in alcohol, forming a green solution, from which the copper salt is deposited in minute green plates, which are generally arranged together in pyramidal clusters (W. C. Williams, *Chem. Soc. J.* xxxi. 542; xxxv. 128).

Ethyl Isoctoate, $C^8H^{15}O^2.C^2H^5$, obtained by saturating an alcoholic solution of the acid with hydrochloric acid gas, is lighter than water, has a strong characteristic odour, and boils at about 175° . Vapour-density obs. 84.39; calc. 86.

Di-isobutyl Isoctoate, $C^8H^{15}O^2.C^4H^9$, formed in small quantity in the preparation of the acid by oxidation of the primary alcohol, is a colourless liquid, lighter than water, and boiling at 278° – 281° . It is slowly saponified by heating to 120° in sealed tubes with alcoholic potash (Williams).

(3). A third iso-octoic acid, probably having the constitution

$(\text{CH}_3)_2\text{CH}_2\text{CH} \begin{smallmatrix} \text{CH}^* \\ \text{COOH} \end{smallmatrix}$ is produced by oxidation of isodibutylene (p. 1130). It is a colourless oily liquid, smelling like trimethylacetic acid, and distilling with partial decomposition at 205° – 218° , the greater part passing over at about 215° (Butlerow).

OCTYL ALCOHOLS AND ETHERS. (1). Several derivatives of the iso-primary octyl alcohol, $(\text{CH}_3)_2\text{CH}(\text{CH}_2)_4(\text{CH}_2\text{OH})$, obtained by saponification of the volatile oil of *Heracleum sphondylium* and *H. giganteum* (vi. 878; vii. 868; viii. 1027), have been examined by W. Möslinger (*Deut. Chem. Ges. Ber.* ix. 998).

Isocetyl iodide, $\text{C}^8\text{H}^{17}\text{I}$, is best obtained by passing dry hydrogen iodide into octyl alcohol to saturation, and afterwards heating the liquid to 100° in closed vessels. The product contains 90 per cent. of pure octyl iodide boiling at 218° – 222° .

Isocetyl oxide, $(\text{C}^8\text{H}^{17})_2\text{O}$, was obtained by mixing equivalent quantities of sodium octylate (formed by the action of sodium on octyl alcohol) and isocetyl iodide, and heating the mixture to 100° for some time. It is a transparent oily-looking liquid, of specific gravity 0.805 at 17° , and boiling at 280° – 282° .

Isocetyl-ethyl ether, $\text{C}^8\text{H}^{17}\text{O.C}_2\text{H}_5$, formed by heating together equivalent quantities of sodium octylate and ethyl iodide, is a colourless mobile liquid of agreeable odour, boiling at 182° – 184° . Sp. gr. 0.794 at 17° ; vapour-density, 78.79.

Isocetyl sulphide, $(\text{C}^8\text{H}^{17})_2\text{S}$.—Isocetyl chloride and potassium sulphide in alcoholic solution rapidly decompose each other when heated together. The isocetyl sulphide thus formed is a slightly yellow mobile liquid having a peculiar alliaceous odour and boiling with decomposition above 310° . Sp. gr. 0.8419 at 17° . It forms a crystalline compound with mercuric chloride.

Barium Isocetylsulphate, $(\text{C}^8\text{H}^{17}\text{SO}_4)_2\text{Ba}$, formed by carefully mixing equal weights of pure strong sulphuric acid and isocetyl alcohol, and after 24 hours neutralising the mixture with barium carbonate, crystallises in thin pearly laminae, which decompose at 100° , giving off isocetylene. The salt is very sparingly soluble in water.

Potassium Isocetylsulphate, obtained by decomposing the barium salt with potassium sulphate, is a white indistinctly crystalline mass, soapy to the touch, and easily soluble in water.

Isocetyl-phosphine, $\text{C}^8\text{H}^{17}\text{PH}_2$.—This body is formed when a mixture of phosphonium iodide, isocetyl iodide, and zinc oxide is heated to 160° – 180° in sealed tubes. It is a transparent mobile liquid, highly refractive, and having the powerful, stupefying odour of all phosphines. Its boiling-point is 184° – 187° ; sp. gr. 0.8209 at 17° . It absorbs oxygen from the air, but only slowly, the process going on for several days. The substance thereby formed is an acid intermediate between isocetyl-phosphine and the corresponding phosphinic acid, and hence may be termed *Isocetyl-phosphinous acid*. Its silver salt is a white curdy precipitate, which is reduced by heat.

Isocetyl-phosphine in the pure state is very violently attacked by fuming nitric acid, but when it is diluted with glacial acetic acid, the action proceeds quietly, the product being isocetyl-phosphinic acid, a body which dissolves in hot glacial acetic acid and separates as the solution cools in a spermaceti-like mass. Isocetyl-phosphine is easily soluble in alcohol, benzene, and chloroform, but insoluble in water and in sulphuric, nitric and hydrochloric acids, with which it does not combine. It forms, however, a solid compound with hydriodic acid.

(2). The following derivatives of the secondary octyl alcohol, $\begin{smallmatrix} \text{CH}_3 \\ | \\ \text{C}^6\text{H}_{13} \end{smallmatrix} \text{CHOH}$ from castor oil (vi. 879; vii. 868) have been prepared by Hans Jahn (*Ber.* viii. 803). The *thiocarbimide*, $\text{CS}=\text{N}-\text{C}^6\text{H}_{13}$, formed from the corresponding amine, $\text{H}_2\text{N.C}^6\text{H}_{13}$, by Hofmann's reaction (p. 606), is a colourless liquid boiling at 234° , and converted by prolonged contact with ammonia into *octyl thioisinnamine*, $\text{NH}_2\text{CS.NH.C}^6\text{H}_{13}$, which crystallises in colourless laminae nearly insoluble in water, more soluble in alcohol and in ether, melting at 112.5° . The corresponding *octylamine*, $\text{C}^8\text{H}_{18}\text{N}$, obtained by treating the thiocarbimide with sulphuric acid, forms a platinochloride, $(\text{C}^8\text{H}_{18}\text{N.HCl})_2\text{PtCl}_4$, which crystallises in laminae having a golden lustre. The *normal thiocyanate*, $\text{CN.S.C}^6\text{H}_{13}$, prepared by heating an alcoholic solution of potassium thiocyanate with the secondary octyl iodide in a reflux apparatus, then precipitating with water, washing, drying, and rectifying, is a liquid smelling like conine and boiling at 142° .

(3). A mixture of iso-primary and iso-secondary octyl chlorides (boiling at 179° – 180°) is produced by passing chlorine into the vapour of boiling di-isobutyl in diffused daylight. On heating this mixture of chlorides with potassium acetate and glacial acetic acid, there is formed—together with an octylene boiling at 122° , and having a density of 0.7526 at 16° —a mixture of acetates (b. p. 193° – 205°),

from which by saponification with potash there is obtained a mixture of primary and secondary octyl alcohols distilling between 175° and 187°, and yielding by oxidation the iso-octioic acid above mentioned (p. 1424), together with a ketone. The formulae of the two alcohols are:

(W. C. Williams, *loc. cit.*)

The *iso-primary alcohol* has a pleasant orange-like odour, and a hot burning taste, remains liquid at -17°, and boils at 179°-180° under 765 mm. pressure (not reduced). It dissolves in alcohol, ether, and chloroform, sparingly in water, and is separated by water from the alcoholic solution. Its specific gravity compared with that of water at 4° was determined at the following temperatures:—

0°	·	·	·	·	0·841	40°	·	·	·	·	0·814
12°	·	·	·	·	0·833	50°	·	·	·	·	0·807
20°	·	·	·	·	0·828	100°	·	·	·	·	0·767
30°	·	·	·	·	0·821						

Its vapour-density (H=1) was found by experiment to be 66·02; by calculation 65·0.

The *iso-secondary alcohol* is obtained in much smaller quantity, and is much more difficult to separate from traces of undecomposed chloride. It boils at 160°-163° under 755 mm. pressure, and remains liquid at -17°. It differs from the *iso-primary alcohol* by having a fainter smell, a lower specific gravity, and a larger coefficient of expansion.

Temperature	·	·	·	15°	30°	40°	50°
Sp. gr.	·	·	·	0·820	0·811	0·801	0·793

Vapour-density (H=1); exp. 65·38; calc. 65·0.

The ketone, $\text{C}^8\text{H}^{16}.\text{CO}.\text{C}^8\text{H}^{16}$, formed by oxidising the secondary alcohol with a cold mixture of potassium dichromate and sulphuric acid, has a density of 0·865 at 14°, and boils under 743·1 mm. pressure at 159°-161°. It remains liquid at -17°, and does not form a crystalline compound with acid sodium sulphite. The chief product of its oxidation is acetic acid, but a small quantity of a higher acid, probably isobutyric acid, is formed at the same time (Williams).

(4). Another *iso-secondary octyl alcohol*, probably having the constitution $(\text{C}^2\text{H}^5)_2\text{CH}.\text{CHOH}.\text{C}^2\text{H}^5$, is formed by treating bromoacetyl bromide with zinc-ethyl and decomposing the product with water. It is slightly soluble in water, remains liquid at -30°, and boils at 164°-168° (Winogradow, *Liebigs Annalen*, xcxi. 125).

OCTYLENES, C^8H^{16} . An octylene is obtained, together with iso-octyl acetate, when the mixture of chlorides resulting from the chlorination of octane (p. 1425) is heated to 200° in sealed tubes with potassium acetate and glacial acetic acid. On extracting the contents of the tubes with water, drying the resulting liquid over potassium carbonate, and subjecting it to fractional distillation, one-third passed over below 130°, the remainder, consisting of iso-octyl acetate, at 193°-205°. The lower fraction, treated with potash to remove traces of the acetate, yields octylene, having a density of 0·7526 at 16°, and boiling at 122° (Williams).

An octylene is also obtained, together with other hydrocarbons, by the action of dilute hydrochloric acid on spiegeleisen (p. 1064).

CENANTHOL, $\text{C}^8\text{H}^{18}.\text{CHO}$. See HEPTOIC ALDEHYDE (p. 1022).

CENANTHYLIC or NORMAL HEPTOIC ACID, $\text{C}^8\text{H}^{16}\text{O}_2 = \text{CH}^3(\text{CH}^2)_5.\text{COOH}$. Several derivatives of this acid have already been described under HEPTOIC ACIDS (pp. 1021, 1023). The following have been obtained by A. Helms (*Ber.* viii. 1167).

Monobromocenanthylic acid is formed by heating 1 mol. bromine and 1 mol. cenanthylic acid together at 140°-160°, but has not been isolated in the pure state.

Amidocenanthylic acid, $\text{C}^8\text{H}^{18}(\text{NH}^2)\text{O}_2$, formed by saturating an alcoholic solution of bromocenanthylic acid with ammonia, and digesting it for three or four hours in the water-bath, separates on cooling in crystals, which may be purified by washing with alcohol, conversion into lead salt, separation therefrom by hydrogen sulphide, and recrystallisation from weak spirit. It is thus obtained in hexagonal tables or laminae, soluble in water and weak spirit, but not in absolute alcohol or ether. When heated, a small portion only volatilises without decomposition, the greater part being carbonised, with evolution of alkaline vapours. The *copper salt* is a dark blue amorphous powder, nearly insoluble in water, alcohol, and ammonia. A

solution of the acid in hydrochloric acid, when evaporated under the air-pump, yields crystals of a *hydrochloride*, $\text{C}^{\text{H}}\text{H}^{15}\text{NO}_2\cdot\text{HCl}$, easily soluble in alcohol and water, and forming, when perfectly dry, a yellowish powder, fatty to the touch, giving off hydrochloric acid over the water-bath. It forms with platinic chloride a double-salt, soluble in water, alcohol, and ether.

Hydroxyanthranthyllic acid, $C^7H^4O^3$, is obtained by heating an aqueous solution of potassium monobromenanthylate to 140° for some hours, and agitating the strongly acid liquid thereby formed with ether, which leaves it behind when evaporated. It is very easily soluble in alcohol and ether, and remains, after rapid evaporation of its solutions, in the form of an oil, which soon solidifies; on slow evaporation it crystallises in long prisms. It dissolves sparingly in cold, but freely in hot water, and on cooling is deposited as an oil which does not solidify under water. It melts at 59° – 60° , and sublims partly undecomposed at a higher temperature. Many of its salts have been prepared, but only the *copper* and *silver* salts have been obtained in crystals.

Methyl hydroxyacanthylate, obtained by the action of methyl iodide on silver oxyacanthylate, is a colourless neutral liquid, boiling at 160° – 165° , soluble in all proportions in alcohol and ether; insoluble in water, but slowly decomposed thereby.

Hydroxyenanthylamide, $\text{C}^7\text{H}^{13}\text{O}_2\text{NH}_2$, formed by the action of ammonia on methyl hydroxyenanthylate, crystallises in hexagonal tables, melting at 147° . It dissolves easily in hot water, and is soluble also in hydrated alcohol. It does not combine with hydrochloric acid, and is resolved by fixed alkalis into enanthylic acid and ammonia.

Hydroxybenzanthrylic acid, when treated with potassium bichromate and sulphuric acid, yields a small quantity of a granular crystalline mass, which melts at 170°, the melting point of pimelic acid; an indication that in the foregoing compounds the bromine, hydroxyl, and amidogen atoms respectively replace an atom of hydrogen in the methyl group of benzanthrylic acid. The formulæ of monobromobenzanthrylic, amidobenzanthrylic, and hydroxybenzanthrylic acids must accordingly be written:

GENOLIN. This substance, the red colouring matter of wine (iv. 178), may be prepared by precipitation with lime instead of basic lead acetate (Varenne, *Bull. Soc. Chim.* [2], xxix. 109; *Chem. Soc. J.* xxxiv. 438).

OILS, FATTY. *Properties, Reactions, Testing.*—On p. 1428 is a table of the behaviour of fatty oils with various reagents, drawn up by C. Glössner (*Chem. Centr.* 1873, 57) with a view to their detection, and to their distinction one from the other.

The following determinations of the *specific gravities* of various oils are given by S. A. Goldschmidt (*Amer. Chem.* vi. 107) with the view of facilitating the detection of adulterations :

Specific Gravity at 15°.

Tallow oil (Olefin)	. . .	0.9003	Beech-nut oil	. . .	0.9207
		0.9150	Sesame "	. . .	0.9235
		0.9169	Whale "	. . .	0.9240
Winter Rape oil	. . .	0.9154	Poppy "	. . .	0.9253
Summer " "	. . .	0.9157	Hemp "	. . .	0.9270
Earth-nut "	. . .	0.9170	Cod-liver "	. . .	0.9270
Olive "	. . .	0.9170	Cotton-seed,,	. . .	0.9306
Almond "	. . .	0.9180	Linseed "	. . .	0.935

Animal oils are turned brown by chlorine, whereas vegetable oils remain colourless. *Rape-oil* may be detected by mixing the ethereal solution of the oil with a few drops of alcoholic solution of silver nitrate, whereupon a black colour is produced. Pure *olive-oil*, intimately mixed with a solution of mercury nitrate, forms a homogeneous mixture, but if it contains *earth-nut oil*, black streaks are produced (Goldschmidt).

On the determination of the value of Animal and Vegetable Oils, see also J. J. Coleman (*Chem. News*, **xxix**, 138, 140, 149; *Chem. Soc. J.* **xxvii**, 606).

On the detection of the oils of *Turpentine* and *Rosemary* in fixed oils used as Lubricants, see Burstyn (*Dingl. pol. J.* ccxiv. 300; *Chem. Soc. J.* xxviii. 920).

To estimate the amount of Acid (Oleic, &c.) in fixed oils, Burstyn (*Zeitschr. anal. Chem.* 1872, 283; *Dingl. pol. J.* cxxvii. 314) dissolves out the acid with alcohol, which exerts scarcely any action on fixed oils, and determines the quantity of acid in the

Table for the Detection of the Fat Oils.

	At the ordinary temperature.				After boiling.	
	Snow-white : Almond oil, good rape oil, bleached. Olive oil.	Yellowish : Poppy oil, olive oil, rape oil. Sesame oil.	Greenish : Linsced oil; hemp oil; oils containing copper, and other faintly coloured oils.	Rose : Refined rape oil.	Brown and solid : Hemp oil.	Yellowish-brown fluid : Linsced oil.
5 vols. oil and 1 vol. caustic potash 1·34 are well shaken together. The mass is :—						Red : Train oil.
Equal volume of oil and fuming red nitric acid are carefully poured into a test-glass. At the point of contact a ring is formed, and this is :—	Small and bright green, the oil itself is floccy and non- transparent. Almond oil.	Dark green, rose- coloured above. Poppy oil.	Broad and beautifully bright bluish- green. Olive oil.	Brown-red : Cod-liver oil.	Green, red above. Linsced oil.	The whole of the oil is after a time coloured red. Linsced oil.
10 drops of oil and 2 drops of acid.						
Without carbon sulphide.				Equal volumes of oil and acid.		
The oil is mixed with pure concentrated sulphuric acid in a test-glass; the point of contact between the two is coloured :				With carbon sulphide.		
By the emaline test the oil becomes :—	Fine green, with brown streaks. Rape oil.	Yellow, on slaking, brownish olive- green. Poppy oil.	Red, soon passing into serpentine black streaks. Train oil.	After shaking, fine fall dark green. Rape oil.	Green : Linsced oil, Hemp oil.	Red : Train oil.
By boiling with lead oxide and water, a plaster is formed, the consistency of which is :—	Solid, curdy white olive oil : almond oil : bleached rape oil.	Solid, curdy, yellow. Rape oil.	Solid and red. Sesame oil.	Wax-like white. Castor oil.	Streaks and drops of oil show them- selves in the emaline; a mix- ture containing drying oils.	Unchanged : Linsced oil, Poppy oil, Nut oil.
By the emaline test the oil becomes :—	Solid. Olive oil.	Greasy : rape oil : almond oil. Sesame oil.	Greasy, but drying after a time. Drying oils.	—	—	—
Solubility of one part of oil in alcohol :—	1 : 1 Castor oil.	1 : 25. Poppy oil.	1 : 30. Hemp oil.	1 : 40. Linsced oil.	1 : 60. Almond oil.	—
Specific gravity :	·913. Poppy oil, and oil of <i>Brassica napus</i> ,	·914. Almond oil, and oil of <i>Brassica Camp.</i>	·918. Olive oil.	·923. Sesame oil.	·926. Sunflower oil.	·930. Linsced oil.
Temperature of liquefaction Centigrade :	—27°. Hemp oil.	—18°. Castor oil. + 25°. Olive oil.	—10° to —20°. Linsced oil. —20° to —25°. Almond oil.	—16°. Sunflower oil.	—6° of <i>Brassica napus</i> .	—5°. Sesame oil.

solution either by titration with potash, &c., or by measuring with a hydrometer the increase of sp. gr. of the alcohol arising from the presence of the acid.

Estimation of Mineral Oil or Paraffin Wax in other Fats or Oils.—For this purpose the oil is saponified with an alcoholic solution of caustic soda, and the unsaponified oil or wax is separated with petroleum spirit. 200 pts. of the oil are placed in a basin with 350 pts. of an alcoholic caustic soda-solution (strength, 9 per cent. Na^2O), and boiled until the mixture begins to froth. 200 pts. of methylated spirit are added to dissolve the soap, &c., 90 pts. of sodium bicarbonate to convert any caustic soda into carbonate, and finally 500 pts. of washed and ignited mortar sand. The mixture is boiled for a few minutes, and then the alcohol and water are distilled off from a water bath. The residue when cold is transferred to a wide-mouthed stoppered bottle and shaken with petroleum spirit; the sand and soap are allowed to settle; the spirit containing the wax and mineral oil is drawn off and filtered through asbestos; the residual soap and sand is thrown on a cloth; and the liquid pressed out. The petroleum spirit is distilled from the mineral oil at 100° , and the residue transferred to a flask, with a hole blown in the side, which is fitted with a cork bearing a thermometer and small piece of glass tubing; the whole is previously weighed; and the last traces of spirit are distilled at 220° ; dry air is then blown through; and the whole is weighed. Certain corrections have to be made, in consequence of oil capable of saponification containing small quantities of non-saponifiable oil soluble in petroleum spirit. The correction in the case of Russian tallow amounts to .64 per cent. (W. Thomson *Chem. News*, xxviii. 167).

Solubility of Fixed Oils in Glacial Acetic Acid.—The following determinations have been made by J. B. Barnes (*Pharm. J. Trans.* [3], vi. 221):

1 vol. Glacial Acetic Acid dissolves	7 vols. Fixed Oil of Almonds
1 " " " "	8 " Olive Oil
1 " " " "	7 " Cod-liver Oil
1 " " " "	7 " Linseed Oil
2 " " " "	1 " Turpentine Oil
20 " " " "	1 " Copaiba Oil
1 " " " "	2 " Lemon Oil
1 " " " "	1 " Juniper Oil

Castor oil and croton oil are dissolved by glacial acetic acid in all proportions.

Action of Fixed Oils on Copper.—W. H. Watson (*Chem. News*, xxxvi. 200), by exposing 8 square inches of copper surface to 500 grain-measures of various oils, has obtained the following results:—

	Grains of Copper in Solution after 10 days	after 77 days
Linseed	0.3	0.5435
Olive	0.22	0.24
Colza	0.017	0.14
Almond	0.103	0.22
Seal	0.0485	0.08
Sperm	0.003	0.06
Castor	0.0065	0.01
English Neat's-foot	0.11	—
Sesame	0.17	—
Paraffin	0.0015	0.003

See also COPPER (p. 558).

Lubricating Oils.—The mineral lubricating oils known as 'Vulcan oil' (petroleum of sp. gr. 0.87–0.89 purified by sulphuric acid and mixed with 5 per cent. rape-oil), and 'Opal-oil' (petroleum of sp. gr. 0.85–0.87, purified in like manner and mixed with rape-oil), have not been found to act well as lubricators for parts of machinery which move with great rapidity, such as railway axles, spindles, &c. Better results are obtained with purified 'rosin-oil.' The strong odour of this oil and its liability to deposit rosin are removed as follows: 100 pounds of dry thick rosin-oil are heated in a pan till of thin fluidity. The fire is then removed, and 3 pounds of fuming sulphuric acid are gradually dropped in, with constant stirring. After half an hour's mixing, the oil is left to stand for twelve hours, then drawn off by a siphon into a wooden vat, washed with hot water, and drawn off after twelve hours' settling, the washing being repeated till the water runs off without acid reaction. After several days' separation, a dark yellow, faintly odorous rosin-oil is obtained without blue reflex. This oil, mixed with olive or rape oil, may be used advantageously for lubricating the heavy parts of machinery.

To obtain the oil perfectly free from odour, and of clear yellow tint, the dark

yellow rosin oil is run into a flask or globe; 1 pound of water is added to 100 pounds of it; the whole is well shaken; and 8 pounds of hydrochloric acid diluted with 10 pounds of water are gradually stirred in. To this mixture 1 pound of red lead and 5 pounds of dilute hydrochloric acid are added; the whole is frequently shaken; and after some days the oil is drawn off, washed with water till free from acid, and set in the sunlight for about eight days in the flask. Thus treated it becomes of a light yellow tint.

The yellow rosin oil, when mixed with one-third of rape or olive oil, yields a good lubricating oil for all machine purposes, as it does not deposit rosin; it can also be mixed with petroleum (B. Hoffmann, *Dingl. pol. J.* cviii, 237).

OILS, VOLATILE. *Estimation.*—The following method is given by O. Osse (*Arch. Pharm.* [8], vii. 104). The oil is dissolved in petroleum spirit distilling below 40°, and evaporated in a watch-glass in a current of carefully dried air until nearly every trace of petroleum spirit is removed. It is then left to evaporate spontaneously in the open air, and weighed at the end of every minute. When the loss in weight during one minute becomes constant, this loss is considered to represent the evaporation-constant from which to correct the weight of oil obtained. This correction is effected by adding to the weight of the oil when the loss in weight became constant, the amount of the constant loss multiplied by the number of minutes during which the oil has been previously allowed to evaporate in the open air.

The method has been applied to the determination of the percentage of volatile oils in the aromatic waters of pharmacy, and of the solubility of these oils in water.

In presence of resinous or fatty substances, after the total amount of the mixed volatile oil and resinous or fatty bodies has been determined as above, the weight of these last can be found by heating the whole to 110° for an hour or two to drive off all the volatile oil. By these means the following determinations were made:

	Volatile oil	Fatty and resinous bodies
Buchu leaves. . . .	1.75 per cent.	2.25 per cent.
Laurel	13.25 "	25.00 "
Cascarilla	2.50 "	4.50 "
Indian Anise	13.00 "	13.50 "
Clove	24.75 "	1.75 "

On the Adulterations of Volatile Oils, see Leonhardi (*Arch. Pharm.* [3], xii. 490; *Chem. Soc. J.* xxxiv. 811).

Oxidation.—Volatile oils and other volatile organic bodies are rapidly oxidised by a mixture of potassium permanganate and strong sulphuric acid, in some cases with inflammation and explosion. The best way of producing the effect is to place 10 or 12 drops of the oil on a capsule; and touch it with a glass rod, the end of which has been dipped into the oxidising mixture just mentioned. The following oils then burn with explosion: *Thyme, mace, rectified turpentine, valerian, cassia, wild marjoram, rue, cubeba, lemon.* The following mostly take fire without explosion, especially if a small quantity be dropped on bibulous paper and then touched with the mixture: *Oil of rosemary, lavender, cloves, rose, geranium, gaultheria, caraway, cajuput, bitter almonds, and rectified coal-oil.*

The oxidising properties of *turpentine oil* and other volatile oils which have been exposed to the air—formerly attributed to the presence of ozone—was shown by Kingzett in 1874 to be due to the formation of an oxidised organic compound which readily gives up a portion of its oxygen. This compound from turpentine oil was at first supposed to be monohydrated terpene oxide (vii. 887); but from later experiments (*Chem. Soc. J.* xxviii. 210; xxxiv. 127, 135), Kingzett infers that it is the peroxide of the radicle of camphoric acid, (C¹⁰H¹⁴O²), which, however, has not yet been isolated. The aqueous solution obtained by shaking up the oxidised oil with water, or dissolving it in alcohol and precipitating with water, contains hydrogen dioxide, together with formic, acetic, and camphoric acids. This solution exhibits powerful antiseptic properties due to the hydrogen dioxide and camphoric acid. Evaporated to dryness over the water-bath, it leaves a dark-coloured substance having, when hot, a sugar-like odour and viscid consistence, and solidifying on cooling to a firm but adhesive mass, which, when treated with strong sulphuric acid, gives a colour somewhat resembling that obtained in Pettenkofer's bile reaction. This substance, whose composition may be represented by the empirical formula C¹⁰H¹⁸O³, is for the most part soluble in hot water, about 5 per cent. remaining as a viscid, insoluble, nearly black substance having the same composition (Kingzett, *Chem. News*, xxxix. 279).

OKENITE. The relations between okenite (iv. 191), centrallassite (i. 822), and

gyrolite (ii. 963) have been examined by H. How (*Phil. Mag.* [5], i. 128), who represents these minerals by the following formulæ:

OLEFINES, C^nH^{2n} . *Synthesis.*—By heating a mixture of amylene and methyl iodide with excess of dry lead oxide at 210° for several hours, a product boiling between 36° and 85° is obtained, one-third of which comes over between 70° and 83° , and consists of a mixture of C^6H^{12} and C^7H^{14} ; this portion forms with bromine a solid compound, apparently $\text{C}^6\text{H}^{12}\text{Br}^2$, melting at 139° – 140° . The hydrocarbons dissolve in sulphuric acid (2 acid to 1 water), and on the addition of water a liquid and a solid body separate out. The latter, which is the hydrate, $2\text{C}^7\text{H}^{14}\text{O} + \text{H}^2\text{O}$, of Butlerow's *pentamethylethol*, melts at 75° . The action of fuming hydrochloric acid on the mixed olefines also gives rise to a solid product, melting at 100° and boiling at 120° – 125° , which appears to be a mixture of $\text{C}^6\text{H}^{12}\text{Cl}$ and $\text{C}^7\text{H}^{14}\text{Cl}$.

Olefines are also formed by the action of lead oxide on alcoholic chlorides, bromides, and iodides, at 220° . Isobutyl iodide is thus completely decomposed: $2\text{C}^4\text{H}^8\text{I} + \text{PbO} = 2\text{C}^4\text{H}^8 + \text{PbI}^2 + \text{H}^2\text{O}$, and isopentyl iodide gives a pentylene isomeric with that obtained by the action of alcoholic potash (Eitehoff, *Ber.* xi. 112).

Action of Hydrochloric Acid.—From the action of hydrochloric acid on the butylenes, pentylenes, and hexylenes, Le Bel (*Compt. rend.* lxxxv. 832) infers that the olefines of the constitution $\text{CH}^2=\text{CRR}'$ and $\text{CHR}=\text{CR}'\text{R}''$, in which R, R', and R'', are different or the same alcohol-radicles, combine with hydrochloric acid in the cold, whereas those of the constitution $\text{CH}^2=\text{CHR}$, and probably $\text{CHR}=\text{CHR}'$, are not attacked thereby. This conclusion, however, requires to be verified by further examples.

Action of Sulphuric Acid. Polymerisation.—From experiments by Gorjanow a. Butlerow (*Liebig's Annalen*, clix. 146), it appears that ethylene is not absorbed by strong sulphuric acid at ordinary temperatures, but that at 100° , or better at 160° – 175° , rapid and complete absorption takes place; and on subsequently distilling the liquid with a sufficient quantity of water, and treating the distillate with potassium carbonate, ethyl alcohol is obtained. In Berthelot's well-known experiment, the violent and continued shaking doubtless served, not only to bring the gas into intimate contact with the liquid, but likewise to develop the heat required to induce the absorption.

Contact of ethylene with sulphuric acid, at the temperatures above mentioned, did not result in condensation of the hydrocarbon. Neither did a still further elevation of temperature or the employment of fuming sulphuric acid or of fluoride of boron produce signs of polymerisation. This remarkable stability in circumstances under which its higher homologues are easily affected, indicates that the constitution of ethylene is symmetrical, and not analogous to that of propylene, isobutylene, &c.

Propylene and isobutylene are readily polymerised by the action either of sulphuric acid or of boron fluoride. A preliminary experiment with isobutylene gave, besides trimethyl-carbinol, oily condensation products, a fraction of which boiled at 173° – 176° , and had a vapour-density corresponding with the formula $\text{C}^{12}\text{H}^{24}$. *Di-isobutylene* did not appear to be formed under these circumstances.

Action of Oxidising Agents.—O. and F. Zeidler (*Liebig's Annalen*, excvii. 143) have examined the reactions exerted on the olefines by the following oxidising agents: (a) an aqueous solution of potassium permanganate; (b) a solution of potassium permanganate acidified with sulphuric acid; (c) an alkaline solution of potassium permanganate; (d) a solution of chromic acid; and (e) a mixture of potassium dichromate and sulphuric acid. In each case 2–3 litres of the gaseous olefine were used, and the proportion of oxidising agent is taken so as to represent 4 mols. of oxygen to 1 mol. of olefine.

Ethylene yielded the following results:—With (a) formic, acetic, and oxalic acids; (b) carbonic, formic, acetic, and oxalic acids (traces); (c) carbonic, formic, acetic, and oxalic acids; (d) no action at the ordinary temperature, but at 100° carbonic acid, and small quantities of formic, acetic, and oxalic acids are formed; (e) the same as (d). These results differ somewhat from those obtained by Truchot (*Annalen*, cxli. 108); Berthelot (*Compt. rend.* lxi. 35; *Annalen Suppl.* v. 95; *Compt. rend.* lxxviii. 333; *Annalen*, cl. 373; *Ann. Chim. Phys.* 1875 [5], vi. 449); and by Chapman a. Thorpe (*Annalen*, cxlii. 182).

Propylene yielded (a) carbonic, oxalic, and acetic acids, and traces of an acid, perhaps succinic or malonic acid; (b) carbonic, acetic, oxalic acids, a little formic acid, and traces of an acid which may be either malonic or glycollic acid; traces of acetone;

(c) carbonic, acetic, oxalic acids, traces of formic acid, and probably malonic acid, also a small quantity of acetone; (d) small quantities of carbonic acid, but large quantities of formic and acetic acids, and only a trace of oxalic acid; (e) the same result as (d).

Isobutylene, $\text{CH}^3\text{CH}=\text{CH}^2$, prepared from fermentation butyl iodide, yielded the following results:—(a) carbonic acid, small quantities of acetic and formic acids, and, as chief product, oxalic acid; (b) carbonic, formic, acetic, and oxalic acids; (c) carbonic, small quantity of formic, acetic, and oxalic acids; (d) no action in the cold, only at the temperature of steam-bath, yielding carbonic, formic, acetic, and oxalic acids, also acetone; (e) the same as (d), the action is, however, more energetic. Isobutylene does not in any case yield succinic acid.

F. Zeidler (*Annalen*, clxxxvi. 247) obtained by the oxidation of amylene, b. p. 35° , butyric and succinic acids. Since then, Wischnegradsky (*Annalen*, exc. 328) has shown that this olefine consists of two isomerides, one of which is trimethylethylene, and the other either propylethylene or ethylmethylethylene. The latter (b. p. 35° – 37°), prepared from ordinary amylene by means of its insolubility in sulphuric acid, yields on oxidation with an alkaline solution of potassium permanganate, succinic and oxalic acids, also formic and butyric acids, and traces of carbonic acid. These results show the constitution of this amylene to be $\text{CH}^3\text{CH}^2\text{CH}=\text{CH}^2$, i.e. propylethylene, and not ethylmethylethylene (see AMYLENES, p. 81).

The difference in action of the several oxidising agents on the olefines is a difference, not of kind, but only of degree; in other words, it is quantitative, but not qualitative. Moreover, the olefines are attacked at the point of double union, and the resulting monobasic acids are, as shown by P. de St. Gilles (*Compt. rend.* xli. 811) and Berthelot (*Annalen*, *Suppl.* v. 95; vi. 181), further oxidised to bibasic acids. The formation of acetic acid from ethylene, and of malonic acid from propylene, may be explained by supposing the addition of water as H and OH to take place; for instance, in the case of ethylene, a primary alcohol would be first formed, and the molecule not broken up. In the case of propylene, the addition may take place so as to form the primary or secondary alcohol, which by further oxidation may yield malonic acid and acetone:

or

Formation of Glycols, Aldehydes, and Ketones from the Haloid Compounds of the Olefines.—The haloid compounds of ethylene, when heated with water and lead oxide, yield glycol and aldehyde, whilst propylene chloride and bromide, under the same circumstances, yield propyl-glycol, acetone, and propaldehyde. Similarly isobutylene bromide yields isobutyl-glycol and the corresponding aldehyde, and trimethylethylene bromide yields isopropylmethyl ketone. These results show that the first product of the action in every case is a glycol, which by elimination of water is partially or entirely converted into aldehyde or ketone (Eltzoff, *Ber.* xi. 989).

Decomposition of Olefine Bromides, R^2Br^2 , by the Copper-zinc couple and by Zinc alone.—The decomposition of ethylene bromide by zinc and by the couple has been already described (vii. 489). Propylene and amylene bromide are decomposed in the same manner, the action in all cases being a simple abstraction of the bromine by the zinc and liberation of the olefine. In the case of propylene bromide the dry couple produces very little decomposition, but the action is facilitated by water, as with ethylene bromide. Zinc alone acts but slightly when wetted with water, but in presence of alcohol it decomposes the bromide rapidly after about 17 minutes' contact. *Amylene bromide* is not attacked by the couple wet with water at 15° , but rapid action takes place at 60° . In contact with alcohol, zinc alone effects the same decomposition at ordinary temperatures (Gladstone & Tribe, *Chem. Soc. J.* xxvii. 408).

OLEIC ACID, $\text{C}^{18}\text{H}^{34}\text{O}^2$. When a mixture of glacial acetic acid and water is gradually added to an alcoholic solution of *oleic acid*, a point is reached at which the oleic acid remains entirely dissolved, but is completely separated by the addition of one-tenth of a c.c. more of the acid, whereas *stearic acid* in alcoholic solution begins to precipitate as soon as the acetic acid is added, and is entirely insoluble in a mixture of alcohol and acetic acid, and even in presence of oleic acid. This difference of behaviour affords the means of separating and estimating the two acids in mixtures produced by the saponification of fats (J. David, *Compt. rend.* lxxxvii. 1416; *Chem. Soc. J.* xxxiv. 1011).

Conversion into Stearic Acid.—This conversion may be effected by heating oleic acid with hydriodic acid (b. p. 127°) and amorphous phosphorus to 200° – 210° in a sealed tube for eight hours, then opening the tube to allow hydrogen phosphide to escape, resealing it, and heating it again. By this treatment the liquid oleic acid is

completely converted into a crystalline mass of stearic acid, which may be purified by melting it under water, recrystallising it from hot alcohol, treating it with sodium-amalgam to remove any small quantity of iodine that it may retain, and once more crystallising it from alcohol (G. Goldschmiedt, *Wien. Akad. Ber.* lxxii. 366). See also M. A. Muter (*Analyst*, ii. 73).

Mercury Oleate.—For the preparation of this salt from mercuric oxide and oleic acid, A. Hilger (*Arch. Pharm.* [3], iii. 490) recommends the use of mercuric oxide prepared in the wet way and dried as quickly as possible. The temperature of the mixture should not be allowed to rise above 70°, otherwise reduction of the mercuric oxide will take place. The preparation containing not more than 15 to 16 per cent. mercuric oxide forms viscid masses of yellow to red-brown colour. As the proportion of mercuric oxide increases, the mixture acquires an unctuous consistence, and when more than 30 per cent. HgO is added, immediate decomposition takes place, attended with separation of mercury. The same decomposition appears to take place after long keeping in preparations containing smaller proportions of the oxide. It does not appear possible to prepare pure mercury oleate by double decomposition. See also C. Rice (*Pharm. J. Trans.* [3], iii. 582; vi. 147; *Chem. Soc. J.* xxvi. 510).

OLENES. Syn. with OLEFINES.

OLIBENE, C¹⁰H¹⁸. A volatile oil obtained from incense. This substance, distilled with water, yields an oil which passes over at 160°–170°; and this oil is resolved by fractional distillation into olibene boiling below 160°, and a small portion of an oxygenated oil which boils above 175°. Olibene, treated with dry hydrochloric acid gas, forms a crystalline hydrochloride, smelling like camphor, easily soluble in alcohol, melting at 127°. The resin of incense appears therefore to consist of condensation-products of a terpene (Kurbatow, *Liebig's Annalen*, clxxiii. 1).

OLIGOCLASE. The following analyses of this mineral have lately been published in addition to those given under FELSPAR (pp. 773, 774): 1. From Unionville, Pennsylvania, occurring in yellowish and brown-white grains, in a few instances with recognisable and then striated cleavage-faces; enclosing corundum and a second mineral, probably spinel; analysed by Chatard (*Jahresb. f. Chem.* 1873, 1152). 2. From the granitic gneiss of New York. Sp. gr. 2.644 (P. Schweitzer, *Am. Chemist*, iv. 444). 3. From the lava of Santorin, which is rich in oligoclase. Sp. gr. 2.629 (Fouqué, *Compt. rend.* lxxx. 631). 4. From the graphite-garnet gneiss, called *Kinzigite*, of Schenkenzell near Wittichen in the Schwarzwald (Hebenstreit, *ibid.* 417).

	SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	K ² O	Na ² O	H ² O

On the action of water containing carbonic acid on Oligoclase, see MINERALS (p. 1329).

OLIVE OIL. *Extraction.*—The calcareous soil of the district of Sahil in Tunis is very well adapted to the culture of the olive. In this district there are five million olive-trees, which, if the winter and spring rains occur in normal amount, yield annually 40,000 tons of oil. The gathering of the olives takes place in December and January. The olives are crushed between horizontal millstones; the pulp is immediately thrown into water; and the oil which then comes to the surface is sold as best quality (*Drab-el-ma*). By pressure a strong-smelling oil of inferior quality (*Masri*) is obtained. The press-cakes are used as fodder for camels. The quantity of oil exported from Tunis in five years (1869–73) represented a value of 300,000*l.* sterling.

Testing.—The following method of testing the purity of olive oil by means of its conversion into solid elaidin was given by E. Kopp (*Deut. Chem. Ges. Ber.* viii. 979). 10 vols. of the oil and 1 vol. ordinary nitric acid are introduced into a test-tube together with a few pieces of copper wire; and as soon as the gas-bubbles begin to pass somewhat rapidly through the supernatant oil, the acid and oil are intimately mixed by stirring with a glass rod, the mixture then left to itself for a few minutes, and the separated liquids again mixed by stirring and heating. If it be then left in a cool place, the oil after some time begins to solidify, the solidification being quicker in proportion as the oil is purer. In mixtures with other oils the solidification is much slower, and the elaidin formed, instead of being white and hard, is soft, and has a more or less yellowish or brownish colour.

On the Detection of Earthnut Oil in Olive Oil, see vol. vii. p. 443.

On the Characters by which Olive Oil is distinguished from other Fixed Oils, see Glössner's table (p. 1428).

OLIVES. The following analyses of the fruit and leaves of the olive, 'Blanquet' variety, collected at intervals of a month from May 30 to November 30, are given by A. Roussille (*Compt. rend.* lxxxvi. 610).

Composition of the leaves	May 30	June 30	July 30	Aug. 30	Sept. 30	Oct. 30	Nov. 30
Fat and chlorophyll	5.432	4.330	4.578	4.577	3.631	3.766	3.702

P ₂ O ₅ in the alkaline salts	—	—	1.675	4.421	4.784	5.164

Fatty Matter and Chlorophyll.—The chlorophyll, which is very abundant in the leaves at the end of May, gradually diminishes in quantity; it does not migrate to the fruit.

Nitrogenous Matter.—In the leaves, the nitrogen increases until the end of July. In August it greatly diminishes, and accumulates in the pericarp. A migration of nitrogen in the fruit then takes place, probably going to the endosperm, for the amount diminishes two-thirds by the end of September. Afterwards (when the kernel should be forming) the proportion slightly increases in both leaves and fruit.

Lignin.—In the leaves, this substance decreases in June, after which it continues to increase.

Mineral Matter.—In the leaves, the mineral matter increases to the end of August, and then diminishes until the fruit ripens. The proportion of alkaline salts increases until the end of July: in August it goes to the fruit, forming the chief mineral constituent. A steady increase in the leaves again takes place, and continues until the fruit is gathered. Magnesium and calcium phosphates increase in the leaves until July, rapidly diminishing in August, as is the case with the alkaline salts. It appears that the migration of the phosphates precedes that of the alkalis, corresponding with the migration of the nitrogenous matter; whereas that of the alkaline salts corresponds with the non-azotised proximate principles, and to their conversion into fatty substance. In the fruit, the mineral matter reaches its maximum by the end of August, and then diminishes, but again gradually increases as it ripens. The alkaline salts increase with the fatty matter in almost a definite proportion with the potassium phosphate, thus (combined with potassium):—

1.675 P ₂ O ₅ at the end of August	with 29.190 fat.
4.421 " " " September	" 62.304 "
4.784 " " " October	" 67.213 "
5.164 " when the fruit was gathered	" 68.575 "

The calcium and magnesium phosphates are at their maximum in August, at the same time as the nitrogenous matter. Phosphoric acid can enter the endosperm only in the form of alkaline phosphate.

Silica.—Probably an accidental impurity.

OLIVIL. When pure olivil (m. p. 119° – 120°), obtained from the gum of the olive-tree (iv. 200), is digested for an hour with concentrated hydriodic acid (b. p. 127°), a mixture of the iodides of methyl and ethyl is obtained, together with a black non-volatile solid substance of glistening aspect. This substance is insoluble in water, only slightly soluble in ether, but readily soluble in alcohol, especially when hot, and precipitated therefrom by water (D. Amato, *Gazz. chim. ital.* 1878, 83).

OLIVINE. The following are recent analyses of this mineral: 1. Transparent pale-yellow olivine, sp. gr. 3.261, from Vesuvius (E. v. Dingelstedt, *Jahrb. f. Min.* 1874, 86). 2. Small, light brownish crystals, sp. gr. = 3.183, occurring, together with humite, in the geodes of a block ejected from Vesuvius (G. vom Rath, *Berl. Akad. Ber.* 1874, 745). 3. From the basalt of Kosakov (Farsky, *Verh. geol. Reichsanst.* 1876, 205). 4. From the basalt of the Lützelberg, a mountain of the Kaiserstuhl range, where it occurs, to the amount of 78 per cent., in nodules together with chrome-iron ore and two pyroxenes, viz. a chrome diopside and a mineral nearly allied to bronzite (A. Knop, *Jahrb. f. Min.* 1877, 697). 5. From the palaeopierite of the Black Stones of Nassau (K. Oebbecke, *ibid.* 844).

	SiO ²	MgO	CaO	FeO	NiO, CaO	MnO	CrO	Cr ² O ³	Al ² O ³	
1.	42.30	51.64	1.08	5.01	—	—	—	—	0.42	= 100.45
2.	39.93	48.70	—	8.43	—	1.03	—	—	0.10	= 98.19
3.*	41.22	49.36	—	9.13	0.24	0.16	—	0.05	0.14	= 100.30
4.	41.2	49.7	—	8.7	—	—	—	—	—	= 99.6
5.	42.53	35.68	14.09	6.48	—	—	—	—	—	= 98.78

Relations between Olivine and Serpentine.—Olivine occurring in small granules in the serpentine of Snarum, the well-known locality of pseudomorphs of serpentine after olivine, has been analysed, together with the accompanying serpentine, by A. Helland (*Pogg. Ann.* cxlviii. 329):

	SiO ²	MgO	FeO	CrO	Al ² O ³	Loss by ignition	Sp. gr.
Olivine	41.32	54.69	2.39	0.05	0.28	0.20 =	98.93
Serpentine	42.72	42.52	2.25	trace	0.06	13.39 =	100.94

Supposing that the conversion of the olivine into serpentine has taken place without alteration of volume, and taking into account the difference of density of the two minerals, the weights of the two in grams contained in 1 cubic centimeter of substance will be as follows:

Olivine	1.345	0.009	0.078	0.002	1.780	0.006 =	3.220
Serpentine	1.071	0.002	0.056	—	1.065	0.336 =	2.530

Increase or Decrease -0.274 -0.007 -0.022 -0.002 -0.715 +0.330

All the other minerals found in the serpentine bed, viz. magnesite, hydrotalcite, quartz, mica, magnetic iron oxide, and titanite iron, may, with the exception of the last, be regarded as secondary products of the transformation process, admitting the access of a small quantity of carbon dioxide (for the magnesite) and of alkalis (for the mica). The titanite iron appears, from the mode of its occurrence, to be a pre-existing mineral.

Several hydrated silicates related to serpentine, and therefore to olivine, have been analysed by F. v. Kobell (*Jahrb. f. Min.* 1874, 733):

1. *Chrysotil* from Zermatt: pale yellow fibrous masses. 2. *Antigorite* from Zermatt: dark grey crystalline monatomic masses. 3. A mineral from Kraubath in Styria, nearly allied to the marmolite of Hoboken: compact, yellowish-white; sp. gr. = 2.13. 4. *Marmolite* from Hoboken: crystallo-laminar.

	SiO ²	MgO	FeO	Al ² O ³	H ² O	
1.	42.5	43.0	2.0	—	13.1	= 100.6
2.	42.73	36.51	7.20	1.33	11.66	= 99.43
3.	42.0	38.5	1.0	trace	17.5	= 99.0
4.	42.00	41.00	0.90	0.26	15.00	= 99.16

Also very slight traces of Cr²O³ in 1, of Mn²O³ in 3.

* Mean of three analyses.

According to these results, the minerals in question may be referred to two species, viz. chrysotil and antigorite to *serpentine*, $3\text{MgO} \cdot \text{SiO}_2 \cdot 2\text{H}^2\text{O}$; vorhausserite (v. 1006) and the Kraubath mineral to *marmolite*, $5\text{MgO} \cdot 3\text{SiO}_2 \cdot 4\text{H}^2\text{O}$.

The numerical relation of these species to olivine is shown by the following comparison:

The processes of transformation may, however, be equally well regarded as separation, with simultaneous assumption of water, provided that we start, not from one but from several molecules of olivine regarded as pre-existing:

OLIVINE-ROCK. The olivine-rocks of the granulite district of Saxony have been described by H. Möhl (*Jahrb. f. Min.* 1876, 225; *Chem. Soc. J.* xxx. 338); they are of two kinds, *garnet olivine-rock* and *enstatite olivine-rock*, accordingly as garnet or enstatite is the predominating constituent, next to the olivine. Several varieties of olivine-rock, including the *dunite* of New Zealand, the *therzolite* of the Pyrenees, the eruptive rocks of the Richtelgebirge, of Ellgost in Austrian Silesia, and of the Hessian Hinterland, have been described by H. Möhl (*Jahrb. f. Min.* 1877, 413; *Chem. Soc. J.* xxx. 119).

The following are analyses of olivine-rocks. (1). From the Culsagee Mine near Franklin, Macon County, North Carolina. (2). Rock consisting of serpentinised olivine with plagioclase from the Cullikenee or Buck Creek Mine in Clay County, North Carolina: analysed by Chatard (*Jahresb. f. Chem.* 1873, 1156). (3). Diallogite olivine-rock of Mohsdorf in the Saxon granulite district (Leuchardt, *ibid.* 1876, 1280) (4). Olivine-rock from the Ultenthal (J. R. Müller, *Jahrb. f. Min.* 1877, 739):

	SiO ³	MgO	CaO	FeO	Fe ² O ³	Al ² O ³	H ² O	
1.	41·58	49·28	0·11	7·49	—	0·14	1·72	= 100·32
2.	35·19	40·99	—	9·70	—	0·64	13·48	= 100
3.	41·99	31·49	1·84	1·66	9·14	6·73	7·09	= 99·94
4.	40·82	45·81	trace	12·35	—	0·86	—	= 99·84

OMPHACITE. Analyses of this mineral have been made by Fikenscher (*Jahresb. f. Chem.* 1874, 1301) and Lüdecke (*ibid.* 1876, 1232): 1. From the eclogite of Obernpferdt, near Schwarzenbach in Saxony. Sp. gr. = 3·263 (Fikenscher). 2. From the glaucophane of the island of Syra (Lüdecke):

	SiO ³	Al ² O ³	FeO	CaO	MgO	K ² O	Na ² O	H ² O
52·57	9·12	5·32	17·41	12·75	0·28	1·11	0·32	= 99·88
52·53	4·6	11·8	12·8	16·1	—	—	1·69*	= 99·52

* Loss by ignition.

ONYX. Damour (*Compt. rend.* lxxxii. 1085) has analysed a so-called alabaster which, under the name 'Onyx of Tecali,' has lately been largely imported into France from Mexico for the fabrication of ornaments. It is milk-white, yellowish-white, or pale green, sometimes with red-brown veins, and exhibits wavy layers. Sp. gr. = 2·77. A. Direct result of analysis. B. Constituents grouped as carbonates:

	CO ²	CaO	MgO	FeO	MnO	H ² O	
A.	43·52	50·10	1·40	4·10	0·22	0·60	= 99·94
Traces of silica.							
	CaCO ³	MgCO ³	FeCO ³	MnCO ³	H ² O		
B.	89·46	2·92	6·60	0·36	0·60	=	99·94

Damour has found manganese in other limestones, Iceland spar for example.

OPAL. Opal is found, as *perlite* and *florite*, in the neighbourhood of San Piero, Elba, in kaolin, also in the form of a crust and globular. At Vallicella, in the same

neighbourhood, opal occurs usually as *hyalite*, in cavities in a granite vein. The opal of Sant' Ilario and San Piero encloses garnets, those of the former locality being light yellow, and those from the latter black (G. Roster, *Jahrb. f. Min.* 1877, 531).

F. M. Endlich describes an opal occurring as a deposit of the Upper Geyser basin on the Firehole River. An analysis by A. C. Peale of a milk-white variety, sp. gr. = 2.4903, gave 95.84 per cent. silica, 2.68 Fe²O³ and 1.50 loss by ignition (= 100.02), with traces of alumina, magnesia, potash, soda, and lithia. A light greenish-brown specimen, of sp. gr. 2.0816, gave 6.3 per cent. water.

An opal containing 8.85 per cent. water, and answering to the formula 3SiO².H²O, when exposed to a stream of dry air at 100°, gave off 5.01 per cent. water very quickly, whereby it was converted into 6SiO².H²O, the rest very slowly. An artificially prepared hydrate, SiO².4H²O, was quickly converted, under similar conditions, into SiO².H²O, less quickly into 6SiO².H²O, the remainder of the water in this case also being given off very slowly.

OPIANIC ACID.

OPINIC ACID.

} See NARCOTINE-DERIVATIVES (pp. 1383, 1384).

OPIUM. Twelve sorts of opium, analysed by Flückiger (*Pharm. J. Trans.* [3], v. 845), gave the following results:

	I	II	III	IV	V	VI
Ethereal Extract	24.2	21.7	22.0	20.6	14.1	17.4
Crude Narcotine	10.0	9.0	8.5	7.6	7.6	8.0
Wax	14.2	12.7	13.5	13.0	6.5	9.4
Pure Narcotine	4.0	6.1	5.5	4.5	4.7	3.1
Crude Morphine	11.2	11.2	14.2	10.6	14.4	—
Pure Morphine	8.6	4.3	3.5	4.6	6.1	3.8

	VII	VIII	IX	X	XI	XII
Ethereal Extract	20.4	—	25.0	23.7	18.1	23.6
Crude Narcotine	9.7	—	10.2	12.2	9.3	11.6
Wax	10.7	—	14.8	11.5	8.8	12.0
Pure Narcotine	5.4	7.7	6.4	8.7	6.0	8.1
Pure Morphine	3.2	6.07	7.1	5.8	4.3	8.3

I. Patna Opium. II. Indian Opium, 1852–3. III. Akbari Opium. IV. Behar Opium. V. Maliva Opium. VI. Sind Opium. VII. Hyderabad Opium. VIII. Opium from Candeish. IX. Persian. X. Egyptian. XI. Opium from Playford, Suffolk, 1823. XII. English, 1859.

W. D. Howard (*Pharm. J. Trans.* [3], vi. 721) found in a sample of Persian opium said to be perfectly pure:

Morphine	Cocaine	Narcotine	Thebaine	Cryptopine	Papaverine
16.40	0.29	2.50	0.57	0.09	trace per cent.

A cheap sort of Persian opium was found by Proctor (*ibid.* 1024) to contain only 0.25 per cent. morphine. A very hygroscopic variety of Persian opium, examined by Carles (*ibid.* iii. 883) yielded 52 per cent. aqueous extract, and contained 8.4 per cent. morphine, 3.6 narcotine, and a small quantity of glucose.

The ash of Behar opium—a mixture of the ashes of various samples from the Government Factory, Patna,—has been analysed by C. Warden (*Chem. News*, xxxviii. 146). It was of a light grey colour, and contained 0.8575 per cent. of charcoal, which was deducted before calculating the percentage composition, which is as follows:—

Fe ² O ³	CaO	MgO	K ² O	Na ² O	SO ²	P ² O ⁵	SiO ²
1.9839	7.1344	2.3104	37.2405	1.7006	23.1419	10.9021	15.2740

There are also traces of alumina, manganese, carbon dioxide, and chlorine. The sulphuric acid, of which there is an unusually large quantity present, is supposed to be united with the potash and lime.

On the methods of estimating Morphine in Opium, see p. 1338.

On the reaction of Opium-bases with *Iodised Hydriodic Acid*, see ALKALOIDS (p. 56); with *Hydrogen Sulphide*, *Auric Bromide*, *Sodio-aurous Thiosulphate*, *Lead Tetrachloride*, and *Ammonium Molybdate*, see p. 56; with *Sulphuric Acid* and *Ferric Chloride*, see PLANT-BASES.

OPOPONAX. See RESINS.

ORANGE-PEEL OIL. See vii. 877.

ORCINOL, C⁶H³O² = C⁶H³(CH³)(OH)². *Orcin.* Estimation in *Dye-lichens*.—The quantity of orcinol in a dye-lichen may be estimated by titration with bromine-water,

the reagent being added till the suspended precipitate, which for a while has become white, again acquires a yellowish tint, and an excess of bromine is indicated by the smell. The reaction, which is quite definite, consists in the formation of tribromorcinol, so that from the quantity of bromine used (the excess being determined by means of potassium iodide and sodium thiosulphate), it is easy to calculate the quantity of orcinol in the liquid (S. Reymann, *Ber.* viii. 790).

Action of Ammonia.—Liebemann a. Troschke (*ibid.* vii. 247), by acting on orcinol with ammonia in contact with the air, have obtained two colouring matters which appear to have the formulæ $C^{14}H^{12}NO^4$ and $C^{14}H^{12}N^2O^3$. The first is probably formed as represented by the equation,

Dinitroso-orcinol, $C^8H^4(NO)^2(OH)^2$ (Stenhouse a. Groves, *Chem. Soc. J.* xxxi. 544). This compound is formed, but in small quantity only, by treating orcinol with potassium nitrite and acetic acid; much more readily by the action of nitrosyl sulphate on orcinol:

It is advisable to use a solution of nitrosyl sulphate containing 15 per cent. N^2O^8 , prepared in the manner already described (p. 1419), so as to ensure the absence of nitric acid. Of this solution, 100 pts. are added gradually and with continued agitation to 20 pts. of crystallised orcinol dissolved in 2000 pts. of water. As the liquid is somewhat apt to froth, and the nitrosyl-solution is decomposed instantly on coming in contact with water, it is best to run it into the orcinol solution below the surface of the liquid by means of a long-necked funnel or a bulb-dropping tube furnished with a stopcock. The dinitroso-orcinol then begins to separate in a few seconds, and in the course of eighteen to twenty-four hours is completely deposited in the form of a yellowish-brown powder. For purification, it is washed with cold water; converted into an ammonium salt by suspending it while moist in 10 to 15 pts. of alcohol; adding alcoholic ammonia by small successive portions till the brown powder is completely changed into a green crystalline powder; finally adding a slight excess of ammonia; leaving the whole at rest for a few minutes; and separating the green crystals from the brown mother-liquor by pressure on a cloth filter. This purified ammonium salt is decomposed by stirring it up with water and dilute sulphuric acid, and leaving the mixture to itself for some hours, the dinitroso-orcinol thereby separated being collected on a vacuum-filter and well washed with cold water to remove adhering ammonium salt. Another treatment or two with alcoholic ammonia serves to remove all soluble impurities from the nitroso-orcinol, yielding a product which is of a very pale colour, but as it is liable to contain some lead sulphate derived from the concentrated sulphuric acid employed in the preparation of the nitrosyl sulphate, it is advisable to dissolve it in a dilute solution of sodium hydrate, and precipitate the filtered liquid by an acid. This is most conveniently done by suspending the purified dinitroso-orcinol in 10 to 15 pts. of water, and adding a solution of sodium hydrate until nearly the whole is dissolved. The solution is then filtered and strongly acidulated with dilute sulphuric acid.

Pure dinitroso-orcinol, prepared by the decomposition of the sodium or ammonium compound, is a pale-coloured crystalline powder, but it may be obtained in distinct crystals by adding a solution of 4 pts. of orcinol in 400 of water to a dilute aqueous solution of nitrous acid (made by pouring 20 pts. of the nitrosyl sulphate solution containing 3 of N^2O^8 into 1600 of water). The liquid becomes deep-yellow, and on standing for twenty-four hours, deposits the dinitroso-orcinol in sharply-defined transparent prisms of a deep-yellow colour. It is almost insoluble in water, alcohol ether, benzene, &c., but dissolves in hot glacial acetic acid, and is reprecipitated apparently but little altered, on diluting the solution with water. It dissolves when boiled with alcohol, but undergoes decomposition at the same time. Cold concentrated sulphuric acid dissolves it with deep-red colour, and the solution, if at once poured into water, deposits unaltered nitroso-orcinol; on heating the solution in the concentrated acid, however, or even on allowing it to stand for some time, it is decomposed. When nitroso-orcinol is heated in a narrow tube, it begins to turn dark rapidly at 110° , but without fusing, and at 140° it becomes almost black. Heated rapidly on platinum-foil, it melts and decomposes, but without deflagration.

The potassium-, sodium-, and ammonium-derivatives of dinitroso-orcinol are green crystalline compounds, soluble in water, but only slightly soluble in alcohol. The ammonium compound is decomposed by prolonged contact with alcoholic ammonia. The derivatives containing the metals of the alkaline earths and the heavy metals are brown amorphous insoluble precipitates,

Nitro-orcinols. 1. *Mononitro-orcinols*.—An ethereal solution of orcinol treated with a mixture of nitrous and nitric acids, deposits on standing a brownish-red crystalline body, almost insoluble in ether, very sparingly soluble in alcohol, and crystallising from acetic acid in brown granular crystals with beetle-green lustre. Water containing a trace of an alkali dissolves this compound with a splendid purple colour, and the solution, when very dilute, exhibits a vermilion-red fluorescence. With concentrated sulphuric acid it forms a purple solution, which, on standing, or on heating, turns brown. The empirical formula of this body, which is not explosive, is $C^{14}H^{11}NO^3$:

On dissolving it in hot concentrated nitric acid, a dark reddish-brown liquid is formed, from which, on cooling, glistening bright-red prisms, $C^{14}H^7N^2O^{10}$, crystallise out; they dissolve in water and alcohol with a crimson colour, which turns brown on addition of ammonia. The ethereal solution, even if very dilute, exhibits a magnificent vermilion-red fluorescence.

On distilling the ethereal mother-liquor of the first of these compounds, a brown syrup is left behind, containing two mononitro-orcinols; one of them, called *α-nitro-orcinol*, volatilises with steam, and is obtained by resublimation in long, soft, glistening, orange-red needles, melting at 120° and dissolving readily in alcohol and ether, but very sparingly in cold water. On boiling it with baryta-water, the normal salt, $C^7H^5(NO^2)O^2.Ba$, is obtained in bronze-coloured needles, which, when suspended in water are decomposed, the acid salt $[C^7H^5NO^2(OH)O]^2Ba$ being formed, which crystallises in small greenish-brown plates with a metallic lustre. *β-nitro-orcinol* is isolated by boiling the tarry residue left after the *α*-compound has been driven off with water, concentrating the solution, and purifying the compound, which crystallises out by boiling a dilute alcoholic solution with animal charcoal. It forms short, slender, dark lemon-yellow needles, containing 1 mol. of water and melting at 115° . The normal barium salt, $C^7H^5(NO^2)O^2Ba + 3H^2O$, forms red granular crystals, and the acid salt, $[C^7H^5NO^2(OH)O]^2Ba + 4H^2O$, crystallises in tufts of golden-yellow prisms. On adding bromine to an ethereal solution of *β*-nitro-orcinol, the compound $C^7H^3Ba^2(NO^2)(OH)^2$ is obtained in dark-yellow plates, melting with decomposition at 112° . The acid barium salt contains 1 mol. of water, and crystallises in red needles. By adding iodine and mercuric oxide to an alcoholic solution of the *β*-compound, dark-yellow woolly needles of the corresponding iodine-compound are formed (Weselsky, *Ber.* vii. 439).

2. *Dinitro-orcinol*, $C^7H^5N^2O^6 = C^6H(CH^3)(NO^2)^2(OH)^2$.—Strong nitric acid acts readily on nitroso-orcinol, especially when heated, forming trinitro-orcinol, together with some oxalic acid. With dilute nitric acid in the cold, however, the action was different, dinitro-orcinol and oxalic acid being produced, but only traces of trinitro-orcinol. When finely-powdered nitroso-orcinol was added to four times its weight of nitric acid of sp. gr. 1.3, care being taken to keep the mixture cool by immersing the beaker in cold water, it gradually acquired a reddish-brown colour; the odour of nitrous fumes soon became apparent; and in the course of five or ten minutes the whole solidified to a pasty crystalline mass, which had to be stirred up at frequent intervals, to prevent its becoming warm, otherwise much trinitro-orcinol would have been formed. In this operation, it is not necessary to employ pure dry nitroso-orcinol, as the crude moist substance answers every purpose—the amount of acid being adjusted so that for every 100 pts. of orcinol originally taken, about 550 of the nitric acid shall be employed. After standing for twenty to twenty-four hours, the product, which had become of an orange colour, was mixed with an equal bulk of cold water, collected on a vacuum-filter, and well washed with cold water. The dry product was then dissolved by agitation with cold ether, in which it is readily soluble; the solution filtered and evaporated to dryness in the water-bath; and the dinitro-orcinol was finally purified by two or three crystallisations from boiling spirit.

Dinitro-orcinol crystallises in deep yellow rhomboidal plates, which are almost insoluble in cold water, more soluble in boiling water, but crystallises out again almost entirely on cooling. It is very soluble in ether, and requires about 18 pts. of alcohol at 15° for solution. It is also slightly soluble in carbon bisulphide, and readily in hot benzene, but almost insoluble in light petroleum. Dinitro-orcinol melts at 164.5° , two degrees higher than trinitro-orcinol, but, unlike the latter, which explodes a little above its melting point, dinitro-orcinol may be heated to above 190° without alteration, and with care may even be sublimed at a somewhat higher temperature. Heated rapidly on platinum foil, it fuses and deflagrates. It is slightly soluble in strong sulphuric acid, with a yellow colour, but when heated with the acid, it dissolves with effervescence, forming a deep orange-coloured solution,

which does not yield a precipitate on the addition of water. It dissolves in hot concentrated nitric acid, and is at the same time converted into trinitro-orcinol.

The derivatives which dinitro-orcinol forms with the alkali-metals, as also the corresponding ammonium-compound, are very soluble in water, and difficult to obtain in the crystalline state; they are of an orange-red colour. When dinitro-orcinol is boiled with water and silver oxide or carbonate, it is decomposed, the silver being reduced, and forming a metallic mirror on the side of the vessel. With barium, it forms two compounds, one of which is almost insoluble in water, and of a deep crimson colour; the other, which forms long silky needles of a bright yellow colour, is sparingly soluble in boiling water, but crystallises out almost entirely on cooling. The crimson barium compound may be obtained by adding an excess of an aqueous solution of barium hydrate to a solution of dinitro-orcinol in spirit: on boiling the mixture, the salt is thrown down as a crystalline powder. It dissolves on boiling it with water and excess of dinitro-orcinol, and the solution, on cooling, deposits the acid salt in orange-yellow needles. In order to obtain them free from dinitro-orcinol, however, it is best to operate in the following manner:—2 pts. of dinitro-orcinol are dissolved in 40 of alcohol, and the solution divided into two parts, one of which is slightly less than the other. The smaller portion is then heated, diluted with its own bulk of hot water, and boiled; a cold saturated aqueous solution of barium hydrate is now added in slight excess (a quantity rather more than equal in volume to the solution of dinitro-orcinol in alcohol and water); the mixture is left to cool in a closed vessel to prevent formation of barium carbonate by absorption of carbonic anhydride from the air; and the precipitate is collected on a vacuum filter and thoroughly washed with cold water. The crimson basic salt thus obtained is converted into the acid salt by boiling it with a considerable quantity of distilled water, and adding the second larger portion of the alcoholic solution of dinitro-orcinol. The crimson salt soon dissolves, and the clear liquid, on cooling, solidifies to a mass of the needle-shaped crystals of the acid barium salt; a second crystallisation from boiling water suffices to purify it. Determinations of the amount of barium gave 23.69 per cent. and 23.61 per cent. Ba, agreeing with the formula $[C^6H^3(NO^2)_2OH]^2BaO^2 + H^2O$ (Stenhouse a. Groves, *loc. cit.*)

3. *Trinitro-orcinol*, $C^6H^3N^3O^8 = C^6(CH^3)(NO^2)_3(OH)^2$, may be prepared by heating orcinol at 100° with excess of sulphuric acid, treating the resulting sulphonic acid after cooling, first with dilute, then with concentrated, and finally with fuming nitric acid in excess, and pouring the product into cold water (Merz a. Zetter, *Ber.* xii. 681).

Aldehydes from Orcinol, and their Derivatives (Tiemann a. Helkenberg, *Ber.* xii. 999). When a solution of orcinol in very dilute soda is boiled with chloroform, three aldehydes are formed, which may be separated by acidifying the mixture with sulphuric acid, and distilling in steam, when *α-orcendialdehyde* will be found in the distillate. By extracting the residue in the retort with ether, a mixture of *orcylaldehyde* and *β-orcendialdehyde* is obtained, from which the latter is removed by shaking up the ethereal extract with a solution of sodium-hydrogen sulphite.

Orcylaldehyde, $C^6H^2(CH^3)(OH)^2.COH$.—The crude product is purified by solution in potash, and reprecipitation by acids; it is then recrystallised from benzene, and finally from water. The pure substance forms colourless needles (m. p. 177°), which dissolve freely in alcohol, ether, chloroform, hot benzene, and boiling water. It unites with aniline to form *orcylaldehydeanilide*, $C^6H^2(CH^3)(OH)^2.C(N.C^6H^5)^2H$, which crystallises in yellow prisms (m. p. 125°), soluble in alcohol, and chloroform.

Homoacetoxycoumarin, $CH^3(OC^2H^3O)C^6H^2\langle\overline{O}\rangle_{CH=CH}CO$, obtained by the action of acetic anhydride and sodium acetate on *orcylaldehyde*, crystallises in colourless needles (m. p. 126°), which are soluble in alcohol and ether. This compound gives a blue coloration with alkalis.

α-Orcendialdehyde, $C^6H(CH^3)(OH)^2(COH)^2$, forms long needle-shaped crystals (m. p. 117°), soluble in alcohol, ether, chloroform, and in hot water. This aldehyde unites with aniline, forming *α-orcendialdehydedianilide*, $C^6H(CH^3)(OH)^2[C(N.C^6H^5)^2H]^2$, a yellow crystalline powder, which melts at 281° .

β-Orcendialdehyde is obtained in pale yellow crystals by decomposing its sodium-sulphite compound with sulphuric acid, extracting with ether, and recrystallising from benzene and from dilute alcohol. This substance melts at 168° , but sublimes at a lower temperature. It is soluble in alcohol, ether, chloroform, benzene, and hot water.

Isorcinsols. Two compounds isomeric with orcinol, and distinguished as *α*- and

γ -isorcinsols, are produced, by the action of melting potassium hydroxide on the respective toluenesulphonic acids (*q. v.*)

α -Isorcinol, obtained in this manner, together with salicylic acid and slight traces of paraoxybenzoic acid, from α -toluenedisulphonic acid, crystallises from water in thickly felted groups of small needles containing water of crystallisation and melting at about 95°. In the anhydrous state it melts at 87°–88°, boils at about 270°, and yields by distillation a thick liquid which takes a long time to solidify. α -Isorcinol is not altered by exposure to the air. With ferric chloride and with silver nitrate and ammonia it produces a violet-blue coloration, which soon disappears. It is coloured yellow by chloride of lime, and blue by contact with ammonia and moist air. By fusion with sodium formate, it yields a dicarboxylic-acid which forms sparingly soluble white flocks exhibiting signs of fusion below 270° (Hakansson, *Ber.* v. 1087).

γ -Isorcinol is formed, also together with salicylic acid, by fusing γ -toluenedisulphonic acid with potassium hydroxide and a little water. On acidifying the aqueous solution of the melt with sulphuric acid, agitating with ether, and treating the resulting ethereal solution with sodium carbonate, the salicylic acid is removed, while the isorcinol remains in the ethereal solution, and may be separated by precipitating with basic lead acetate, and decomposing the precipitate with hydrogen sulphide. It forms a radio-crystalline mass, containing 1 mol. water which is given off at 100°. It differs considerably from orcinol in its properties and reactions, has a sweet but not nauseous taste, melts at 87° and boils at 260°. It dissolves in water, alcohol, and ether; the aqueous solution, syrupy at first, soon solidifies throughout the entire mass. It does not change colour in contact with the air; produces a brownish-green colour with ferric chloride, and a black precipitate with ammoniacal silver solution; is coloured red and gradually yellow by chloride of lime; and when exposed to moist air in contact with ammonia, acquires a brownish colour, which is removed by acetic acid (Senhofer, *Liebig's Annalen*, clxiv. 126).

Betorcinol, $C^6H^{10}O^2 = C^6(CH^3)^2H^2(OH)^2$. This homologue of orcinol, obtained by the destructive distillation of the lichen, *Usnea barbata*, was discovered in 1848 by Stenhouse (iv. 214)—who named it β -orcini—and has lately been further investigated by Stenhouse & Groves (*Chem. Soc. J.* xxxvii. 366), the name being changed, in accordance with present usage, to *Betorcinol*.* It was originally regarded as a product of the decomposition of usnic acid, but recent experiments have shown that pure usnic acid does not yield a trace of it, and that it must therefore be produced from some other constituent of the lichen; this constituent has, in fact, been isolated, and will be described further on.

To prepare betorcinol, *Usnea barbata*, carefully freed from other lichens, is exhausted with milk of lime, the solution precipitated by hydrochloric acid, and the precipitate boiled with lime and water. The clear solution is neutralised with hydrochloric acid and evaporated, whereupon the crude betorcinol crystallises out. When purified by crystallisation from benzene and from water it melts at 163°. It is less soluble than orcinol; gives a bright crimson colour with hypochlorites, orcinol giving a purplish red; and its ammoniacal solution is rapidly coloured on exposure to air, whereas the corresponding orcinol solution is but slowly changed thereby.

Chlorobetorcinsols. *Tetrachlorobetorcinol*, $C^6H^2Cl^4O^2 = C^6(CH^3)^2Cl^2(OCl)^2$, is obtained by the action of chlorine in excess on betorcinol, the best mode of preparation being to add a solution of betorcinol to a solution of chlorine hydrate. A mixture of crystalline chlorine hydrate is first prepared by passing a current of chlorine, with occasional agitation, through water to which about one-fourth part of crushed ice has been added; betorcinol is then dissolved in 50 parts of boiling water; the cooled solution is gradually added to a portion of the chlorine hydrate mixture, leaving the latter in slight excess, and the colourless mixture is left to itself for twelve to twenty hours: it then deposits the tetrachlorinated compound in colourless crystals which may be purified by one or two crystallisations from light petroleum. This compound forms large white prismatic crystals which melt at 109°, and are easily soluble in benzene, but insoluble in water.

Dichlorobetorcinol, $C^6H^4Cl^2O^2 = C^6(CH^3)^2Cl(OH)^2$, is obtained by the action of reducing agents on the tetrachloro-compound just described. The best mode of preparation is to add the tetrachloro-compound by small portions to a solution of hydriodic acid containing 15 per cent. iodine and a small quantity of red phosphorus, in a flask with reversed condenser, taking care that each portion of the tetrachloro-compound is reduced before the next is added, and continuing the boiling, till the last portions are reduced and the whole assumes the appearance of a mass of slender

* β -Orcinol would signify an isomeride rather than a homologue of orcinol.

colourless needles. The dichlorobetorcinol thus obtained forms, after washing and recrystallisation from light petroleum, long colourless needles which melt at 142° and dissolve in carbon bisulphide, benzene, and ether.

Bromobetorcinols. The *tetrabromo-compound*, $C^6H^2Br^4O^2 = C^6(OH)^2Br^2(OBr)^2$, may be prepared by adding betorcinol to bromine and water, keeping the bromine in excess, or better by pouring a mixture of 5 pts. bromine and 30 pts. by measure of carbon sulphide on 1 pt. of finely powdered betorcinol, and gently heating the mixture in a flask furnished with a condensing tube. As soon as the whole of the betorcinol is dissolved, the dark brown solution is decanted from traces of black tar and agitated with an equal bulk of warm water, whereupon the colour gradually becomes lighter; if it should disappear entirely, more bromine must be added. The solution of tetrabromobetorcinol in carbon sulphide is then separated from the supernatant liquid, concentrated by distillation, and left to evaporate, and the crystals which form are purified by recrystallisation from light petroleum. A very pure product may be at once obtained by acting on pure colourless dibromobetorcinol with bromine and water at a gentle heat, and crystallising the product from carbon sulphide and light petroleum.

Tetrabromobetorcinol crystallises in large colourless prisms melting at 101° , and very similar in appearance to the tetrachloro-compound. It is very soluble in ether, benzene, and carbon sulphide, less so in petroleum.

Dibromobetorcinol, $C^6H^2Br^2O^2 = C^6(CH^3)^2Br^2(OH)^2$, may be prepared, like the corresponding chlorine-derivative, by reducing the tetrabromo-compound with hydriodic acid and red phosphorus, taking care that the reduction does not go too far: much more conveniently however by treating betorcinol with bromine diluted with carbon sulphide, the action then going no further than the production of the dibromo-derivative, since the presence of water is necessary to convert this compound into tetrabromo-betorcinol. The resulting solution concentrated by distillation yields the dibromo-compound in nearly colourless crystals, which may be purified by washing with a little carbon sulphide and recrystallisation from light petroleum. Dibromobetorcinol forms long needles melting at 155° , and closely resembling the dichloro-derivative.

The fact that the action of bromine on betorcinol when water is carefully excluded displaces only two atoms of hydrogen, whereas, in presence of water, a tetrabromo-derivative is formed, is due to the great difference between the amount of energy involved in the formation of gaseous hydrogen bromide by the direct union of bromine and hydrogen, and that which is manifested in the formation of hydrobromic acid in aqueous solution, the quantities of heat evolved in the two cases being, according to Thomsen (vii. 612), $H + Br = 8440$, and $H + Br + aq. = 28376$ gram degrees. Now in betorcinol the two H-atoms united with carbon in the benzene-nucleus are displaced by bromine with comparative facility, the compound $C^6(CH^3)^2Br^2(OH)^2$ being produced, with evolution of HBr ; but in the case of the two H-atoms united with oxygen in the OH-groups, it is only when the much greater energy involved in the formation of hydrobromic acid in presence of water is exerted, that substitution takes place, resulting in the formation of the tetrabromo-derivative. A precisely similar difference is observed in the action of bromine on orcinol, accordingly as water is present or absent, the substitution in the latter case going no further than the production of tribromorcinol.

Iodobetorcinol, $C^6H^2IO^2 = C^6(CH^3)^2HI(OH)^2$. This compound, the only known iodo-derivative of betorcinol, may be prepared similarly to iodorcincin (vii. 879) by the action of lead oxide on betorcinol and iodine in ethereal solution. After crystallisation from light petroleum, it melts at 93° . It dissolves very readily in ether, benzene, and carbon sulphide, very sparingly in boiling water, more freely in dilute spirit, but does not crystallise well from the latter.

Nitrosobetorcinol, $C^6H^2NO^2 = C^6(CH^3)^2H(NO)(OH)^2$, is readily prepared by the action of nitrosyl sulphate, $SO^2(NO)OH$ (p. 1419) on betorcinol in aqueous solution. Betorcinol (2 pts.) is dissolved in 100 pts. of boiling water, and the solution, after filtering and cooling, is poured into a mixture of 7 pts. nitrosyl sulphate solution (containing 15 per cent. N^2O^3) with 200 pts. of water, whereupon a brilliant orange-red precipitate makes its appearance. This, after a few minutes, is collected on a vacuum-filter, washed by stirring it up with 100 pts. of water, and again collecting, repeating the washing once more in the same manner so as to remove the last trace of free acid, and finally dried at a gentle heat.

Nitrosobetorcinol is moderately soluble in water and readily in alcohol, but is not easily recovered from either of these solvents in the crystalline state. It dissolves very readily in hot glacial acetic acid, and separates on cooling in small bright-red prismatic crystals. It is sparingly soluble in light petroleum and in carbon sulphide,

somewhat more freely in hot benzene, from which it crystallises on cooling; easily soluble in ether.

This compound, in which only one of the hydrogen-atoms is replaced by NO, appears to be the only nitroso-derivative of betoreinol, whereas orcinol and resorcinol, when treated with nitrous acid, yield dinitroso-derivatives. Considering now that the action of nitrous acid on phenol, the *mon*hydroxy-derivative of benzene, gives rise to a *mon*nitroso-phenol in which the NO-group occupies the para-position with respect to the OH-group, and that, of the three *metadi*hydroxy-derivatives of phenol, resorcinol and orcinol yield *di*-nitroso-derivatives, whilst betoreinol yields only a *mon*-nitroso-derivative, it seems not improbable that, in the latter, the para-position with respect to one of the OH-groups is occupied by a CH³-group.

Of the four possible formulae for betoreinol, or *dimethyl-dihydroxybenzene*, viz.

I. is capable of yielding a dinitroso-derivative in which the NO-groups can occupy a para-position with respect to the OH-groups, and in IV. the para-positions are occupied by CH³-groups, so that it could not yield a nitroso-derivative of this class, whilst in II. and III. there is *only one* para-position into which the NO-group could enter, whence it follows that these bodies would yield *mon*nitroso-derivatives. Our knowledge of the laws which govern the introduction of the nitrosyl-group into the hydroxyl-derivatives of benzene is at present far too limited to enable us to pronounce with certainty on this point; but it seems most probable that the constitution of betoreinol is represented by the formula II. or III. rather than by I. or IV.

The acid which yields betoreinol may be separated from usnic acid by means of its greater solubility in cold ether. It melts at 186°, and decomposes at a somewhat higher temperature, yielding carbon dioxide and betoreinol. It is represented by the formula C¹⁸H²⁰O⁷, and is related to betoreinol in the same manner as evernic acid, C¹⁷H¹⁶O⁷, to orcinol, and might therefore be regarded as *dimethyl-evernic acid*. As however this constitution cannot at present be assigned to it with certainty, Stenhouse a. Groves have provisionally named it *barbatic acid*. Hesse (*Ber. x.* 1326) obtained from an *usnea* growing on Calisaya bark, an acid which he called *usnetic acid*. This acid is probably not identical with barbatic acid, but may be an ethereal salt thereof, as alcohol was used in its extraction and purification.

ORCINOL-PHTHALEIN. See PHTHALEINS.

ORGANIC COMPOUNDS. *Decomposition of Organic Liquids by the Electric Spark.*—Berthelot inferred from his experiments on the action of a red heat on hydrocarbons (vi. 259), that when a hydrocarbon of high molecular weight is submitted to destructive distillation, the four fundamental hydrocarbons, acetylene, ethylene, methane, and ethane are first separated, and these, immediately entering into combination with each other, produce the more complex hydrocarbons which are actually obtained; and this view has been considerably strengthened by the recent experiments of Truchot (*Compt. rend.* lxxxiv. 714), in which organic compounds were decomposed in such a manner that the simpler hydrocarbons produced in the first instance were prevented from recombining, and thus obtained in the free state. This was effected by passing a powerful induction spark through the liquid itself, and collecting the resulting gases.

Volatile liquids, such as pentane, pentylene, and ethyl oxide thus treated give about 1 litre of gas per hour, but compounds of higher boiling point give considerably less. The gas invariably contains hydrogen in addition to the hydrocarbons already mentioned, but no compound containing more than two atoms of carbon in the molecule is present. With the liquid paraffins, no deposit of carbon occurs during the decomposition, provided the liquid be kept slightly warm; and a trace of carbon only is obtained in the case of an olefine. With the less saturated hydrocarbons, however, such as the terpenes and benzene derivatives, a tolerably abundant deposition of carbon always takes place. Compounds containing oxygen, such as alcohol, ether, and

the aldehydes, give no carbon; but, in addition to the fundamental hydrocarbons, they evolve carbon monoxide, unaccompanied by carbon dioxide or water-vapour.

Action of Boron Fluoride.—The action of this compound on hydrocarbons and oxygenated organic bodies has been studied by F. Landolph (*Ber.* x. 1812). By passing the gas over comminuted *camphor*, a crystalline mass is obtained which melts below 200°, gives off the whole of the absorbed gas on distillation, leaving the *camphor* in the pure state, but when heated to 250° in a sealed tube for 24 hours is completely resolved into boric acid, gases having an acid reaction, and a mixture of hydrocarbons, the chief constituent of which (amounting to 40 per cent. of the *camphor* decomposed) is *cymene*. At the same time there is formed a yellowish-green viscid hydrocarbon which boils above 350°.

Anisöl is violently attacked by boron fluoride, yielding a body which distils over at 158°–163°, and hydrocarbons of high boiling point, together with a heavy liquid which is partially decomposed by contact with the air, with separation of boric acid, and is resolved by water into boric acid and hydrogen fluoride.

With *benzaldehyde*, boron fluoride unites in definite proportions, forming a well-crystallised compound, which on exposure to the air splits up into *benzaldehyde*, boric acid, and hydrogen fluoride, and when heated to 250° in a sealed tube for 24 hours, is converted into a black solid mass from which ether extracts a hard white substance melting at 123°–124°, solidifying again at 80°, and crystallising from water in slender shining needles.

Chloral is converted by boron fluoride into *metachloral*; *acetic acid* into the anhydride; *succinic acid* is not acted on. With *ethylene*, boron fluoride forms *ethylene fluoboride*, a liquid which boils at 126°, and when exposed to the air immediately evaporates, giving off white strongly acid fumes, together with *ethylene*, and leaving a small quantity of boric acid.

Action of Chromyl Chloride, CrO_2Cl_2 (Etard, *Compt. rend.* lxxxiv. 127; *Bull. Soc. Chim.* [2], xxvii. 249). 1. *Chloroform* treated with this compound yields *carbonyl chloride*, COCl_2 . 2. *Glacial acetic acid* heated to 100° in sealed tubes with *chromyl chloride* yields a crystalline salt, $\text{Cr}^2\text{O}^2[\text{Cr}^2(\text{C}^2\text{H}^3\text{O}^2)^2]^2 + 8\text{H}^2\text{O}$, which exhibits dichroism (being yellow-green by transmitted, dark green by reflected light), together with free chlorine and chromic chloride; no acetyl chloride was observed. 3. *Ethyl acetate* is converted into *acetic acid* and *aldehyde*. 4. *Pentane* from petroleum and *inactive amyl chloride* yields *chloromethyl-isobutyl ketone*, $\text{CH}^2\text{Cl}-\text{CO}-\text{CH}^2\cdot\text{CH}(\text{CH}^3)_2$, a colourless liquid having a pungent aromatic odour, and boiling without decomposition at about 120°. 5. *Hexane* is converted into an acid, and a liquid, $\text{C}^6\text{H}^{11}\text{ClO}$ (probably a chlorinated ketone), which boils at 145°–150°, easily reduces ammoniacal silver solution, does not unite with acid sodium sulphite, and is not attacked by potassium hydrate. 6. *Benzene* is converted into *quinone*. 7. *Paradibromobenzene* yields a compound, probably $\text{C}^6\text{Cl}^2\text{Br}^2\text{O}^2$, converted by soda-ley into *chloranilic acid*. 8. *Nitrobenzene* yields *nitroquinone*, $\text{C}^6\text{H}^3(\text{NO}^2)_2\text{O}^2$, which crystallises in yellow shining scales, melts at 232°, and sublimes at a higher temperature. 9. *Phenol* yields *quinolic ether*, $\text{C}^6\text{H}^4(\text{OH})\cdot\text{O}\cdot\text{C}^6\text{H}^4(\text{OH})$, a white uncrystallisable substance convertible by oxidation into *quinone*. 10. *Toluene* yields *benzaldehyde*, together with *benzyl chloride*. 11. *Nitrotoluene* is converted into *nitrotoluquinone*, $\text{C}^6\text{H}^3(\text{NO}^2)(\text{CH}^3)\text{O}^2$, which forms large brown-yellow crystals melting at 237°, and easily subliming. The reaction is attended with the formation of a somewhat considerable quantity of *ozone* (Etard).

Anthracene dissolved in *acetic acid* is converted by *chromyl chloride* into *anthraquinone* (Haller, *Ber.* x. 734).

Analysis.—A method of determining the carbon, hydrogen, oxygen, nitrogen, sulphur, phosphorus, and halogen elements in an organic compound by a single combustion is described by A. Mitscherlich (*Ber.* vi. 1000). It consists in burning the substance with mercuric oxide in a combustion-tube from which the air has been displaced by a current of pure nitrogen, the mercuric oxide in contact with organic matter being reduced at a temperature below that which is required for its decomposition by heat alone. The water and carbon dioxide thereby formed are estimated by absorption and weighing in the usual manner; the mercury reduced by the combustion is driven by a strong stream of nitrogen into a weighed tube; and the quantity of oxygen equivalent to this reduced mercury, deducted from the total amount of oxygen contained in the carbon dioxide and water together, gives the quantity of that element contained in the substance under examination. Chlorine, bromine, or iodine, if present, unites with a portion of the liberated mercury, forming a compound which passes over with the metallic mercury, and may be estimated by weighing. Sulphur and phosphorus are oxidised to sulphuric and phosphoric acid respectively, which may be esti-

mated by known methods. *Nitrogen-compounds* yield nitrogen dioxide, which may be absorbed by a mixture of chromic acid and stannous chloride in an apparatus placed between the calcium chloride tube and the potash-balls.

A similar method for the simultaneous determination of carbon, hydrogen, nitrogen, and oxygen is given by Frerichs (*Ber.* x. 26). The substance is burned with mercuric oxide in a tube exhausted of air, and the evolved gases are dried, passed into a eudiometer, and analysed in the usual way. The water formed is absorbed by phosphoric anhydride.

A method of analysis by *reduction*, whereby the carbon, hydrogen, and oxygen in an organic compound may be determined directly, is described by H. Cretier (*Zeitschr. anal. Chem.* 1874, 1). The vapour of the organic body or of its products of decomposition is passed over ignited magnesium-powder, which abstracts the whole of the oxygen, yielding a gaseous mixture consisting only of carbon and hydrogen, in which these elements can be estimated by the usual methods of gas-analysis. In this manner the entire weight of hydrogen in the organic substance is at once obtained; and that of the carbon may be ascertained by adding the weight of the charcoal remaining after the decomposition to that contained in the gaseous mixture. The amount of oxygen is calculated from the weight of the unaltered magnesium. The results, however, are not very exact.

On the estimation of *Chlorine, Bromine, and Iodine* in Organic Compounds, see HALOGENS (p. 924).

To obviate the errors arising from the use of reduced copper for decomposing the nitrogen oxides evolved in the combustion of azotised organic bodies (p. 183), Perkin has devised a method of removing these compounds by oxidation and absorption, instead of reducing them with copper. The best absorbent for the purpose is a mixture of potassium chromate and manganese dioxide. In making a combustion, about 6 inches of the mixture are placed in the front part of the tube (the oxygen process being used) and the whole of the tube is heated and dried with air in the usual way. The temperature of the mixture is then allowed to fall to about 200° to 250°, and the combustion is conducted in the ordinary way. By re-heating the mixture strongly and passing a current of air over it, the oxides of nitrogen are removed and the mixture is ready for a second combustion. If the organic substance contains sulphur, a greater length of the mixture must be used, the back part being strongly heated to absorb the sulphur dioxide, and the front part maintained at 200° to 250° to absorb the oxides of nitrogen (*Chem. Soc. J.*, 1880, xxxvii. 121, 418).

An indirect method for the quantitative analysis of a mixture of organic compounds of known composition, by means of equations with several unknown quantities, is proposed by R. Popper (*Zeitschr. anal. Chem.* x. 429). An ultimate analysis of the mixture is first made, and the resulting equation, $x + y + z \dots = u$, is combined with those which are deduced from the percentages of carbon and hydrogen in the several proximate constituents of the mixture. Suppose, for example, that a mixture of stearic acid, naphthalene, and pyrocatechin, weighing 0.555 grams, gives by ultimate analysis 0.3936 carbon and 0.0422 hydrogen: then we have the three equations:

$$\begin{aligned} x + y + z &= 0.555 \\ \frac{216}{284}x + \frac{120}{128}y + \frac{72}{110}z &= 0.3936 \\ \frac{36}{284}x + \frac{8}{128}y + \frac{6}{110}z &= 0.0422 \end{aligned}$$

in which the denominators are the molecular weights of the three constituents, and the numerators are the atomic weights of the quantities of carbon and hydrogen contained therein.

On the Incineration of Organic Matter preparatory to testing for Metallic Poisons, see Verryken (*Chem. Centr.* 1873, 696; *Chem. Soc. J.* xxvii. 603).

On Incineration with Barium or Potassium Hydrate for the estimation of Chlorine and Alkalis, see Behagel von Adlerskron (*Zeitschr. anal. Chem.* 1873, 390; *Jahresb. f. Chem.* 1873, 949).

ORGANOIDS. The organoids of the peninsula of Abscheron on the Caspian Sea have been described by H. Abich (*N. Petersb. Acad. Bull.* xxi. 493). The petroleum has lately been obtained in this locality by numerous borings, and rises in the bore-holes under very high pressure. In one shaft near Balachani, Abich found a brownish layer resembling sandstone, covered with alluvial argillaceous sands, con-

taining numerous concretions in its lower part, and gradually passing into true sandstone. An analysis of the mass by C. Schmidt gave:

X (%)	NaCl	K ² SO ⁴	Na ² SO ⁴	CaSO ⁴	MgSO ⁴	CaCO ³	Y (%)	Z (%)
10.150	0.011	0.008	0.034	0.126	0.053	9.382	33.059	47.177 = 100

(¹) Volatile matters, of which 1.690 per cent. consisted of water and other matters given off at 100°, 0.793 per cent. at 100°–110°, and 7.667 per cent. above 110°. (²) Silicates, and silica soluble in hydrofluoric acid. (³) Quartz-sand insoluble in hydrofluoric acid.

The silicates included under Y consisted for the most part of:

SiO ²	Al ² O ³	Fe ² O ³	Mn ² O ³	MgO	CaO	Na ² O	K ² O
29.405	1.799	0.529	0.005	0.345	0.223	0.429	0.324 = 33.059

According to these results, the rock is a mixture of about 10.1 per cent. naphtha and paraffin, 0.3 sea-salts, 0.4 fragments of shells, 10.4 felspar with a little mica, and 63.8 quartz-sand.

ORNITHINE, C⁵H¹²N²O² (Jaffe, *Ber.* x. 1925). A base obtained by prolonged boiling of ornithuric acid (*infra*) with hydrochloric acid:

It has not yet been obtained quite pure, but it forms well-crystallised salts with acids. Two *hydrochlorides* have been obtained, viz. 3C⁵H¹²N²O²·2HCl and C⁵H¹²N²O²·HCl; also an *oxalate* probably having the composition 3C⁵H¹²N²O²·2C²H²O⁴. Ornithine is regarded by Jaffe as diamidovaleric acid, C⁴H⁷(NH²)²·CO²H.

Benzoyl-ornithine, C⁹H¹⁴(C⁷H⁵O)N²O², is obtained by boiling ornithuric acid with hydrochloric acid until the whole is just dissolved. It crystallises in hard colourless needles; melts at 225°–230°; dissolves readily in water, but is insoluble in alcohol and in ether; unites with acids, forming easily soluble salts. By prolonged boiling with hydrochloric acid it is resolved into benzoic acid and ornithine.

ORNITHURIC ACID, C¹⁰H²⁰N²O⁴ (Jaffe, *loc. cit.*) An acid formed by the decomposition of benzoic acid in the organism of birds. It is extracted from the excrements of birds whose food has been mixed with benzoic acid, by boiling with alcohol, evaporating the filtrate, redissolving the residue in absolute alcohol, and again evaporating the filtered solution. The residue which then remains is mixed with a small quantity of water and shaken up with ether, which dissolves fat, benzoic acid and ornithuric acid (because it is still impure); the ethereal solution is decanted, and the residue is mixed with dilute sulphuric acid and again shaken up with ether. The united ethereal solutions, left at rest in a cool place, deposit ornithuric acid only slightly coloured. The greasy mass left undissolved by the ether is set aside to crystallise; the solidified crystalline mass is left to drain on a filter, then washed on the filter with water, and dissolved in hot water and ammonia; the solution boiled with milk of lime and filtered; the strongly coloured filtrate cautiously decolorised by small quantities of potassium permanganate; and the clear nearly colourless filtrate is mixed with hydrochloric acid, whereupon it deposits ornithuric acid. For further purification, the united products are repeatedly crystallised from alcohol.

Ornithuric acid crystallises in small colourless anhydrous needles; melts at 182°; is nearly insoluble in ether, sparingly soluble in water, more freely in ethyl acetate, most easily in hot alcohol. When somewhat strongly heated, it gives off an odour of bitter almonds and yields a woolly sublimate. It reddens litmus, forms soluble salts with the alkalis and alkaline earths, insoluble salts with the oxides of the heavy metals. Its decomposition by hot hydrochloric acid has been already mentioned.

In constitution ornithuric acid is analogous to hippuric acid, being formed by the union of 2 mol. benzoic acid and 1 mol. ornithine, with elimination of 2 mol. water.

OROSELONE, C¹⁴H¹²O⁴. See PEUCEDANIN.

ORTHITE. This mineral has been found, together with albite, in a trachyte-enclosure of the trachytic conglomerate of the Langenberg, near Heisterbach, in the Siebengebirge. This is the third instance of the occurrence of orthite—formerly known only as belonging to the palæocrystalline rocks (iv. 237)—in volcanic rocks, the other two volcanic localities in which it has been found being Laach in the Eifel and Vesuvius (G. vom Rath, *Pogg. Ann. Mineral.* 1874, 547).

From numerous analyses of orthite from various localities, Engström (*Ber.* x. 1727) deduces the formula 2(2RO·SiO²) + 3RO²·4SiO², with 1 or with 2H²O, regarding the first, viz. Si⁴R³H²O²⁰, which is analogous to the formula of epidote (p. 736), as the true formula of undecomposed orthite.

On the microscopic characters of orthite, allanite, and gadolinite, see Sjögvén (*Jahrb. f. Min.* 1877, 730; *Chem. Soc. J.* xxxiv. 387).

ORTHOCLASE. Well-defined orthoclase crystals from a granite cleft at Schiltach in Baden, are described by F. Klocke (*Jahrb. f. Min.* 1874, 568). They belong partly to the ordinary type $\infty P. \infty R \infty . 0P. P \infty$, partly to the rarer type, $\infty P. \infty P \infty . 0P. P \infty$. Some of the crystals exhibit also the well-known occurrence of implanted crystals of albite. Westphal (*ibid.* 33) found orthoclase crystals resembling sanidin in a vein of porphyry near Weistropp between Dresden and Meissen. C. Doelter (*Min. Mitth.* 1875, 180) describes orthoclase in simple crystals and in Carlsbad twins, from the quartz-porphyry of the Val di Madonna, a side valley of the Val Floriana on the north-west declivity of the Zocchialti mountain, South Tyrol. A fine pseudomorphous penetration-twin crystal of tin-stone after orthoclase, from Redruth, Cornwall, has been examined by H. Laspeyres (*Jahrb. f. Min.* 1877, 529) who finds the twin law to be one entirely new to orthoclase, viz.: 'the twin-plane a face of ∞P .' The two halves of this penetration-twin are extremely well developed contact-twins according to the Carlsbad law, viz.: 'the two individuals of each Carlsbad-twin being a right and left crystal.'

The following are recent analyses of orthoclase: 1. From Greenland granite (Kottal, *Wien. Akad. Ber.* [1]. lxi. 94). 2—4. From the granitic gneiss of New York. 2. Colourless, translucent, distinctly cleavable; 3. Flesh-coloured, indistinctly cleavable, enclosing numerous crystals of mica; 4. Of medium purity and colour (P. Schweitzer, *Amer. Chem.* iv. 444):

SiO ²	Al ² O ³	Fe ² O ³	K ² O	Na ² O	H ² O	Sp. gr.
65.00	17.85	0.28	15.75	0.83	— = 99.71	2.57
64.99	18.55	0.64	12.24	3.48	0.13 = 100.03	2.559
65.47	18.22	0.67	13.71	2.21	0.19 = 100.47	2.562
65.50	17.94	0.87	13.11	2.40	0.23 = 100.05	2.558

A sodium felspar with orthoclastic cleavage, allied, therefore, to loxoclase, occurs in the slags and tufas of the island of Rachgoun, Algeria. See LOXOCLASE (p. 1242). For other analyses of orthoclase, see FELSPAR (p. 773).

ORTHO-DERIVATIVES, AROMATIC. *Ortho-acetobromanilide* and *-chloranilide*. See ACETAMIDES (pp. 4, 5).

Ortho-aldehydo-salicylic Acid. See BENZOIC ACIDS (OXY-), (p. 288).

Ortho-aldehydo-vanillic Acid. See BENZOIC ACIDS (DIOXY-), (p. 292).

Ortho-amidodibromobenzenesulphonic Acid, C⁶H³SO³H.NH².Br.H.Br.H. On the reaction of this acid with bromine, see BENZENESULPHONIC ACIDS (p. 281).

Ortho-amidodiphenyl. See PHENYL (DI-).

Ortho-amidophenolsulphonic Acid. See PHENOLSULPHONIC ACIDS.

Ortho-amidosalicylic Acid. See BENZOIC ACIDS (OXY-), (p. 283).

Ortho-benzenedisulphonic Acid, or *Benzene-orthodisulphonic Acid*, C⁶H⁴SO³H.SO³H.H⁴. This acid is formed by boiling metadiazobenzenesulphonic acid with alcohol. Its *chloride*, C⁶H⁴(SO²Cl)², crystallises in large colourless four-sided plates, melting at 105°; the *amide*, C⁶H⁴(SO²NH²)², in small needles, separate or grouped in nodules, and melting at 233°. The following is a comparison of the melting points of the chlorides and amides of the three benzenedisulphonic acids (compare p. 257):

	Ortho	Meta	Para
Chloride	105°	63°	132°
Amide	233	229	288

(Drebes, *Ber.* ix. 553; compare table, p. 257).

Ortho-cresol. See PHENOLS.

Orthodiazobenzoic Nitrate. See BENZOIC ACIDS (DIAZO-), (p. 274).

Orthonitranilinesulphonic Acid, C⁶H³(NO²)(NH²)(SO³H), is formed by heating orthonitrobenzanilide (m. p. 94°) with pyrosulphuric acid on the water-bath for several hours. The free acid and its barium salt, [C⁶H³(NO²)(NH²)SO³]²Ba + H²O, crystallise in thick yellow needles (Behrens a. Post, *Ber.* viii. 1558).

Orthonitrobenzonitril, C⁶H⁴NO².CN. [NO²:CN = 1:2], is obtained by heating orthonitrobenzamide (m. p. 174°) with phosphoric anhydride to 180°. It crystallises in needles easily soluble in water and alcohol, and melting at 109° (Hübner a. Bärthlein, *Ber.* x. 1713).

On *Meta*- and *Paranitrobenzonitril*, see p. 307.

Orthonitrobenzyl Chloride, $C^6H^4(NO^2).CH^2Cl$, is formed by the action of chlorine at 150° – 200° , on orthonitrotoluene, as a viscid oil, having a pleasant aromatic odour, producing a burning sensation on sensitive parts of the skin, and solidifying after some time to a network of slender needles. It reacts with silver acetate, forming orthonitrobenzyl acetate, $C^6H^4(NO^2).CH^2(OC^2H^3O)$.

Orthonitrobenzyl Bromide is very much like the chloride, may be prepared in a similar manner, and produces an analogous reaction with silver acetate.

Para-nitrotoluene appears to react with halogens in the same manner as the ortho-compound (Wachendorff, *Ber.* viii. 1101).

Orthonitrochlorobenzene, $C^6NO^2.Cl.H^4$, is formed by the action of nitrous acid on paranitro-metachloraniline, $C^6.NO^2.Cl.H.NH^2.H^2$. It is solid at ordinary temperatures, melts at 32.5° , and boils at 243° . Jungfleisch's β -nitrochlorobenzene, described as liquid at ordinary temperatures (vii. 144), was probably impure (Beilstein a. Kurbatow, *Ber.* ix. 633).

Orthonitro-metadichlorobenzene, (1 : 2 : 4), or $C^6.NO^2.Cl.H.Cl.H^2$ (p. 186), yields by reduction with tin and hydrochloric acid, a chlorophenylenediamine from which the chlorine cannot be removed by sodium-amalgam (Beilstein a. Kurbatow, *Ber.* ix. 633). See, on the contrary, Körner (p. 186 of this volume). The same nitrodichlorobenzene heated with alcoholic potash yields a compound melting at 62° – 63° , probably $C^6H^3Cl(NO^2)(OC^2H^3)$ (B. and K.). *Nitro-orthodichlorobenzene*, $C^6.NO^2.H.Cl.Cl.H^2$ (p. 187), melting at 43° , is converted by heating with ammonia into a chloronitraniline, $C^6H^3Cl(NO^2)(NH^2)$, which crystallises in light yellow needles melting at 104° – 105° , easily soluble in alcohol and carbon sulphide. Its *acetyl-derivative* crystallises in colourless needles melting at 139° , and is converted by nitrous ether into metachloronitrobenzene (B. and K.).

Orthonitrometachloraniline, $C^6.NO^2.NH^2.H.Cl.H^2$ (m. p. 124° – 125°), is converted by heating with alcoholic soda into ethylic chloronitrophenate, $C^6H^3Cl(NO^2).OC^2H^3$ (Beilstein a. Kurbatow, *Liebig's Annalen*, clxxxiii. 110).

Orthonitro-paracresol. See PHENOL, HOMOLOGUES OF.

Ortho-oxyphenylurethane. See OXYPHENYLURETHANE.

OSMIUM. *Atomic Weight* 200 (Deville a. Debray, *Compt. rend.* lxxxiii. 709). Crystallised osmium may be obtained by passing vapour of osmium tetroxide carried forward by a stream of nitrogen through a red-hot porcelain tube lined with pure carbon.* The osmium is thereby reduced, with formation of carbon dioxide, and the inner surface of the carbon cylinder soon becomes coated with metallic osmium, which prevents the carbon from acting directly on the osmium tetroxide. Part of the carbon, however, penetrates the layer of osmium and is oxidised to carbon monoxide, which meets the osmium tetroxide at a farther part of the tube and reduces it to metal. In this manner there is formed a tube of osmium very much like the tube of zinc oxide which is produced when zinc vapours issue and burn from a round opening. Frequently also this process is attended with the formation of copper-red crystalline scales, consisting of osmium sesquioxide, Os^2O^3 . Amorphous pulverulent osmium is readily produced by passing the vapour of osmium tetroxide mixed with carbon monoxide containing carbon dioxide through an ignited porcelain tube. This amorphous metal may be converted into crystallised osmium by fusing it in a graphite crucible with three or four times its weight of pure tin, dissolving out the excess of tin with hydrochloric acid, and finally heating the residual crystals in a stream of hydrochloric acid gas.

Pure osmium has a fine blue colour, with a grey to violet glitter; crystallises in thin funnel-shaped groups composed of cubes or of rhombohedrons very near to cubes; it is harder than glass, which it scratches, and has the highest sp. gr. of all known bodies, viz. 22.477 (uncor.)

Oxysulphides.—When an aqueous solution of osmium tetroxide is treated with hydrogen sulphide, a precipitate is formed which, when suspended in water, and submitted to the further action of hydrogen sulphide, yields a loosely crystalline body, easily oxidised on exposure to the air, and having the composition $Os^2S^2O^5.2H^2O$. The oxidation of this body by air at 70° – 80° yields an unstable, odourless, insoluble substance having the composition $OsSO^3.3H^2O$, and converted by further exposure to air into osmium tetroxide. The replacement of an atom of oxygen in osmium tetroxide by sulphur is attended with a complete alteration in the properties of the compound, osmium tetroxide being a stable strong-smelling substance soluble in water, whereas

* Such a lining may be formed by passing benzene-vapour through the red-hot tube.

the oxysulphide, OsSO_3 , is easily decomposable and peculiarly easy to reduce with hydrogen. Ammonia converts this oxysulphide, with separation of water and great rise of temperature, into a brown product, which contains osmium and nitrogen, in the atomic ratio 1 : 1, and gives off ammonia only after prolonged boiling with caustic soda (E. v. Meyer, *J. pr. Chem.* [2], xvi. 77).

On the separation of Osmium from Platinum, see PLATINUM.

OSSEIN. See PROTEÏNS (Appendix to).

OSTEOLITE. According to Petersen (*Jahrb. f. Min.* 1873, 386), osteolite from the Rossberg, near Darmstadt, contains 34.7 per cent. phosphoric acid.

OSTRUTHIN. A neutral body obtained by Gorup-Besanez (*Ber.* vii. 564) from the root of Master-wort (*Imperatoria Ostruthium*) in treating that root with hot alcohol, with the view of obtaining peucedanin (iv. 386). The chopped roots were exhausted with hot alcohol; the filtrate freed from alcohol by distillation; the sticky residue exhausted with ether, with addition of a little petroleum-spirit (ligroin); and the ethereal solution mixed with a quantity of ligroin sufficient to produce a strong turbidity, and filtered after a resinous mass had separated from it. The filtrate freed from ether by evaporation yielded ostruthin in yellow rhombic crystals; and on leaving these to drain, dissolving them in potash, precipitating with carbonic acid, redissolving in alcohol, and precipitating with water, the ostruthin was obtained in slender, colourless silky needles whose composition is represented by the empirical formula $\text{C}^{14}\text{H}^{17}\text{O}^2$.

Ostruthin prepared as above is accompanied by a small quantity of another body containing less carbon and more hydrogen.

The following table exhibits a comparative view of the characters of imperatorin, peucedanin, and ostruthin:

Imperatorin of Osann and Wackenroder	Peucedanin of Schlatter, Bothe, and Erdmann	Ostruthin
Thick, well-formed, hard rhombic prisms or silky scales.	White, light prisms united into clusters.	Fine, white, silky needles.
Burning taste.	Burning acrid taste.	Tasteless.
Melts at 75° .	Melts at 60° .	Melts at 115° .
Hardly soluble in cold spirits of wine.	Hardly soluble in cold spirit. The solutions yellow.	Easily soluble in cold spirit. The solutions fluorescent and colourless.
Soluble in ether.	Soluble in ether and petroleum spirit.	Soluble in ether; slightly soluble in petroleum spirit.
Insoluble in ammonia; slightly soluble in weak potash.	Soluble in hot ammonia and weak potash.	Soluble in cold ammonia and diluted potash.

From this comparison, Gorup-Besanez concludes that imperatorin and peucedanin are not identical, but distinct constituents of the root, produced at different stages of development of the plant. R. Wagner, on the other hand (*Ber.* vii. 590), regards them as identical.

Ostruthin Hydrochloride, $\text{C}^{14}\text{H}^{17}\text{O}^2.\text{HCl}$, and the *hydrobromide*, $\text{C}^{14}\text{H}^{17}\text{O}^2.\text{HBr}$, are produced by passing gaseous hydrogen chloride and bromide into an alcoholic solution of ostruthin. The hydriodide has not been obtained.

Ostruthin fused with potash yields resorcinol, acetic acid, and butyric acid. Heated with *strong nitric acid*, it is violently attacked, with formation of oxalic acid; by prolonged boiling with *dilute nitric acid*, on the other hand, it yields styphnic acid.

With *bromine*, ostruthin yields substitution-products, viz. $\text{C}^{14}\text{H}^{14}\text{Br}^2\text{O}^2$ and $\text{C}^{14}\text{H}^{12}\text{Br}^2\text{O}^2$; with *chlorine*, mixtures for which no definite formulæ can be established. Heated with acetyl chloride it yields acetylostruthin in nacreous laminae (Gorup-Besanez, *Liebig's Annalen*, clxxxiii. 321).

OXALAN. Syn. with OXALURAMIDE.

OXALCARBAMATE, ETHYLIC, $C^2H^1NO^3 = NH \begin{smallmatrix} CO.OC^2H^3 \\ CO.CO.OC^2H^3 \end{smallmatrix}$. This

compound is formed by treating oxalic ethochloride with urethane in a flask with upright condenser, heated on an oil bath :

It crystallises from ether in tufts of vitreous brittle needles, dissolves in water, alcohol, and ether, but crystallises well only from the last. Melts at 45° (F. Salomon, *J. pr. Chem.* [2], ix. 290).

By heating oxamethane, $NH^2.C^2O^2.OC^2H^3$, with oxalic ethochloride, Salomon a. Peitzsch obtained the compound $NH \begin{smallmatrix} C^2O^2.OC^2H^3 \\ C^2O^2.OC^2H^3 \end{smallmatrix}$, which they regard as isomeric

with ethylic mesoxalcarbamate, $NH \begin{smallmatrix} CO.OC^2H^3 \\ C^2O^3.OC^2H^3 \end{smallmatrix}$. It crystallises from ether in radiate tufts of slender needles melts at 67° , and decomposes with great facility. With alcoholic ammonia it yields oxamide; potassium ethylate added to its alcoholic solution immediately throws down potassium ethoxalate; silver oxide added to its aqueous solution throws down silver ethoxalate.

OXALETHYLINES. Wallach, by acting on diethyloxamide with phosphorus pentachloride, obtained a base, $C^6H^9ClN^2$, which he called chloroxalethyline (p. 453); and from this a number of other bases have been obtained by Wallach a. Oppenheim (*Ber.* x. 1193).

Di-oxalethyline, $C^{12}H^{16}N^4$, produced by the action of sodium on chloroxalethyline dissolved in petroleum-ether, boils above 300° , and forms an amorphous very sparingly soluble platinumchloride, $C^{12}H^{16}O_4.2HCl.PtCl^4$.

When chloroxalethyline dissolved in carbon disulphide is treated with bromine, two compounds are formed, chlorbromoxalethyline dibromide, $C^6H^8ClBrN^2.Br^2$, and a compound of this with hydrobromic acid, $C^6H^8ClBrN^2.Br^2.BrH$, which latter is also produced by the action of hydrobromic acid on the former dissolved in chloroform. The tetrabromine-compound is the less soluble of the two in chloroform. The tribromine-compound dissolves easily in chloroform, and separates in large red crystals melting at 133° . From measurements by Bodewig, these crystals appear to be monoclinic; $a : b : c = 2.0645 : 1 : 1.796$; angle $\beta = 74^\circ 27'$. Observed forms $\infty P, 0P, -P \infty$, also $\infty P \infty$ and $\pm P$. Angle $\infty P : \infty P = 126^\circ 37'$; $\infty P : 0P = 96^\circ 55'$; $-P \infty : \infty P = 110^\circ 3'$. Both these bromine-compounds dissolve readily in carbon sulphide and in alcohol, their dissolution in the latter and in water being attended with separation of bromine. Alkaline solutions dissolve them slowly.

Bromchloroxalethyline Hydrobromide, $C^6H^8ClBrN^2.HBr$, is formed by boiling either of the bromine-compounds just described with water. The base separated therefrom is a thick, gradually solidifying oil. Its hydrochloride crystallises in hydrated prisms; the nitrate in curve-faced needles; the platinumchloride, $(C^6H^8ClBrN^2.HCl)^2PtCl^4$, in laminæ. The argentonitrate, $(C^6H^8ClBrN^2)^2NO^3Ag$, dissolves easily in alcohol, sparingly in water, and crystallises from dilute alcohol in well-defined limpid prisms having a vitreous lustre. With other metallic salts this base forms precipitates similar to those obtained with chloroxalethyline. Bromchloroxalethyline is but slowly attacked by potash either in aqueous or alcoholic solution, but is completely decomposed by distillation; its hydrobromide is converted by hydrobromic acid into the tetrabromine-compound, $C^6H^8ClBrN^2.Br^2.BrH$.

The formation of the two bromine-compounds above described is often attended with that of a third, probably $C^6H^8ClN^2.Br^2$.

Iodine acts on chloroxalethyline in the same manner as bromine.

Chloroxethyline, the yield of which is usually 75 per cent. of the theoretical amount, is difficult to separate from diethyloxamide, and when contaminated therewith solidifies with comparative facility and completeness, whereas the perfectly pure base solidifies but very slowly, and only at very low temperatures.

OXALIC ACID, $C^2H^2O^4 = COOH.CO OH$. On the occurrence of this acid in Fungi, see p. 832.

Formation.—Oxalic acid is produced, together with oxamic, carbamic, and carbonic acids, by oxidising ammonium glycinate, $C^2H^4(NH^1)^2NO^2$, with permanganate (Drechsel, *J. pr. Chem.* [2], xii. 417).

Preparation.—Experiments on the preparation of oxalic acid from sawdust and other vegetable matters have been made by W. Thorn (*Dingl. pol. J.* cxx. 24). A

weighed amount of sawdust was added to an alkaline solution of 30°–42° Bm., which was kept boiling in an iron dish: strong solutions are to be preferred for this operation, as they prevent spitting of the melt. The results showed in the first place that the largest yield of oxalic acid is obtained by the use of pure potassium hydrate; a mixture of the hydrates of potassium and sodium yielded a smaller amount, and sodium hydrate alone a still smaller quantity. The highest yield obtained with soda alone was 52.14 per cent. of the sawdust used, 25 grams of sawdust being heated to 240° C with 100 grams NaHO in a thin layer. With a mixture of the two alkalis the yield was greater the larger the proportion of potash used, and with potash alone the yield was 65 per cent. of the wood employed. When however the wood was allowed to come more directly in contact with the air by being heated in a thin layer, different results were obtained. When 50 grams of wood were heated for 1–1½ hours with 100 grams of the alkaline hydrate of 40° Baumé in a layer 1 centimeter thick to 240°–250°, pure sodium hydrate gave 33.14 per cent. of oxalic acid; 40 grams of potassium hydrate to 60 of sodium hydrate gave 80.57 per cent., and this did not differ materially from that obtained with pure potassium hydrate (81.23). When heated air was passed over the surface of the sawdust and alkali, the results obtained were not higher than the former. The addition of manganese dioxide had no influence on the reaction, the temperature being much too low to effect its decomposition.

Different sorts of wood yielded different amounts of oxalic acid.

	Per cent. of hygroscopic water	Per cent. oxalic acid	Per cent. oxalic acid calculated to wood dried at 100°
Pine	15.0	80.5	94.7
Poplar	14.0	80.1	93.14
Box	8.6	79.00	86.43
Oak	6.5	78.12	93.42

In the foregoing experiments 50 grams of wood were heated with 100 grams of alkali. When equal quantities of wood and alkali were employed, the yield of oxalic acid was larger in proportion to the quantity of alkali employed, and smaller in proportion to the wood. Thus, when heated in a thin layer, 50 grams of wood yielded oxalic acid equivalent to 81.0 per cent. of the wood employed, and to 40.0 per cent. of the alkali, and 100 grams of wood gave a quantity of oxalic acid equivalent to 54.14 per cent. of the wood and to 54.14 per cent. of the alkali.

To separate the oxalic acid from the melt, the latter is boiled with water, the solution concentrated to 38° Bm. (sp. gr. 1.35) and left to cool, whereupon nearly the whole of the oxalic acid separates in granules of sodium oxalate. This salt after washing is boiled with milk of lime; the resulting calcium salt is decomposed by sulphuric acid; and the liquid concentrated to 15 Bm. (sp. gr. 1.16), whereupon the dissolved gypsum crystallises out, and the solution freed therefrom and evaporated down to 30° Bm. (sp. gr. 1.261), yields crystals of oxalic acid.

The alkali contained in the several mother-liquors of this process may be recovered by concentration to sp. gr. 1.380, addition of sawdust till it assumes a pasty consistence, evaporation to dryness, and ignition. The mass is then treated with water or with the dilute alkaline liquor obtained after addition of milk of lime to the sodium oxalate, made caustic with lime, and after concentration till its specific gravity is 1.407, again heated with sawdust as at first.

C. O. Cech (*Dingl. pol. J.* cccxiv. 70) recommends as a substitute for sawdust, in the preparation of oxalic acid, the clippings of parchment paper, which can be obtained at a very cheap rate.

Purification.—To obtain pure oxalic acid for titration, E. Reichardt (*Arch. Pharm.* [3], ii. 235) stirs a hot saturated solution of the commercial acid till it is cold, and dries the fine-grained crystalline powder thus obtained between filter paper. Similar methods are recommended by L. Siebold (*Pharm. J. Trans.* [3], vi. 441), and F. Stolba (*Zeitschr. anal. Chem.* 1874, 50).

Estimation.—For the titration of oxalic acid and its salts, Jean a. Pellet (*Bull. Soc. Chim.* [2], xxvii. 204) recommend the use of baryta-water. The free acid is first exactly neutralised with soda, the solution then mixed with excess of baryta-water, and the uncombined baryta titrated back with sulphuric acid.

Reactions.—1. With Chlorates, Bromates, and Iodates. A boiling super-saturated aqueous solution of oxalic acid decomposes solutions of chlorates, bromates, and iodates, with evolution of chlorine, bromine, and iodine respectively. In the case of *potassium chlorate*, a large quantity of chlorine is evolved, but still a considerable quantity of the chlorate is reduced to chloride. With *potassium bromate* a similar reaction takes place, but the proportion of the bromine evolved to the bromide formed

is greater than that of chlorine to chloride in the case of the chlorate. *Iodates* evolve all their iodine in the free state, no traces of iodides being formed.

In the case of mixtures of these bodies, the chlorates are first decomposed, then the bromates, and finally the iodates, that which is attacked first being completely decomposed before the others are acted on. The steam accompanying the gas evolved expels all traces of it before vapours of the second halogen make their appearance. This can be distinctly seen, as there is a certain interval between the two reactions, it being necessary in some cases to add more oxalic acid to start it again.

These reactions afford a means of testing chlorine and iodine in commercial bromine, also the purity of bromides and bromates. The bromine is dissolved in a slight excess of concentrated potash, and treated with oxalic acid. Bromides are oxidised to bromates by means of chlorine, and then treated with oxalic acid, and bromates are treated directly with oxalic acid (A. Guyard, *Bull. Soc. Chim.* [2], xxxi. 299).

2. With Potassium Permanganate. On the effect of temperature on the rate of action between this salt and oxalic acid, see CHEMICAL ACTION (p. 426).

3. With Sodium Silicate. When a solution of oxalic acid, 75 grams to the litre, is introduced into a vessel containing 500 c.c. of a solution of sodium silicate, the liquids do not mix, but a crust is formed at their surface of contact, consisting of amorphous hydrated silica. This crust sets quite hard, and decrepitates when heated, giving a fine white sand hard enough to polish glass (Monier, *Compt. rend.* lxxxv. 1053).

4. With Monatomic Alcohols. When a primary monatomic alcohol is treated with dehydrated oxalic acid, a large quantity of the corresponding oxalic ether is formed, whereas in the case of secondary alcohols, only a small quantity of an oxalic ether is obtained; thus 3 mols. *methyl alcohol* and 1 mol. oxalic acid heated together at 50° for several hours and then distilled, yielded carbon monoxide and dioxide, unchanged methyl alcohol, methyl oxalate about equal in weight to the oxalic acid employed, and a small quantity of methyl formate; *ethyl, normal propyl, isobutyl, isopentyl* (amyl), and *allyl alcohols* yield mixtures of normal and acid oxalic ethers. On subjecting the product to distillation, the normal ether goes over undecomposed, while the acid ether is resolved into carbon dioxide (with a little monoxide) and the corresponding formic ether, the quantity of the latter increasing with the proportion of oxalic acid, and in the case of ethyl alcohol, attaining the proportion of 0.28 formic to 1 pt. oxalic ether. *Benzyl alcohol* yielded only normal benzyl oxalate. *Pseudopropyl alcohol* reacts in general like the normal alcohol, but is less easily etherified.

Primary octyl alcohol from the essential oil of *Heracleum sphondylium*, on treatment with dehydrated oxalic acid yielded octylene (b.-p. 120°-125°), and octyl formate (b.-p. 195°-197°), these substances being formed by the decomposition of the octyl oxalate—

Secondary octyl alcohol (methyl-hexyl carbinol) under similar conditions gave carbon monoxide and dioxide, formic acid, and a small quantity of octyl formate. *Trimethyl carbinol* and *dimethyl-ethyl carbinol* are split up by the action of oxalic acid into water and hydrocarbons, viz., butylene and amylene respectively (Cahours a. Demarcay, *Compt. rend.* lxxxiii. 668; lxxxvi. 991).

5. With Polyatomic Alcohols (Lorin, 1873, *Ann. Chim. Phys.* xxix. 367; xxx. 447; *Compt. rend.* lxxvii. 129, 363; lxxxiv. 1136). It has long been known that oxalic acid when heated with glycerol (glycerin) and water is resolved into carbon dioxide and formic acid, ($\text{C}^2\text{H}^2\text{O}^4 = \text{CO}^2 + \text{CH}^2\text{O}^2$), the glycerol being commonly supposed to take no part in the reaction, but merely to prevent the temperature from rising so high as to give rise to the resolution of the formic acid into CO and H^2O . It is remarkable, however, that the greater portion of the formic acid does not at once distil over, but remains in the retort together with the glycerol, and can be separated therefrom only by distillation with a considerable quantity of water (ii. 686). According to Lorin, the decomposition of oxalic acid under these circumstances into CO^2 and CH^2O^2 is preceded by the formation of a glyceryl oxalate or oxalin, $\text{C}^8\text{H}^6\text{O}^8 = \text{C}^8\text{H}^5(\text{OH})(\text{O.CO})^2$, which when heated with water is resolved into glycerol, formic acid, and carbon dioxide; *

and in fact when a mixture of glycerol and oxalic acid is heated for some time at 65°

* When the mixture of glycerol and oxalic acid is heated without addition of water, the products are allyl alcohol, water, and carbon dioxide, $\text{C}^8\text{H}^6\text{O}^8 + \text{C}^2\text{H}^2\text{O}^4 = \text{C}^8\text{H}^6\text{O} + 2\text{CO}^2 + 2\text{H}^2\text{O}$ (Tollens a. Henniger, vi. 90).

a product is obtained from which ether extracts a white silky body of unctuous aspect, easily altered by moisture, fusing readily in the dry state, and resolidifying at 53° . At a higher temperature it is said to be resolved into carbon monoxide and glycerol, and by distillation in a vacuum partly into aqueous formic acid and a gas. The aqueous solution of this body, which Lorin regards as a mixture, gave with ammonia a large quantity of oxamide, which compound was likewise obtained when mixtures of glycerol and oxalic acid in various proportions were heated at various temperatures, or left to themselves for some time; in the latter case the reaction takes place with peculiar facility when the anhydrous compounds are employed, and then treated with ammonia.

In the same manner are formed the oxalins of ethylene and octylene glycol, mannitol, dulcitol, erythritol, and quercitol, the temperature at which the decomposition of the oxalic acid begins being lower for the glycols, and higher for erythritol, &c., than for glycerol, with which it begins at 75° , and is in full activity at 90° ; it is higher also for dulcitol than for mannitol. No action upon oxalic acid is exerted by cane-sugar, grape-sugar, milk-sugar, or orcinol; hydrate of turpentine-oil heated with oxalic acid is resolved into turpentine-oil and water. Monatomic alcohols heated with oxalic acid exhibit only a faint turbidity. Lorin regards the reaction with oxalic acid above described as characteristic of polyatomic alcohols.

Metallic Oxalates. On the Heat of Formation and Solution of Oxalates, see *HEAT*, pp. 954, 957, 958, 982.

On the Action of Alkaline Oxalates on Earthy Carbonates, and of Alkaline Carbonates on Earthy Oxalates, see *CARBONATES* (p. 410).

Electrolysis.—According to Bunge (*Ber.* ix. 78), aqueous solutions of oxalates yield by electrolysis hydrogen at the negative pole, and at the positive, either carbon dioxide alone or a mixture of that gas with oxygen. The proportion of these two gases in the mixture varies according to the conditions of the experiment, the relative quantity of oxygen being increased by strengthening the current, enlarging the surface of the anode, using stronger solutions, and lowering the temperature.

Ammonium Oxalate, $C^2(NH^4)^2O^4$.—This salt has been found, to the amount of 5.54 per cent., in Guanapi guano, in combination with 2 mols. water, the ordinary salt containing 1 mol. (*J. A. Tanner, Chem. News*, xxxii. 162).

Calcium Oxalate may be obtained in crystals of the various forms occurring in plants, and others besides, by causing solutions of potassium oxalate and calcium chloride, or of oxalic acid and calcium sulphate, to mix slowly in a liquid medium by means of strips of filter-paper or dialysing diaphragms, the particular forms obtained varying according to the nature of the reaction and the constitution of the medium. Thus in a medium containing glucose or dextrin, needles are formed exactly like the 'raphides' occurring in plants; in a medium containing a small quantity of albumin, crystals of hour-glass shape are produced, like those which sometimes occur in urine (*Vesque, Compt. rend.* lxxviii. 149). Similar results were previously obtained by Monier (*vi.* 887),

Potassio-chalcio-chromic Oxalate, $KCaCr(C^2O^4)^3$, is formed by mixing warm dilute solutions of blue potassio-chromic oxalate and calcium chloride: $K^3Cr(C^2O^4)^3 + CaCl^2 = 2KCl + KCaCr(C^2O^4)^3$; or by boiling a solution of red potassio-chromic oxalate with recently precipitated calcium oxalate: $KCr(C^2O^4)^2 + CaC^2O^4 = KCaCr(C^2O^4)^3$. The former method is to be preferred.

This salt loses 1 mol. of water in a dry atmosphere, changing from a greenish-black to a greenish-violet tint; at 100° it is dehydrated and becomes violet. 1 pt. of it dissolves in about 22 of water at 16° , and in 5 pts. at 100° . The solution, of a greenish-purple colour, becomes more decidedly green when boiled, and resumes its original colour on cooling. The salt is exceedingly stable, and crystallises with the greatest ease from hot or cold, acid or neutral solutions, and can be precipitated in the crystalline state. It is almost insoluble in strong hydrochloric acid. The crystals, when slowly deposited, are formed in clusters, the individual crystals being never more than $\frac{1}{300}$ of an inch in thickness and $\frac{1}{2}$ an inch long. They have a greenish-black lustre, and apparently consist of prisms with a rectangular base; they reflect white light. From hot solutions much smaller crystals are deposited, which, as well as their powder, are olive-green in daylight, and beetroot-red by gaslight. Minute crystals, examined in daylight by the microscope, are of a pale green tint; fragments of large crystals coarsely powdered appear of almost all tints, rich-green and blue prevailing. Larger crystals, deposited by spontaneous evaporation of a cold solution, appear of two colours, chiefly a beautiful blue and rich green, with sometimes a tinge of deep red.

A crystal mounted in such a manner that it could be rotated on its principal crystalline axis while under microscopic examination, showed in each revolution two phases of blue, two of green, and two of opacity with a tinge of red. When a crystal so small as to be quite transparent in any position was examined in this manner, pure red light was transmitted through its edges. These effects show that the play of colour is due to pleochroism, or the property which, by virtue of double refraction, some minerals possess of transmitting light of different tints through their different crystalline axes. The two axes of *thin* crystals give spectra which do not differ from each other materially, or from the solution of this salt in particular, or from chromium salts generally.

By examination with a Nicol's prism, and with similar crystals used as analysers, it was found that this salt is a powerful polariser. There is a marked difference when the blue and the green rays are examined with a Nicol's prism, the former being much more completely polarised than the latter, so that in rotating the Nicol there is an alternation of brilliant blue and perfect darkness, or, if the crystal be thin, of blue and reddish-green. If, however, a crystal transmitting green rays of equal brilliancy be examined, the light is not cut off, but only obscured. In like manner, if both analyser and polariser consist of these crystals, the effect when they are in a position at right angles to each other is the same as that produced by a Nicol's prism, viz., only green rays are transmitted. The green ray is more strongly refracted, and at the same time more absorbed than the blue, in accordance with Babinet's law (*Pogg. Ann.* xli. 116). This was made evident from the apparent change of colour when white light was admitted to them at different angles. These observations account for the facts already noticed—namely, that minute crystals appear green even under the microscope, and also that the powder is green.

Taking a number of crystals, or fragments of crystals, lying in all directions over each other, it is easy to see that no blue rays can be transmitted; for where two crystals cross, the light transmitted is green. The green rays being more absorbed (that is to say, travelling with less facility) than the blue, it is possible to have a blue crystal so thin as to transmit white light through one axis, while green rays would pass at right angles through the other; under these circumstances the crystals would appear green. The red colour seen by gaslight is of course due to the suppression of the green and blue by the yellow illumination. This substance strikingly exemplifies the fact that pleochroism results from the polarisation of light traversing a doubly-refracting coloured medium.

This chromium-compound is a remarkably delicate test for the purity of white light, showing a red tint by gas-light, red and blue by the lime-light, while by the light of magnesium wire or the sun it displays red, blue, and green. Altogether it is the most remarkable example of pleochroism at present known (W. N. Hartley, *Proc. Roy. Soc.* xxi. 499).

From the microscopic examination of many similar compounds, it was found that the efficiency in displaying pleochroism is inversely as the molecular weight of the compounds, the property depending upon the amount of colour the chromium gives to the crystals.

Monorubidium Dioxalate, $\text{RbHC}^{\circ}\text{O}^{\cdot}\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\cdot} + 2\text{H}^{\circ}\text{O}$, is prepared by digesting together 100 grams of rubidium-alum, 72.6 grams of crystallised oxalic acid, and 170 c.c. water at the boiling heat, and separates out almost completely on cooling. By slow evaporation it is obtained in fine, transparent, many-faced prismatic crystals, apparently triclinic; and by cooling from a hot concentrated solution, in translucent laminar groups of crystals, becoming milk-white when dried at 100° , but not efflorescing perceptibly in the air. The pulverised salt has a density of nearly 2.1246 at 18° . The salt dissolves very easily in boiling water, and in 47 pts. water at 21° , the latter solution having a density of 1.0111. By ignition it is converted into carbonate (Stolba, *Münch. Akad. Ber.* 1877, 6 Heft).

Vanadious Oxalate is obtained, according to Guyard (*Bull. Soc. Chim.* [2], xxv. 350), by fusing a mixture of vanadium pentoxide and crystallised oxalic acid in the water of crystallisation of the latter. The blue mass thus obtained dissolves completely in water, forming a solution which on evaporation yields crystals of the oxalate.

Oxalic Ethers. On the reaction of Ethyl and Methyl Oxalates with Naphthylamine, see NAPHTHYLAMINE.

Methyl Oxalate, $\text{C}^{\circ}(\text{CH}^{\circ})^2\text{O}^{\cdot}$, is very easily prepared by dissolving oxalic acid dehydrated at 100° in boiling methyl alcohol, and leaving the solution to cool. The crystals are freed from adhering mother-liquor by draining on a vacuum-filter, and washed with cold water till the liquid which runs away no longer exhibits the iodoform

reaction. To obtain pure methyl alcohol from this ether, it must be decomposed by prolonged boiling with water and distilled (Erlenmeyer. *N. Rep. Pharm.* xxiii. 624).

Ethyl Oxalate, $C^2(C^2H^3)O^4$.—With *potassium methylate*, this ether forms potassium methyloxalate (Salomon, *Ber.* viii. 1506); possibly thus:

On the reaction of Ethyl Oxalate with Cyanamide, see p. 598.

Propyl Oxalate, $C^3(C^2H^3)O^4$, is obtained by distilling anhydrous propyl alcohol with dehydrated oxalic acid, either alone or mixed with one-third of its weight of sulphuric acid. The distillate, on addition of water, separates into two layers, the upper of which, when dried and rectified, yields propyl oxalate, having an aromatic odour, a density of 1.018 at 22°, and boiling between 209° and 211°. Ammonia easily converts it into crystalline propyl oxamate, $C^3H^7O.CO.CO.NH^2$, which is decomposed by water with reproduction of propyl alcohol and oxalic acid:

(Cahours, *Compt. Rend.* lxxvii. 749).

Butyl Oxalate, $C^4(C^2H^3)O^4$, obtained in like manner, is a very clear, colourless liquid, having a strong aromatic odour, and a density of 1.002 at 14°. It mixes in all proportions with alcohol and ether, but is insoluble in water. Cold water decomposes it slowly; boiling potash-ley more quickly, into oxalic acid and butyl alcohol. By treatment with an alcoholic solution of *potassium hydroxide* containing only a quantity of potassium sufficient to replace one of the butyl-molecules, it is converted into potassium-butyl oxalate, $CO^2C^4H^9.CO^2K$. With *aqueous ammonia* it forms oxamide. By addition of *alcoholic ammonia* in small portions it is converted into butyloxamate, $NH^2.CO.CO.OC^4H^9$, which separates from its solution on spontaneous evaporation in beautiful prisms (Cahours, *ibid.* 1408).

OXALIS. Experiments have been made by Mercadante (*Gazz. chim. ital.* 1875 249) on the growth of wood-sorrel (*Oxalis acetosella*) and several species of *Rumex* in sulphur, to which were added altogether 11 pts. per thousand of ferric oxide, and of the nitrates, phosphates, sulphates, and silicates of sodium, calcium, and magnesium, but no salts of potassium. Under these circumstances the plants did not fructify; their juice contained only an eighth of the quantity of acid present in that of the normal plants; tartaric acid was present as well as oxalic acid; and the proportion of starch and of sugar was greatly diminished.

OXALURAMIDE, $C^3H^3N^2O^3 = \begin{array}{c} CO.NH.CO.NH^2 \\ | \\ CO.NH^2 \end{array}$. *Oxalan*.—This compound is

formed by fusing oxamethane with urea:

(Carstanjen, *J. pr. Chem.* [2], ix. 143); also by heating ammonium parabanate, $C^3H(NH^4)N^2O^3$ (with which it is metameric) with alcoholic ammonia (anhydrous alcohol saturated at ordinary temperatures with NH^3) at 100° in a sealed tube for six or eight hours.

The *amide of dimethyloxaluric acid*, $\begin{array}{c} CO.N(CH^3).CO.NH(CH^3) \\ | \\ CO.NH^2 \end{array}$, is formed in like

manner by the action of an alcoholic solution of ammonia at ordinary temperatures on dimethylparabanic acid. It crystallises in needles melting at 223.5° (Menschutkin, *Ber.* vii. 128; *Liebig's Annalen*, clxxii. 73).

OXALURIC ACID, $C^3H^3N^2O^4 = NH^2.CO.NH.CO.COOH$ (Menschutkin, *ibid.* 89). The potassium salt of this acid, $C^3H^3KN^2O^4$, is formed by the action of water on potassium parabanate, $C^3HKN^2O^3$. According to Strecker (*ibid.* cxiii. 47), it is also produced by the action of potassium carbonate on alloxan in presence of hydrocyanic acid; Menschutkin, however, obtained by this process another salt, the composition of which has not been determined. *Potassium oxalurate* is sparingly soluble in water and crystallises with great facility. Even small quantities of it yield fine well-developed crystals, containing 1 mol. water, which is given off at 100°, and slowly by efflorescence in contact with the air. According to measurements by Erofejeff, they belong to the orthorhombic system. Axial ratio, $a : b : c = 1 : 0.6014965 : 0.5393226$. Observed forms, $P, \infty P, \bar{P} \infty, \infty \bar{P} \infty$.

By the action of *phosphorus oxychloride*, oxaluric acid is converted into oxalyly-

carbamide or parabanic acid: $C^3H^4N^2O^4 - H^2O = C^3H^3N^2O^3$ (Grimaux, *Compt. rend.* lxxvii. 1548).

Ethyl Oxalurate, $NH^2.CO.NH.C^2O^2.CO^2H^2$, which L. Henry obtained by the action of ethoxyoxalyl chloride, $C^2H^3O.C^2O^2.Cl$, on urea (vii. 883) may also be prepared by heating silver oxalurate for half an hour in a reflux apparatus with a slight excess of ethyl bromide or iodide dissolved in absolute alcohol. It melts with decomposition at 177° – 178° ; is converted by silver nitrate into diargentate parabanate, $C^3Ag^2N^2O^3$, and resolved by baryta-water into oxalic acid, urea, and alcohol; by alcoholic ammonia, at 120° , into oxaluramide and alcohol; by hot water and dilute acids into oxalic acid, urea oxalate, and other products (F. Salomon, *Ber.* ix. 374).

OXALYL-CARBAMIDE. Syn. with PARABANIC ACID (*q. v.*)

OXALYL-DIPHENYL-HYDRAZIDE, $(C^6H^5.N^2H^2)^2C^2O^2$. See HYDRAZINES (p. 1053).

OXAMETHANE, $NH^2.CO.CO.CO^2H^2$. *Ethyl Oxamate*. See OXAMIC ETHERS.

OXAMIC ACID, $C^2H^2NO^3 = NH^2.CO.CO.OH$. This acid is formed by the direct oxidation of glycocine, $NH^2.CH^2.CO.OH$, with potassium permanganate. Oxalic and carbonic acids, which are formed at the same time, may be removed by calcium chloride, the oxamic acid then precipitated by solution of basic lead acetate, and the precipitate decomposed by hydrogen sulphide (K. Engel, *Compt. rend.* lxxix. 808).

OXAMIC ETHERS.

Ethyl Oxamate or Oxamethane, $C^4H^4NO^3 = NH^2.CO.CO.CO^2H^2$, is best prepared, according to Weddige (*J. pr. Chem.* [2], x. 193), by adding very gradually to a solution of 1 mol. ethyl oxalate in two or three times its volume of alcohol, 1 mol. ammonia likewise dissolved in alcohol, the whole being carefully cooled by ice, as rise of temperature would lead to the formation of considerable quantities of oxamide. The oxamethane separates, even while the process is going on, in thick crystals, which at the end of the reaction must be freed from small quantities of oxamide by recrystallisation from hot alcohol. The mother-liquor yields additional quantities on evaporation.

On the formation of Oxaluramide by fusing Oxamethane with Urea, see p. 1455.

By the action of *phosphorus pentachloride*, oxamethane is converted into ethylic dichloramidacetate, $NH^2.CCl^2.COOC^2H^2$, which crystallises in hard white needles; fumes in the neighbourhood of ammonia; is reconverted by water into oxamethane; gives off chlorine when kept for some time, and hydrogen chloride when fused, with simultaneous formation of ethylic cyanocarbonate. If the temperature rises somewhat too high during the preparation of the dichloramidacetate, a body is formed having the composition $NH=CCl-COOC^2H^2$ (Wallach, *Ber.* viii. 299).

In the distillation of oxamethane with phosphorus pentachloride, there are also formed, in consequence of the action of water, fine crystals melting at 128° – 130° , and having the composition $C^4H^4O^3Cl^4NP$. This compound dissolves slowly in cold water and in acids, easily in alkalis and ether. When heated above its melting point, it is resolved into phosphorus oxychloride and ethyl-cyanocarbonic acid. Water decomposes it, forming hydrochloric but no phosphoric acid, showing that it is not a compound of ethylcyanocarbonic acid with $POCl^3$, but that its constitution is probably $C^2H^3O.CO.CCl^2.NH.POCl^2$ (Wallach).

Oxamethane Cyanurate, $(C^4H^4NO^3)^3C^3H^3N^3O^3$, metamerie and polymeric with ethyl oxalurate, is obtained by passing the vapour of cyanic acid into 5 grams of pure and dry oxamethane heated to 130° in an oil-bath, treating the product with 30–40 grams of boiling water, and filtering. The cyanurate then separates in needles, which may be purified from oxamethane, if still present, by recrystallisation. It crystallises in shining brittle needles nearly insoluble in cold water, soluble in about 30 pts. of boiling water; melts to a pasty mass at 155° – 160° ; and is resolved at a higher temperature into cyanic acid and a crystalline sublimate. On boiling it for a few minutes with milk of lime, and filtering, the filtrate deposits hard shining prisms of calcium oxamate. Ammonia added to its aqueous solution precipitates crystals of oxamide, and baryta-water throws down barium cyanurate. These reactions demonstrate the composition of the compound (Grimaux, *Bull. Soc. Chim.* [2], xxi. 153).

Acetyl-oxamethane, $NH(C^2H^3O).C^2O^2.CO^2H^2$, formed by heating oxamethane with acetyl chloride, crystallises in radiate groups of needles, soluble in alcohol and ether, melting at 54° . The compound thus formed is probably identical with that which Ossikovsky obtained (*Ber.* v. 667) by the action of ethoxyoxalyl chloride on acetamide (Kretschmar a. Salomon, *J. pr. Chem.* [2], ix. 299).

Benzoyl-oxamethane, produced in a similar manner, is also a finely crystallised compound.

Ethylloxamethane, $\text{NH}(\text{C}^2\text{H}^5)\cdot\text{C}^2\text{O}^2\cdot\text{OC}^2\text{H}^5$, formed by the action of ethyl oxalate on ethylamine, is an oily liquid boiling at 244° – 246° , miscible in all proportions with water, soluble in alcohol and in ether. It is completely decomposed by aqueous ammonia with formation of ethylloxamide, $\text{NH}(\text{C}^2\text{H}^5)\cdot\text{C}^2\text{O}^2\cdot\text{NH}^2$. It is saponified by boiling water, also by milk of lime, with great rise of temperature and formation of a crystalline ethylloxamate of calcium containing 2 mol. H^2O . The acid obtained from this salt sublimates in woolly needles (Wallach a. West, *Ber.* viii. 760).

Ethylloxamethane is converted by PCl^5 into *ethylloxamethane-amidochloride*, $\text{C}^2\text{H}^5\cdot\text{NH}\cdot\text{CCl}^2\text{—COOC}^2\text{H}^5$, which by prolonged heating at 100° is resolved into HCl , $\text{C}^2\text{H}^5\text{Cl}$, CO^2 , and greasy substances, from which a very small quantity of a body melting at 200° may be sublimed (Wallach a. West, *Ber.* viii. 760; ix. 262).

Methylloxamethane, $\text{NH}(\text{CH}^3)\cdot\text{C}^2\text{O}^2\cdot\text{OC}^2\text{H}^5$, obtained by passing methylamine into ethyl oxalate, solidifies at 0° , but at ordinary temperatures is an oil soluble in water (Wallach a. West).

Ethyl Thioxamate, $\text{NH}^2\cdot\text{CS}\cdot\text{CO}\cdot\text{OC}^2\text{H}^5$, is formed by addition of hydrogen sulphide to ethyl cyanocarbonate (vii. 415; viii. 617):

When hydrogen sulphide is passed into this ether or its alcoholic solution, ethyl thioxamate soon separates in yellow crystals, and after some time the entire liquid solidifies to a crystalline pulp; and by pressing out the mother-liquor and recrystallising from ether, the thioxamate is obtained in large lemon-yellow prisms; from hot water it crystallises in needles. It melts at 63° – 64° , and cannot be distilled without decomposition (Weddige, *J. pr. Chem.* [2], vii. 79).

Methyl Thioxamate, $\text{NH}^2\cdot\text{CS}\cdot\text{CO}\cdot\text{OCH}^3$, produced in like manner, crystallises in delicate light-yellow, brilliant needles or laminæ; melts at 86° ; dissolves in alcohol and ether, less easily in water; decomposes when heated above its melting point (*ibid.* x. 193).

Isobutyl Thioxamate, $\text{NH}^2\cdot\text{CS}\cdot\text{CO}\cdot\text{CH}^2\cdot\text{CH}(\text{CH}^3)^2$, crystallises from alcohol in long lemon-yellow needles and prisms, which melt at 58° , dissolve with moderate facility in alcohol and ether, sparingly in water (Weddige, *loc. cit.*)

Phenyloxamic Ethers (H. Klinger, *Ber.* viii. 310). *Ethyllic Phenyloxamate*, or *Phenyloxamethane*, $\text{C}^6\text{H}^5\cdot\text{CO}\cdot\text{NH}\cdot\text{COOC}^2\text{H}^5$, is formed by heating ethyl oxalate and aniline together in molecular proportions, and crystallises in large plates or prisms, melting at 66° , and dissolving readily in ether, alcohol, and benzene. From water it crystallises in small needles, melting at 64.5° – 65° . *Acetyl chloride* converts it into ethyl phenylacetylloxamate, $\text{C}^6\text{H}^5\cdot\text{CO}\cdot\text{N}(\text{C}^2\text{H}^5\text{O})\cdot\text{COOC}^2\text{H}^5$, which forms large prisms or plates melting at 66° – 67° . When the phenyloxamate is treated with bromine, the monobromophenyl-compound, $\text{C}^6\text{H}^4\text{Br}\cdot\text{CONH}\cdot\text{COOC}^2\text{H}^5$, is formed, crystallising in plates or flat needles which melt at 154° – 156° , and yield on saponification parabromaniline melting at 61° – 62° .

Ethyllic phenyloxamate heated, not above 70° , with phosphorus pentachloride is converted into ethyllic phenylamidodichloracetate, $\text{NH}(\text{C}^6\text{H}^5)\cdot\text{CCl}^2\cdot\text{COOC}^2\text{H}^5$; above 70° , however, an imidochloride is produced. By heating the amidodichloracetate for a long time to 90° , or for a shorter time to 120° , or subjecting it to the action of gaseous ammonia, it is converted into ethyllic phenylimidochloracetate, $\text{C}^6\text{H}^5\text{N}=\text{CCl—CO—OC}^2\text{H}^5$, which crystallises in colourless needles melting at 91° . Both the amidodichloracetate and the imidomonochloracetate are converted by aniline into the compound $\text{C}^6\text{H}^5\cdot\text{N}=\text{C}\begin{smallmatrix} \text{NH}\cdot\text{C}^6\text{H}^5 \\ \text{CO}\cdot\text{NH}\cdot\text{C}^6\text{H}^5 \end{smallmatrix}$, which crystallises in yellow-green laminæ, melts at 234° – 235° , and is resolved by boiling with water into oxanilide (m. p. 245°) and aniline. When the amidodichloracetate is heated for twelve hours at 90° , or for two or three hours at 120° – 130° , CO and CO^2 are given off, and the residual liquid is found to contain nothing but ethyllic phenyloxamate and aniline.

Ethyllic Paratolyloxamate or **Paratolyloxamethane** $\text{C}^6\text{H}^4(\text{CH}^3)\cdot\text{CO}\cdot\text{NH}\cdot\text{COOC}^2\text{H}^5$, obtained by heating ethyl oxalate with paratoluidine, crystallises in laminæ and melts at 66° – 67° . Paratolyloxamic acid, obtained from it by the action of alkalis, forms needles melting at 168° – 170° . *Phosphorus pentachloride* converts paratolyloxamethane into ethyllic paratolyamidodichloracetate, $\text{C}^6\text{H}^4(\text{CH}^3)\cdot\text{NH}\cdot\text{CCl}^2\cdot\text{COOC}^2\text{H}^5$, which crystallises in white needles melting at 59° – 60° , and is converted by water, or by alcohol of 98 per cent., into paratolyloxamethane (Klinger).

Phenylene (Meta-) Oxamic Acid, $\text{C}^6\text{H}^3\text{N}^2\text{O}^3 = \text{H}^2\text{N}\cdot\text{C}^6\text{H}^4\cdot\text{NH}\cdot\text{C}^2\text{O}^2\cdot\text{OH}$, is

produced, together with the corresponding phenylenediamine oxalate, when meta-phenylenediamine is boiled with oxalic acid and alcohol for five or six hours, and separates out, while the easily soluble phenylenediamine oxalate remains in the liquid. It likewise separates when a solution of phenylenediamine oxalate is boiled for a considerable time, and is obtained in greatest abundance when a solution of meta-phenylenediamine is gradually added to a boiling solution of oxalic acid. It crystallises from boiling water in slightly reddish needles, which melt only at a very high temperature and carbonise at the same time. The *ammonium salt* forms slightly yellow crystals, sparingly soluble in pure water, easily in slightly alkaline water. The *silver salt* forms long slender needles (Klusemann, *Ber.* vii. 1261).

OXAMIDE, $\text{NH}_2\cdot\text{C}^{\text{O}}\cdot\text{O}^{\text{O}}\cdot\text{NH}_2$. On the Heat of Formation of Oxamide, see p. 960.

Reaction with Alcoholates.—Oxamide, like other amides, does not yield aminobases when heated with alcoholates. Thus, on distilling it with sodium ethylate or with sodium or potassium phenate, not a trace of ethylamine or phenylamine is obtained, the only products being ammonia and cyanide of sodium or potassium. Considerable quantities of potassium cyanide are formed on heating oxamide with potassium hydrate (Weith, *Ber.* vi. 966).

Methylloxamide, $\text{NH}_2\cdot\text{C}^{\text{O}}\cdot\text{O}^{\text{O}}\cdot\text{NH}(\text{CH}^3)$, prepared by the action of methylamine on oxamethane:

crystallises in microscopic needles melting at 227° – 229° , sparingly soluble in water and in alcohol (Wallach a. West, *Ber.* ix. 262).

Methylethylloxamide, $\text{NH}(\text{CH}^3)\cdot\text{C}^{\text{O}}\cdot\text{O}^{\text{O}}\cdot\text{NH}(\text{C}^2\text{H}^5)$, obtained in like manner from methylamine and ethyloxamethane, crystallises from alcohol in needles melting at 155° – 157° , subliming easily, soluble in hot water. By the action of phosphorus pentachloride, it is converted into chloroxalmethylethylene, $\text{C}^6\text{H}^7\text{ClN}^2$, an oily liquid boiling at 212° – 213° , miscible with water, and solidifying at low temperatures. Its *hydrochloride*, $\text{C}^6\text{H}^7\text{ClN}^2\cdot\text{HCl}$, is very hygroscopic, but crystallises on standing over sulphuric acid; the *platinochloride*, $(\text{C}^6\text{H}^7\text{ClN}^2\cdot\text{HCl})^2\cdot\text{PtCl}_4$, crystallises from alcohol in large tablets; the *silver salt*, $\text{C}^6\text{H}^7\text{ClN}^2\cdot\text{NO}^3\text{Ag}$, crystallises in transparent prisms; the *methiodide*, $\text{C}^6\text{H}^7\text{ClN}^2\cdot\text{CH}^3\text{I}$, is very stable, and is purified by crystallisation from alcohol. The reaction of chloroxalmethylethylene with metallic salts closely resembles those of its homologues previously described (pp. 453, 454) (Wallach a. West).

Phenylmethylloxamide, $\text{NH}(\text{CH}^3)\cdot\text{C}^{\text{O}}\cdot\text{O}^{\text{O}}\cdot\text{NH}(\text{C}^6\text{H}^5)$, from methylloxamethane and aniline, crystallises in thin white needles, melting at 171° – 173° , easily sublimable.

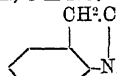

Phenylethylloxamide, $\text{NH}(\text{C}^2\text{H}^5)\cdot\text{C}^{\text{O}}\cdot\text{O}^{\text{O}}\cdot\text{NH}(\text{C}^6\text{H}^5)$, prepared from ethyloxamethane and aniline, or from ethylic phenyloxamate and ethylamine, is very slightly soluble in water, but may be crystallised from alcohol in white shining needles of silky softness, and melting at 169° (Wallach a. West).

OXAMOÏDIN. A compound formed by the action of cyanogen on albumin. See PROTEÏDS.

OXETHYLENE—TOLUIDINE, $\text{C}^6\text{H}^{13}\text{NO} = \text{NH}(\text{C}^7\text{H}^7)(\text{C}^2\text{H}^4\text{OH})$. See TOLUIDINES.

OXIMIDOCYANIC ACID. Syn. with PARABANIC ACID.

OXINDOLE, $\text{C}^8\text{H}^7\text{NO}$. The identity of this compound with orthoamidophenyl-

acetic anhydride, has been already noticed (p. 1086); and this view of its constitution is confirmed by its formation by reduction of orthonitrophenylacetic acid. When a mixture of the three isomeric nitrophenylacetic acids is subjected to the action of tin and hydrochloric acid, and the product is neutralised with marble and precipitated with barium carbonate, the para- and meta-amido-acids form barium salts, while the ortho-acid remains dissolved in the form of an anhydride, which may be extracted by ether. This anhydride is identical with oxindole, prepared by reduction of dioxindole (vi. 736), and yields indole when heated with zinc-dust (A. Baeyer, *Ber.* xi. 582).

After the ingestion of oxindole and dioxindole (by men, dogs, and rabbits), red colouring matters are found in the urine, very much like those which are produced by the oxidation of these bodies in the air (Nencki, *Ber.* vii. 1593).

OXONIC ACID, $\text{C}^4\text{H}^5\text{N}^3\text{O}^4$. An acid discovered by Strecker, who obtained it by the action of atmospheric oxygen on uric acid in alkaline solution. It forms two

series of salts. The *acid potassium salt*, precipitated by acetic acid from the alkaline solution just mentioned, crystallises in needles with $1\frac{1}{2}$ mol. water. The *acid barium salt* contains $\frac{1}{2}$ mol. water. These salts were found by L. Medicus among the preparations left by Strecker (*Liebig's Annalen*, clxxv. 230).

OXYACETANILIDE, $C^6H^5NO^2 = C^6H^5.NH.C^2H^2(OH)O$. Syn. with PHENYL-HYDROXYL-ACETAMIDE. See ACETAMIDES (p. 7).

OXYACETOTOLUIDINE, $C^6H^4NO^2 = C^6H^4(CH^3).NH.C^2H^2(OH)O$ (*loc. cit.*)

OXYACRYLIC or ACRYL-LACTIC ACID,

The barium salt of this acid is formed, together with barium malonate (p. 1257), by the prolonged action of boiling baryta-water on ethyl chloracrylate (Pinner a. Bischoff, *Liebig's Annalen*, clxxix. 85).

OXYANTHRAQUINONES. See ANTHRAQUINONES (pp. 99-112).

OXYAZOBENZENE, $C^{12}H^{10}N^2O = C^6H^5.N=N.O.C^6H^5$, is formed when a mixture of nitrosophenol (20 pts.) and aniline acetate (60 pts.) is left to itself at ordinary temperatures or heated on the water-bath. A brisk action takes place, attended with change of colour and formation of a crystalline pulp, which, when heated with ammonia, yields a solution of oxyazobenzene. This compound crystallises in orange-coloured prisms, melting at 148° (Kimich, *Ber.* viii. 1499); compare vii. 151; viii. 215.

OXYAZOTOLUENE, $C^6H^4(CH^3).N=N.O.C^6H^4(CH^3)$, formed, together with other products, by the action of paratoluidine acetate on nitrosophenol, crystallises in orange-red prisms melting at 151° , somewhat soluble in hot water. It possesses acid properties, and yields a silver salt crystallising in shining orange-coloured needles (Kimich, *loc. cit.*)

OXYBENZALDEHYDES. See OXYBENZOIC ALDEHYDES (p. 1865).

OXYBENZAMIDE (PARA-). See OXYBENZOIC ACIDS (p. 1463).

OXYBENZENE, or OZOBENZENE. An explosive substance formed by treating benzene with ozonised oxygen (p. 159).

OXYBENZOIC or HYDROXYBENZOIC ACIDS, $C^6H^4(OH)COOH$. Many of the reactions and derivatives of these acids have already been described (pp. 278-294). The following are recent additions to our knowledge of them, which have been made by H. Kupferberg (*J. pr. Chem.* [2], xvi. 424).

Normal Sodium Paraoxybenzoate, heated to 240° - 250° , is resolved into a basic salt, phenol, and carbon dioxide, according to the equation:

If the operation is conducted in a stream of carbon dioxide, and the temperature raised to 280° - 295° , the basic salt is left as a white residue, which is then found to yield 36 per cent. of salicylic acid, the quantity decreasing with the rise of temperature. The change of paraoxybenzoic acid into salicylic acid may perhaps be regarded as due to the action of carbon dioxide, and to a more complex action than the mere change of position of the hydroxyl and carboxyl groups, possibly to the formation of an isomeride of orthophenoldicarboxylic acid, which would be resolved by heat into basic sodium salicylate and carbon dioxide, as follows:

This view is supported by the following observations:—(1.) When sodium paraoxybenzoate is heated in a quick stream of hydrogen, no salicylic acid is formed; if the stream is slow, a small quantity is produced. (2.) By Van den Welden's observation (*J. pr. Chem.* [2], xv. 155), that thallous salicylate when heated decomposes into paraoxybenzoic and orthophenoldicarboxylic acids. (3.) By Ost's observation (*ibid.* 306), that basic potassium paraoxybenzoate is converted by heat into potassium orthophenoldicarboxylate. (4.) A nearer examination of the product obtained by heating sodium paraoxybenzoate in a stream of carbon dioxide showed the presence of orthophenoldicarboxylic acid, $C^6H^3(OH)(CO^2H)^2$, and oxytrimelic acid, $C^6H^2(OH)(CO^2H)^3$. By conducting the operation very slowly, the end-product was found to contain basic sodium oxytrimesitate only, the reaction taking place as follows:

Potassium paraoxybenzoate, heated to 240° - 250° in a stream of carbon dioxide, is resolved into basic potassium paraoxybenzoate, phenol, and carbon dioxide, small quantities of orthophenoldicarboxylic and oxytrimelic acids being, however, formed at the

same time, in consequence of the decomposition of the potassium salt of the former acid at high temperatures into basic paraoxybenzoate and carbon dioxide.

The identity of the orthophenoldicarboxylic and oxytrimelic acids obtained above with those obtained from salicylic acid is fully borne out by their characters. The alkaline salts of oxybenzoic acid (meta-) differ from those of the isomeric acids in their behaviour when heated; they yield no basic salts, and only a small amount of impure phenol, the residue becoming carbonised.

Thallious Oxybenzoate, $C^6H^4(OH).CO^2Tl$, prepared by neutralising the acid with thallious carbonate and evaporating the solution, crystallises in colourless shining prisms, easily soluble in hot, less soluble in cold water. Basic thallious oxybenzoate, prepared by heating an aqueous solution of oxybenzoic acid with excess of thallious hydrate, and evaporating the solution, crystallises in yellow prisms more soluble than the neutral salt, and possesses an alkaline reaction.

The basic alkaline oxybenzoates are white hygroscopic powders, which when heated in a stream of carbon dioxide leave a residue containing only oxybenzoic acid.

Tetraphenylammonium Salicylate, $C^6H^4(OH).CO^2N(C^6H^5)^4$, prepared by neutralising the aqueous solution of the base with salicylic acid, and evaporating the solution, is a brown, syrupy, highly hygroscopic mass. When heated to 150° , it is resolved into triethylamine and ethyl salicylate. The metoxybenzoate of this base resembles the salicylate; the paraoxybenzoate is, however, resolved at 170° into carbon dioxide, triethylamine, ethylparaoxybenzoate, and phenetol, as follows:

The *oxybenzoates of triethylphenylammonium*, $C^6H^4(OH).CO^2(C^6H^5)^3(C^6H^3)$, are more stable than those of tetraphenylammonium, but are decomposed by heat in a similar manner, yielding diethylphenylamine and the ethyl-ether of the acid.

The *Salicylate and Paraoxybenzoate of Methylamine*, $C^6H^4(OH).CO^2N(CH^3)^2H^3$, are deliquescent crystalline masses, which are resolved by heat into methylamine, phenol, and carbon dioxide. The metaoxybenzoate, however, yields, when heated, methylamine and oxybenzoic acid.

The *aniline oxybenzoates*, prepared by dissolving equivalent quantities of base and acid in alcohol, and evaporating the solution, are well crystallised compounds, and are decomposed by heat in a similar manner to the methylamine salts, the paraoxybenzoate yielding a small quantity of the anilide.

The three oxybenzoyl-anilides are prepared by heating the aniline salts with PCl^3 or P^2O^3 as crystalline bodies.

Salicyl-anilide crystallises in prisms melting at 132° (134° – 135° , Wanstrat, *Deut. Chem. Ges. Ber.* vi. 336).

Paraoxybenzoyl-anilide crystallises in yellow shining plates, melting at 196° – 197° .

Oxybenzoyl-anilide crystallises in white silky needles, melting at 154° – 155° .

These anilides are all easily soluble in alcohol, and sparingly soluble in water; with the alkali-metals and thallium they form easily soluble compounds by the replacement of the hydrogen in the hydroxyl group by metal, their solutions yielding amorphous precipitates with salts of the heavy metals. Salicyl-anilide differs from the others in giving a violet coloration with ferric chloride.

On the formation of Oxybenzoic Acid (Meta-) together with Salicylic Acid from Orthochlorobenzoic Acid, see p. 284.

Solubility in Water.—H. Ost (*J. pr. Chem.* [2], xvii. 228) has determined the solubility of the three oxybenzoic acids and of benzoic acid in water by filling strong flasks with the hot solutions of the acids, closing them loosely after cooling, and surrounding them with ice for several days, and estimating by titration the amount of acid remaining in solution after the deposition of the crystals. The solubilities at 0° were thus found to be:

Salicylic	Benzoic	Paraoxybenzoic	Metaoxybenzoic
1 in 1050)			
to 1 in 1100)	1 in 640	1 in 580	1 in 265

All four acids require much longer time for the complete deposition of crystals when the solutions are dilute than when they are concentrated.

Oxidation.—The three monooxybenzoic acids, also protocatechuic acid and gallic acid, when subjected to the action of chromic acid mixture, are oxidised, with violent reaction, to carbon dioxide (J. Remsen, *Chem. News*, xxvii. 213, 277).

Action of Ammonia.—Salicylic and paraoxybenzoic acids, heated with dry ammonia, give first the ammonium salts, which when heated yield phenol and carbon dioxide.

Metaoxybenzoic acid however, when similarly treated, yields oxybenzonitril, according to the equation—

This oxybenzonitril melts at 82° , and is identical with that which Griess obtained from the sulphate of diazocyanbenzene, $\text{C}^6\text{H}_3(\text{CN})\text{N}^2\text{H}^2\text{SO}^4$ (*Ber.* v. 669).

The three isomeric acids show a similar behaviour when distilled with potassium thiocyanate, the metaoxybenzoic acid alone yielding the nitril. This method of preparing the nitril is, however, less easy than the former.

The oxybenzonitril yields, by treatment with sulphuric acid and nitric acid, a mononitrated substitution-compound melting at 182° – 183° , which when boiled with alkalis yields a nitro-oxybenzoic acid (*H. J. Smith, J. pr. Chem.* [2], xvi. 218).

Ortho-oxybenzoic or Salicylic Acid, $\text{C}^6\text{H}_4.\text{OH}.\text{CO}^2\text{H}^4$. Experiments on the action of heat on the normal salicylates, $\text{C}^6\text{H}_4(\text{OH})\text{CO}^2\text{M}$, have been made by A. v. d. Velden (*J. pr. Chem.* [2], xv. 151), with the following results. All these salts are decomposed into basic salt, phenol, and carbon dioxide, in accordance with the equation established by Kolbe for the sodium-salt, viz.

the salicylates of the heavy metals however partly yield free salicylic acid, and the copper and silver salts are readily decomposed on account of the easy reducibility of the metals which they contain. This reaction, in the case of the potassium salt, as shown by Ost (p. 285), and likewise in that of the rubidium salt, and at a high temperature partly in that of the thallium salt, is attended with the conversion of the salicylic into paraoxybenzoic acid. The thallium salt is at the same time partly converted, like the sodium salt at high temperatures (p. 280), into phenoldicarboxylate:

Normal Thallium Salicylate, $\text{C}^6\text{H}_4(\text{OH}).\text{COTl}$, prepared with the calculated quantities of salicylic acid and thallium carbonate, is moderately soluble in cold, easily in hot water, has a neutral reaction, and separates on cooling from a hot concentrated solution in thick anhydrous needles. The *basic salt*, $\text{C}^6\text{H}_4(\text{OTl}).\text{CO}^2\text{Tl}$, is precipitated in small, nacreous, faintly-yellowish rhombic plates on mixing a hot solution of the normal salt with the solution of an equivalent quantity of thallium hydroxide. It is nearly insoluble in cold, very slightly soluble in hot water.

Aluminium Salts.—On mixing a solution of normal sodium salicylate with a solution of alum, a white crystalline precipitate is formed which is not always of constant composition, but appears to consist for the most part of *normal aluminium salicylate*, $\text{Al}^2(\text{C}^6\text{H}_3\text{O}^3)^6$. By prolonged standing, and especially by boiling with water, salts richer in aluminium are formed.

Normal Ferric Salicylate, $\text{Fe}^2(\text{C}^6\text{H}_3\text{O}^3)^6$, separates on mixing the normal sodium salt with ferric chloride, as a brown precipitate, which, together with the mother-liquor, quickly acquires the deep violet colour produced on bringing free salicylic acid in contact with ferric chloride. After washing, it forms a brown amorphous body, which yields a violet solution when boiled with water.

Dibromosalicylic Acid, $\text{C}^6\text{H}_2\text{Br}^2(\text{OH}).\text{CO}^2\text{H}$, produced by the action of bromine on salicylic acid, forms colourless needles, which dissolve sparingly in water, easily in alcohol, and melt at 219° . Its solution is coloured violet by ferric chloride. Neither this acid nor monobromosalicylic acid appears to form bimetallic salts (*Hübner, Ber.* x. 1707).

Dichlorosalicylic Acid, $\text{C}^6\text{H}_2\text{Cl}^2(\text{OH}).\text{CO}^2\text{H}$. The modification of this acid, produced by passing the calculated quantity of chlorine into a solution of salicylic acid in acetic acid, is precipitated therefrom in white flocks on addition of water, and may be purified from the monochlorinated acid by conversion into barium salt. It is insoluble in cold, but soluble in boiling water; dissolves easily in cold alcohol, and separates from the solution on spontaneous evaporation in stellate groups of colourless needles. It melts at 214° , and sublimes with partial decomposition. Ferric chloride produces a fine violet colour in its aqueous solution. The *barium salt*, $[\text{C}^6\text{H}_2\text{Cl}^2(\text{OH}).\text{CO}^2]^2\text{Ba} + 3\frac{1}{2}\text{H}^2\text{O}$, is insoluble in water, easily soluble in boiling alcohol, and crystallises therefrom in large colourless needles. The *potassium salt*, $\text{C}^6\text{H}_2\text{Cl}^2(\text{OH}).\text{CO}^2\text{K}$, crystallises from its concentrated aqueous solution in white needles. The *sodium salt*, $\text{C}^6\text{H}_2\text{Cl}^2(\text{OH}).\text{CO}^2\text{Na}$, forms easily soluble needles; the *magnesium salt*, $[\text{C}^6\text{H}_2\text{Cl}^2(\text{OH}).\text{CO}^2]^2\text{Mg}$, very soluble crystals. The *lead salt*, $\text{C}^6\text{H}_2\text{Cl}^2\text{OPbCO}^2$, is a white insoluble precipitate; so likewise is the *silver salt*. The

copper salt forms small brown soluble crystals. The *ethylic ether*, $C^6H^2Cl^2(OH)CO^2C^2H^3$, crystallises from alcohol in needles melting at 47° , and forms a potassium salt, $C^6H^2Cl^2(OK)CO^2C^2H^3$. The acid treated with nitric acid yields a soluble nitro-derivative (E. F. Smith, *Amer. Phil. Soc. Proc.* xvii. 68).

Nitrosalicylic Acids. Two mononitrosalicylic acids, $C^6H^2(NO^2)(OH).CO^2H$, obtained by direct nitration of salicylic acid, were described by Hübner in 1874 (*Ber.* vii. 1320), and distinguished as *ortho*- and *para*-nitrosalicylic acids, because when heated they yielded respectively *ortho*- and *para*-nitrophenol (p. 281). In a subsequent paper (*ibid.* x. 1697) they are named α - and β -*orthohydroxymetanitrobenzoic acid*, or more shortly α - and β -*nitrosalicylic acid*. These two acids may be represented by the following formulæ,

the α -modification being evidently resolvable into CO^2 and *o*-nitrophenol, the β -modification into CO^2 and *p*-nitrophenol.

α -Nitrosalicylic acid yields a diethyl-compound (p. 282), convertible by treatment with alcoholic ammonia into

α -*Orthamidometanitrobenzoic acid*, $C^6H^3.NH^2.NO^2.COOH$, which forms very long delicate golden-yellow needles, melting at 263° . Its *barium salt* forms brownish-yellow crystals. The acid is converted by treatment with nitrous acid into a white diazo-compound, and this, when treated with alcohol, yields a metanitrobenzoic acid which melts at 140° , and is converted by reduction with tin and hydrochloric acid into an amido-acid melting at 173° . This shows that the nitro-group in the acid occupies the meta-position in relation to the carboxyl-group, as the name implies.

Together with the foregoing amidonitrobenzoic acid, there is formed an *amide*, $C^6H^3.NO^2.NH^2.CONH^2$, which crystallises in long, colourless, sparingly soluble needles melting at 225° . Solutions of this substance produce a deep-red colour with ferric chloride. It forms colourless compounds with nitric and hydrochloric acids.

β -Nitrosalicylic acid, when pure, melts at 131° , not at 145° , as formerly stated.

β -*Orthamidometanitrobenzoic acid*, obtained in the same manner as the α -compound (see above), forms long yellow needles melting at 204° , and volatilises easily with steam. It is converted by treatment with nitrous acid and alcohol into metanitrobenzoic acid melting at 142° , and yielding, by reduction with tin and hydrochloric acid, an amido-acid melting at 174° . The *amide*, formed together with the nitro-acid, melts at 109° .

Sulphonic acids.— α -Nitrosalicylic acid is converted by heating with fuming sulphuric acid into a sulphonic acid, $C^6H^2(OH)(NO^2)(COOH)SO^3H$, the calcium and barium salts of which crystallise in hair-like needles. This acid yields by reduction the corresponding *amido-acid*, $C^6H^2(OH)(NH^2)(SO^3H)COOH + H^2O$.

α -Metamidosalicylic acid, when heated with fuming sulphuric acid, yields colourless needles of the sulphonic acid, $C^6H^2(OH)(NH^2)(SO^3H)COOH + 3H^2O$, the calcium salt of which crystallises with 5 mols. of water.

Dinitrosalicylic acid.—The two mononitro-salicylic acids above described are converted by fuming nitric acid into the same dinitrosalicylic acid, $C^6.CO^2H.OH.NO^2.H.NO^2.H$, which crystallises in thick shining prisms and tables containing 1 mol. H^2O , and becoming turbid on drying. It is but slightly soluble in cold water, still less in dilute acids. The aqueous solution is coloured red by ferric chloride. The dehydrated acid melts at 173° . The *dipotassium salt*, $C^6H^2(NO^2)^2OK.CO^2K + H^2O$, forms dark red needles having a velvety lustre. The *monammonium salt*, $C^6H^2(NO^2)^2OH.CO^2NH^4$, crystallises from the solution of the acid in concentrated aqueous ammonia in fiery-yellow needles. The *monobarium salt*, $C^6H^2(NO^2)^2O(CO^2)Ba + 3H^2O$, formed by neutralising the acid with barium carbonate, crystallises in very small soft needles. The *monocalcium salt*, $C^6H^2(NO^2)^2O(CO^2)Ca + 1\frac{1}{2}(? 2\frac{1}{2})H^2O$, prepared like the barium salt, crystallises in nodular groups of small needles, somewhat more soluble than the barium salt. The *monoplumbic salt*, $C^6H^2(NO^2)^2O(CO^2)Pb + 3H^2O$, is a light yellow precipitate very sparingly soluble in water, but moderately soluble in hot dilute acetic acid, from which it crystallises in very brilliant light yellow needles. The *ethylic ether* melts at 99° – 100° (H. Behagel von Adlerskron, *Inaugural dissertation*, Göttingen, 1877; *Ber.* x. 1700).

Paraoxybenzoic Acid, $C^6.CO^2H.H.H.OH.H^2$. An elaborate investigation of the formation, properties, and derivatives of this acid has been made by O. Hart-

mann (*J. pr. Chem.* [2], xvi. 35). In preparing it from potassium phenate, it is advisable first to heat the latter in contact with the air, or better in a stream of hydrogen, and then to pass carbon dioxide gradually into it. The product thus obtained amounts to 80, or, if very pure potassium phenate be used, to 90 per cent. of the theoretical amount. If, on the other hand, the carbon dioxide be passed in before the potassium phenate is heated, or if the retort filled with the gas be suddenly heated to 180°, the mass becomes viscid, and the greater part of the potassium phenate is prevented from coming in contact with the carbon dioxide. On dissolving the product in water and adding hydrochloric acid, the paraoxybenzoic acid is precipitated as a brown crystalline powder, which may be purified by boiling its aqueous solution with hydrochloric acid, or better with animal charcoal. The purification may also be effected through the medium of the ethylic ether. Traces of salicylic acid may be removed by crystallisation from chloroform.

Paraoxybenzoic acid crystallises well from dilute alcohol. The crystals, according to v. Reusch's investigation, are monoclinic, with the axial ratio $a:b:c = 1.3703 : 1 : 1.10224$, and the angle $ac = 105^\circ 26'$.

The following salts were prepared by neutralising the aqueous acid with the corresponding carbonates. The *sodium salt*, $C^6H^4(OH)CO^2Na + 5H^2O$, is obtained by crystallisation from a very strong solution at as low a temperature as possible, in slightly brown translucent plates which effloresce with great facility. The *potassium salt*, $C^6H^4(OH)CO^2K + 3H^2O$, obtained in like manner, is permanent in the air. The *ammonium salt* crystallises with 1 mol. water; its solution gives off ammonia on evaporation, so that it must be neutralised before crystallisation, which takes place only from very strong solutions and at low temperatures. It forms large, slowly efflorescing prisms an inch in length. The *calcium salt*, $[C^6H^4(OH)CO^2]^2Ca + 4H^2O$, forms slender needles; the *barium salt* either flat needles with 1 mol. H^2O , or well-developed acute rhombohedrons with basal pinacoid, containing $2H^2O$. The *strontium salt* mostly forms slender needles, less frequently moderately large crystals. The *cadmium salt* crystallises from hot concentrated solutions in needles with $4H^2O$; from dilute solutions in granules with $6H^2O$. The former salt changes into the latter when left for some time in the mother-liquor. The *zinc salt* forms granular crystals containing $8H^2O$. The *ethylic ether*, $C^6H^4(OH)CO^2C^2H^5$, melts at 116° , also when heated under water, in which it dissolves in small quantity at the boiling heat. It is insoluble in carbon sulphide, only slightly soluble in chloroform and benzene, but dissolves readily in alcohol and ether.

Paraoxybenzamide, $C^6H^4(OH)CO.NH^2 + H^2O$, produced by heating the ether just described with aqueous ammonia at 130° , crystallises from water in needles, and is quickly dehydrated at 100° , slowly over sulphuric acid; dissolves easily in alcohol and in hot water, sparingly in ether and in cold water; is nearly insoluble in chloroform, carbon sulphide, and benzene; melts at 162° . It combines both with bases and with acids. *Sodium-paraoxybenzamide*, $C^6H^4(ONa)CONH^2$, is thrown down by caustic soda from an alcoholic solution of the amide as a white precipitate insoluble in ether; from solution in alcohol it separates in crystals. *Dihydrochloride of Paraoxybenzamide*, $C^6H^4(OH)CONH^2.2HCl$, formed by passing hydrogen chloride over the amide, is easily soluble in water.

Paraoxybenzonitril, or *Paracyanphenol*, $C^6CN.H.H.(OH).H^2$, formed from the amide, or better from the ammonia salt by rapid distillation with phosphorus pentoxide, crystallises from hot water in beautifully iridescent laminae of the thickness of a sheet of paper; by slower formation in tablets, which according to v. Reusch are orthorhombic, exhibiting the combination $\infty P.P.0P$. Angle $\infty P = 81^\circ 4'$; $0P : P = 74^\circ 12'$. Hence $a : b : c = 0.8551 : 1 : 2.308$. Plane of optic axes ac ; first median line e . Dispersion very remarkable $\rho > \nu$. Angle of optic axes for red light about 49° in air. The crystals are optically negative. The nitril dissolves sparingly in cold, more freely in hot water, easily in alcohol, ether, and chloroform; it has a sweet taste, with burning after-taste. Soda-ley added to its ethereal solution throws down the sodium-compound, $C^6H^4(ONa)CN$ (dried at 100°), which crystallises from alcohol as well as from water, in the latter case with water of crystallisation.

On *Dinitromethylparaoxybenzoic* or *Dinitranisic acid*, see Salkowsky & Rudolph, (p. 287).

Aldehyde-oxybenzoic Acids, $C^6H^4O^4 = C^6H^3(COH)(OH)(COOH)$. Reimer & Tiemann in 1876 obtained ortho- and para-aldehyde-salicylic and ortho-aldehyde-paraoxybenzoic acids, by the action of chloroform on *o*- and *p*-oxybenzoic acids in alkaline solution (p. 288), and the following additional details respecting these acids are given by the same authors in a subsequent communication (*Ber.* x. 1576).

The best yield is obtained by dissolving 30 grams of salicylic (or paraoxybenzoic) acid in 100 c.c. of caustic soda-solution of sp. gr. 1.35 (containing about 43 grams of sodium hydroxide), and cohobating with 5-10 grams of chloroform, further quantities of the last substance being from time to time added (20-25 grams in half an hour). When a little chloroform condenses and drops back, more caustic soda-solution is added, so that in the course of 4 to 5 hours about 150 c.c. of the soda-solution and 45-46 grams of chloroform have been used altogether: no appreciable increase in the yield is noticed after this stage.

The resulting deep-red liquid is cautiously neutralised with hydrochloric acid, whereby a dark resinous decomposition-product is thrown down: the filtrate is strongly acidulated with hydrochloric acid, and the resulting liquid (containing in suspension a white precipitate) is agitated with ether; the concentrated ethereal extract is then shaken with 100 c.c. of solution of sodium-hydrogen sulphite of sp. gr. 1.35, diluted with 40-50 c.c. of water, which quantity suffices to take up all the aldehydo-bodies found. By means of sulphuric acid and steam (40 grams concentrated acid diluted with 40 c.c. of water) the sulphite compounds are decomposed, the whole being thrown on a filter after cooling to 60°. If paraoxybenzoic acid is used in the first instance, *ortho-aldehydo-paraoxybenzoic acid* remains on the filter, a little more of this acid being contained in the filtrate, together with a little *paraoxybenzoic aldehyde*; the yield of the aldehydo-acid is about 20 per cent. of the paraoxybenzoic acid employed. If salicylic acid was originally employed, *para-aldehydo-salicylic acid* remains on the filter, the filtrate containing small quantities of the same, together with *ortho-aldehydo-salicylic acid*. *Salicylic aldehyde* is also produced in small quantity when the soda-solution originally used was more dilute than that recommended, and especially if the mixture was not heated to a higher temperature than the boiling point of chloroform, a large quantity of that substance being added at first: this product is easily isolated by distillation with steam, the quantity not exceeding 1 or 2 per cent. of the salicylic acid used: it is possibly formed by the splitting up of the salicylic acid into phenol and carbon dioxide, the former being then aldehydated; or it may be produced by the decomposition of the *ortho-aldehydo-salicylic acid*; or, again, and more probably, it may result from a direct exchange of carboxyl for aldyl (the group COH characteristic of aldehydes).

To separate the *ortho*- and *para*-aldehydo-salicylic acids, the method formerly described (methodical crystallisation) does not suffice, traces of the *para*-acid being always retained by the *ortho*-acid thus prepared. The following process answers well:—The solution of the mixed acids is shaken with ether, the ethereal extract evaporated, and the residue dissolved in considerably diluted ammonia-liquor: copper sulphate solution is then added, and sufficient ammonia to dissolve a portion of the precipitate with a blue colour; the whole is then heated to boiling, when almost the whole of the *ortho*-acid separates as a basic copper salt of a bright green colour, containing when dried at 100°, $\text{C}^6\text{H}^3 \begin{matrix} \diagup \text{CO}^2 \\ \diagdown \text{O} \end{matrix} \text{Cu}$; on treatment with dilute hydrochloric

acid, this salt yields pure *ortho-aldehydo-salicylic acid*, crystallising from water in fine interlaced needles resembling salicylic acid, and melting at 179° when perfectly pure (166° was given as the melting point in a former paper): by careful heating it can be sublimed unchanged, but if quickly heated to 220° in the fused state, it splits up into carbon dioxide and salicylic aldehyde: when crystallised it is represented by the formula $\text{C}^6\text{H}^4\text{O}^4, \text{H}^2\text{O}$; the crystals becoming anhydrous at 100°. Alcoholic solutions of the acid exhibit a faint bluish-violet fluorescence; in caustic soda it dissolves with a yellow colour. Ferric chloride strikes a red tint, and sodium carbonate dissolves the acid with effervescence.

Two classes of salts are formed by each one of the three aldehydo-acids, viz., normal salts, and basic salts in which the phenolic hydrogen is also replaced; the points at which the normal salts are formed with alkalis and the two salicylic derivatives are easily determined by means of litmus, a red coloration being given to the litmus as long as the amount of alkali added is less than that requisite to form the normal salt, and a blue with the slightest excess: with the paraoxybenzoic derivative, however, the point of neutrality cannot be thus determined, as the litmus becomes green before the amount of alkali requisite to form the neutral salt is added; further addition of alkali deepens the green, but there is no characteristic colour change marking the point of neutrality. The alkali-salts of all these acids are very soluble, and crystallise only from extremely concentrated solutions; the normal salts of the two salicylic derivatives are colourless by transmitted light, appearing to possess a green fluorescence with reflected light; traces of excess of alkali give a yellow coloration. The neutral and ammoniacal solutions (concentration about 1 : 50) exhibit the reactions given in the following table:

Reagents	Ortho-aldehydo-salicylic acid		Para-aldehydo-salicylic acid		Ortho-aldehydo-pumoxybenzoic acid	
	Neutral solution	Ammoniacal solution	Neutral solution	Ammoniacal solution	Neutral solution	Ammoniacal solution
Calcium Chloride .	—	Flocculent white basic calcium salt.	—	Crystalline white basic calcium salt.	—	—
Barium Chloride .	—	White granulo-crystalline basic barium salt.	—	White granulo-crystalline basic barium salt.	—	Flocculent white basic barium salt, separating only on heating.
Silver Nitrate .	White granular silver salt, dissolving without alteration in boiling water, and separating therefrom on cooling in stellate groups of scales.	The normal silver salt dissolves in excess of ammonia; the ammoniacal solution blackens on prolonged heating.	Granular white silver salt, dissolving in a large quantity of boiling water, and separating on cooling in tufts of microscopic needles.	The normal silver salt dissolves in excess of ammonia, forming a solution which does not blacken when heated.	Gelatinous silver salt, soluble in excess of ammonia. The solution does not blacken when heated.	The ammoniacal solution of the normal silver salt blackens easily when heated.
Copper Sulphate .	Light green crystalline copper salt, soluble with green colour in excess of ammonia.	Basic gelatinous copper salt, dissolving, when recently precipitated, in excess of ammonia, the solution on standing, or more quickly when heated, depositing a granular salt.	Crystalline copper salt, separating after long standing in needles.	Flocculent basic copper salt, easily soluble in excess of ammonia. The solution does not become turbid when heated.	Hydrated green copper salt, becoming crystalline when heated.	Gelatinous basic copper salt, easily soluble in excess of ammonia; the solution does not become turbid when heated.
Lead Acetate *	Bulky white lead salt.	Bulky basic lead salt.	Dense white lead salt.	Bulky white basic lead salt.	Bulky white lead salt.	Bulky white basic lead salt.
	Soluble in acetic acid.		Easily soluble in acetic acid.		Easily soluble in acetic acid.	

* Aqueous solutions of the three aldehydo-oxy-acids likewise give slight white precipitates with lead acetate.

Ortho-aldehydo-salicylic acid dissolves in 1500–1600 pts. of water at 23°–25°, and in 15–16 pts. at 100°; para-aldehydo-salicylic acid in 2600–2700 pts. at 25°, and in 145–150 pts. at 100°; ortho-aldehydo-paraoxybenzoic acid is slightly more soluble in cold water than the latter.

By fusion with potash, these three aldehyde acids are readily converted into phenol-dicarboxylic acids, $C^6H^3(OH)(COOH)^2$.

See PHENOL-CARBOXYLIC ACIDS.

Reduction of Aldehyde-oxybenzoic Acids to Alcoholic Acids (Reimer, Ber. ix. 790).—This transformation is effected by treating the aldehyde-acids with sodium-amalgam: 1 pt. of the aldehyde-acid is suspended in about 10 pts. of water, and treated gradually with 50 pts. of 3 per cent. sodium-amalgam. The reduction of the aldehyde under these circumstances is nearly complete, but resinous products are invariably formed at the same time. Hydrochloric acid is then added in slight excess, and the alcoholic acid, mixed with resin, is extracted by agitation with ether. The separation of the resin is effected, either by dissolving the mixture in ammonia, adding barium chloride, and leaving the solution for some weeks, when the resin separates completely in combination with barium; or by acidifying the ammoniacal solution with hydrochloric acid, quickly filtering off the resin mixed with some acid, and allowing the rest of the acid to separate spontaneously.

Paraoxymethyl-salicylic acid, $C^6H^3(OH)(COOH)(CH^2OH) = (1 : 2 : 4)$, from para-aldehydosalicylic acid, crystallises from ether in long prisms containing 1 mol. water of crystallisation. It is sparingly soluble in water, more so in alcohol and ether. It decomposes at 160°, and is resinised by warm mineral acids. Permanganate solution converts this acid in the cold into α -oxisophthalic acid; when heated with potassium dichromate it is oxidised to para-aldehydosalicylic acid.

Ortho-oxymethylsalicylic acid, $C^6H^3(OH)(COOH)(CH^2OH) = (1 : 2 : 6)$, is precipitated as an oil, which solidifies to crystals, melting at 142°. A solution of this acid in water, especially in presence of free mineral acid, is resinised by heat. An ammoniacal solution of it, heated with potassic dichromate, gives again the corresponding aldehyde-acid.

Ortho-oxymethylorydracrylic acid (saligeninpara-carbonsäure):

obtained by reduction of ortho-aldehydo-orydracrylic acid, is much more stable than its isomerides, and does not melt at 270°. It is not coloured either by sulphuric acid or by ferric chloride. With the latter reagent its isomerides, mentioned above, give intense violet colours.

OXYBENZOIC ALDEHYDES or OXYBENZALDEHYDES, $C^6H^4O^2 = OH.C^6H^4.CO.H$. Two of these compounds, viz. salicyl-aldehyde, $[OH : COH = 1 : 2]$, and paraoxybenzaldehyde, $[1 : 4]$, produced simultaneously by the action of chloroform on a strongly alkaline solution of phenol, have already been described (p. 303). According to T. L. Phipson (*Compt. rend.* lxxiv. 1034), when salicylic acid (1 gram) is heated with water (30–40 g.) and fuming nitric acid (5 c.c.) there is formed, together with nitro-salicylic acid, a very considerable quantity of salicyl-aldehyde due to the action of nitrous acid, which may be separated from the red liquid, after the nitrosalicylic acid has crystallised out, by agitation with ether. Salicylaldehyde is also formed, together with nitrosalicylic acid, when salicylic acid is heated with a solution of potassium nitrite.

On the conversion of Salicylaldehyde into *Coumaric Acid* and *Coumarin*, see pp. 574, 575.

Paraoxybenzaldehyde, $C^6.CO.H.H.H.OH.H^2$.—The following derivatives of this compound have been prepared and examined by Herzfeld (Ber. x. 1267, 2196):

Chloroparaoxybenzaldehyde, $C^6H^3Cl(OH)(COH)$, is formed in theoretical quantity by passing chlorine gas over the dry oxyaldehyde, and crystallises in long silky needles, which melt at 148°–149°, and are freely soluble in water, alcohol, and ether.

With the alkalis it forms salts, which crystallise in long needles, and are soluble in water. It absorbs ammonia in the proportion of 1 : 2 mols., and differs in this respect from paraoxybenzaldehyde, 1 mol. of which unites with 1 mol. of NH_3 . The compound thus formed crystallises from absolute alcohol in beautiful needles. The aqueous solutions of paraoxybenzaldehyde and of its chlorine-compound give a violet reaction with ferric chloride.

The corresponding *bromine-compound*, $\text{C}_6\text{H}_5\text{Br} \cdot \text{OH} \cdot \text{COH}$ (m. p. 179°), is formed when the dilute alcoholic solution of paraoxybenzaldehyde is allowed to absorb bromine vapour. It resembles, in all respects, both the latter compound and its chlorine-derivative, with the exception that its aqueous solution is not coloured by ferric chloride.

The *iodine-compound*, $\text{C}_6\text{H}_5\text{I} \cdot \text{OH} \cdot \text{COH}$ (m. p. 198°), is formed by heating the dilute alcoholic solution of paraoxybenzaldehyde with iodine for some hours. By the action of potassium hydrate at a high temperature (160° – 170°) upon this body, it is converted into protocatechuic acid.

Nitroparaoxybenzaldehyde, $\text{C}_6\text{H}_5\text{OH}(\text{NO}^2)\text{COH}$, is formed by dropping strong nitric acid into a mixture of 3 pts. of paraoxybenzaldehyde with 20 pts. of strong sulphuric acid. On diluting with water it is deposited as a golden-yellow mass, which crystallises in yellow needles from its aqueous solution. It melts at 139° – 140° , dissolves easily in alcohol and benzene, sparingly in ether and chloroform, sublimes entirely on heating, and volatilises with steam. It forms a crystalline, sparingly soluble compound with acid sodium sulphite, and produces a transient reddish coloration with ferric chloride.

Paraoxybenzaldehyde absorbs 13.46 per cent. (= 1 mol.) of dry ammonia gas, forming with it an oily body, which, on exposure to air, gradually gives off ammonia, and leaves the unaltered aldehyde.

Salicylic aldehyde likewise absorbs 1 mol. of ammonia, forming a compound which is resolved by heat into water, ammonia, and hydrosalicylamide.

Paraoxybenzaldehyde in ethereal solution reacts with aniline to form a pale-yellow crystalline body, which melts at 190° – 191° , and dissolves easily in alcohol and ether, sparingly in benzene and chloroform. From the analysis of the body it appears to be formed by the following reaction:

Paraoxybenzaldehyde also unites with paratoluidine, with elimination of water, according to the equation:

The product of the reaction is an orange-coloured body, which crystallises from its alcoholic solution in four-sided plates, melting at 213° . The inverse reaction is determined by boiling the compound with dilute acids or alkalis.

Paraoxybenzyl alcohol, $\text{C}_6\text{H}_4(\text{OH})\text{CH}_2\text{OH}$, is formed by the action of sodium-amalgam on paraoxybenzaldehyde. It is a solid crystalline substance, melting at 197.5° , soluble in water, alcohol, and ether, and sparingly in benzene and chloroform. It gives a transient blue coloration with ferric chloride, and is coloured brown by strong sulphuric acid.

Hydroparaoxybenzoïn, $\text{C}^{14}\text{H}^{14}\text{O}^4$, is produced on treating with sodium-amalgam a mixture of paraoxybenzaldehyde with more than 10 pts. of water. It is thrown down, on neutralising the liquid, as a white crystalline substance, melting at 222° , easily soluble in boiling water, less easily in alcohol, benzene, and chloroform.

OXYBENZOTRISULPHONIC ACID, $\text{C}_6\text{H}_5\text{S}^3\text{O}^{12} = \text{C}_6\text{H}(\text{OH})(\text{SO}^3\text{H})^3\text{COOH}$.

Trisulphoxybenzoic acid.—This acid is prepared by heating a solution of 10 grams of benzoic acid in 20 grams of sulphuric acid, with 15 grams of phosphorus pentoxide and 20 grams of sulphur trioxide in sealed tubes at 250° for five hours. The contents of the tubes are boiled with water to expel sulphur dioxide, and the sulphuric and phosphoric acids are removed by the addition of calcium carbonate. To obtain the free acid, basic acetate of lead is added to the filtrate, and the precipitated lead salt decomposed by sulphuretted hydrogen.

Trisulpho-oxybenzoic acid is a yellow syrupy hygroscopic liquid, which, after drying at 100° , has the composition $\text{C}_6\text{H}_5\text{S}^3\text{O}^{12} + 4\text{H}_2\text{O}$. Both the acid and its salts produce, with a drop of ferric chloride, an intense carmine coloration, which disappears on the addition of sodium carbonate.

The *basic lead salt*, $(\text{C}_6\text{H}_5\text{S}^3\text{O}^{12})_2\text{Pb}^2 + 6\text{H}_2\text{O}$, forms white opaque needle-shaped crystals, which lose their water of crystallisation at 235° . By the partial decomposition of this compound with sulphuretted hydrogen the *normal lead salt*, $\text{C}_6\text{H}_5\text{S}^3\text{O}^{12}\text{Pb}^2 + 8\text{H}_2\text{O}$, is obtained. *Basic potassium trisulpho-oxybenzoate*,

$C^7H^5O^{12}K^5 + 2H^2O$, crystallises in monoclinic prisms; the normal salt, $C^7H^5S^3O^{12}K^4 + 2H^2O$, separates out on addition of alcohol to trisulpho-oxybenzoic acid which has been nearly neutralised with potassium carbonate.

The *barium salt*, $C^7H^5S^3O^{12}Ba^2$, is decomposed by long-continued heating at 100° , or by boiling with barium carbonate, barium sulphate and barium disulpho-oxybenzoate, $(C^7H^5S^2O^9)^2Ba^3 + 8H^2O$, being formed in the latter case.

Trisulpho-oxybenzoic acid appears to be completely destroyed by fusion with potash, as only traces of pyrogallic and oxalic acids could be detected in the fused product. Attempts to replace the hydrogen in this acid by bromine were unsuccessful, the acid splitting up into monobromodisulpho- and dibromomonosulpho-benzoic acids (Kretschy, *Ber.* xi. 858).

OXYBENZYL ALCOHOL, $C^7H^5O^2 = C^6H^4OH.CH^2OH$ [$OH : CH^2OH = 1 : 3$]. *Benzyl Glycol* (A. v. d. Velden, *J. pr. Chem.* [2], xv. 151).—This alcohol is formed, together with other products, by the action of sodium-amalgam on metaoxybenzoic acid in acid solution; in alkaline solution no reduction takes place. To prepare it oxybenzoic acid in moderate quantity is covered with water in a flat-bottomed flask, and about five times its quantity of 4 per cent. sodium-amalgam is gradually added, care being taken that the temperature of the mixture does not rise above 60° . When the action is over, the product is shaken up with ether, the residue left after evaporation of the ether is treated with water and calcium carbonate, and the filtered liquid is again exhausted with ether. The pure alcohol freed from the solvent by spontaneous evaporation, and left in a vacuum over sulphuric acid, solidifies gradually to a white crystalline mass. It melts at 67° ; boils, with partial decomposition, at about 300° ; dissolves slowly in cold, easily in hot water, easily also in alcohol and ether, sparingly in chloroform. With *oxidising agents* (chromic acid, nitric acid, permanganate), it does not yield any definite products of oxidation; melting potash converts it into meta-oxybenzoic acid (m. p. 200°); alcoholic potash does not act upon it; neither is it attacked by potassium or sodium.

Oxybenzyl Acetates.—The *normal ether*, $C^6H^4OH.CH^2OC^2H^3O$, is obtained by the action of glacial acetic acid and sulphuric acid on oxybenzyl alcohol, as an oil which solidifies on drying to a radiate yellow mass. It has a pleasant aromatic odour, melts at 55° , and boils with partial decomposition at 295° – 302° . It is insoluble in water, but dissolves readily in alcohol and ether, and, like the alcohol, gives a violet-blue coloration with ferric chloride.

The *acid acetate*, $C^6H^4(OC^2H^3O).CH^2OC^2H^3O$, is obtained by heating the alcohol to 160° with excess of acetic anhydride, as a liquid which solidifies at -18° . It has a pungent odour, boils at about 290° , is insoluble in water, but dissolves in alcohol and ether.

Para-oxybenzyl alcohol, [$OH : CH^2OH = 1 : 4$], formed by the action of sodium-amalgam on paraoxybenzaldehyde, is a solid body, melting at 197.5° , soluble in water, alcohol, and ether, sparingly soluble in benzene and chloroform; gives a violet-blue colour with ferric chloride.

OXYBUTYRIC ACIDS, $C^4H^5O^3 = C^3H^4(OH).CO^2H$. The *normal acid*, $CH^3OH.CH^2.CH^2.COOH$, is formed by heating succinic aldehyde with water and lime or baryta:

It is crystalline; forms deliquescent calcium and barium salts; is converted by oxidation into succinic acid (A. Saytzeff, *Ber.* vi. 1255).

On *α -Oxybutyric Acid*, see p. 364.

β -Oxybutyric Acid, $CH^3.CH(OH).CH^2.COOH$ (vi. 891), is formed by oxidation of aldol, $CH^3.CH(OH).CH^2.CHO$, with moist silver oxide. Its *zinc salt* is easily soluble in water and in alcohol, and crystallises indistinctly; its *barium salt* also dissolves easily in water and in alcohol, but is uncrystallisable, and is precipitated by ether from its alcoholic solution in flocks; the *sodium salt* crystallises from solution in alcohol (Wurtz, *Compt. rend.* lxxvi. 1165). The same acid is formed by saponification of the ethyl salt of the chlorobutyric acid obtained by passing chlorine into fermentation butyric acid (Balbiano, *Gazz. chim. ital.* 1878, 90).

α -Oxyisobutyric acid, $(CH^3)^2COH.COOH$, originally produced by the action of moist silver oxide on bromoisobutyric acid, and by that of hydrocyanic and hydrochloric acid on acetone (vi. 891), is also formed by the action of the same acids on propionic aldehyde (p. 364), and by boiling a solution of β -oxisopropyltartaric acid neutralised with baryta-water (Demarçay, *Compt. rend.* lxxxi. 1337):

It appears also to be contained in the mother-liquors of the preparation of β -isopyrotartaric or dimethylmalonic acid (p. 1259).

OXYCAMPIC ACID, $C^{10}H^{16}O^3$. See CAMPIC ACID (p. 372).

OXYCAMPHORONIC ACID, $C^9H^{12}O^6$ (vii. 238). On the crystalline form of this acid, see V. v. Zepharovich (*Wien. Akad. Ber.* lxxiii. 1 Abth; *Zeitschr. Kryst.* i. 220; *Jahresb. f. Chem.* 1877, 640).

OXYCAPROIC ACID, $C^6H^{12}O^3$. An acid of this composition, probably $CH^3.CH^2.CH^2.CH^2.CHOH.CO^2OH$, obtained by oxidation of fermentation caproic acid, crystallises in laminae melting at 57° . Its silver, zinc, cadmium, and barium salts are very slightly soluble, and are deposited from their solutions in the amorphous state. By oxidation, it yields carbon dioxide, a valeric acid, and an aldehyde (N. Ley, *Ber.* x. 230). See also LAURIC ACID (p. 1179).

OXYCARBANIL, $CO=N.C^6H^4.OH$, is formed, together with alcohol, by heating metaoxyphenylurethane to 200° :

It crystallises from water in needles having a faint red colour; melts at 136° – 138° ; dissolves more freely in alcohol than in ether, easily in alkaline liquids; the solution in potash blackens when boiled. The compound is not attacked by ammonia or hydrochloric acid. The *silver salt*, $CO=N.C^6H^4.OAg$, is a precipitate resembling silver chloride. Oxycarbanil is not attacked by gaseous or alcoholic ammonia, but when heated to 160° with aqueous ammonia it is decomposed, with formation of amidophenol (Groenock, *Ber.* ix. 1554).

OXYCHOLESTENIC or **OXYCHOLESTERIC ACID**, $C^{26}H^{42}O^3$. A monobasic acid formed, together with cholestenic acid, $C^{26}H^{42}O^4$, also monobasic, and dihydrocholestenic acid, bibasic, by oxidation of cholesterolin with permanganate (p. 455).

OXYCHRYSAZIN, $C^{14}H^8O^3 = C^{14}H^8(OH)^2O^2$. See ANTHRAQUINONES (TRIOXY-), (p. 113).

OXYCINCHOMERONIC ACID, $C^{11}H^8N^2O^8$. } See CINCHONINE (p. 483).

OXYCINCHONINE, $C^{20}H^{24}N^2O^2$.

OXYCITRACONIC ACID, $C^8H^8O^5$. See CITRIC ACIDS (PYRO-), (p. 515).

OXYCITRIC ACID, $C^6H^8O^8$. See CITRIC ACID (p. 510).

OXYCOLOPHTHALIN, $C^{11}H^8O$. A product of oxidation of colophthalin, $C^{11}H^{10}$, a hydrocarbon found by P. Curie (*Chem. News*, xxx. 189) among the products of the dry distillation of colophony.

OXYCOUMARIN, $C^9H^8O^2 = C^8H^7(OH) \begin{array}{c} \text{CH=CH-CO} \\ | \\ \text{O} \end{array}$. The *acetyl-derivative*

of this compound, $C^9H^7(OC^2H^3O) \begin{array}{c} \text{CH=CH-CO} \\ | \\ \text{O} \end{array}$, is formed on heating resorcylic

aldehyde, $C^6H^3(OH)^2COH$, with 1 pt. sodium acetate and 3 to 5 pts. acetic anhydride. It crystallises from water in large faintly yellow prisms melting at 140° ; distils undecomposed; dissolves but sparingly in water even when hot, easily in alcohol and in ether. The aqueous solution exhibits a splendid blue fluorescence, but does not give any colour-reaction with ferric chloride. It is not attacked by alkalis or alkaline carbonates in the cold, but dissolves when heated, forming a solution from which ether extracts oxycoumarin. This substance, after purification, crystallises in small white needles, which dissolve in water (the solution is coloured brown-red by ferric chloride), and decompose without melting at 200° .

Oxycoumarin and its acetyl-derivative have the same composition as β -umbelliferone and β -acetyl-umbelliferone; but whether they are identical with these latter is a point not yet determined (Tiemann & Lewy, *Ber.* x. 2210).

OXYDIBENZYL SULPHONIC ACID, $C^{14}H^{12}(OH)(SO^3H)$, is obtained by fusing potassium dibenzylsulphonate (p. 322) with potash, and precipitating the solution of the melt with hydrochloric acid (Kude, *Ber.* vi. 953).

OXY-DIIMIDO-DIAMIDO-DIISATIN, $C^{16}H^4(NH)^2(NH^2)^2N^2O^3$. See ISATIN (p. 1125).

OXYFLUORESCEIN and **OXYGALLEIN**. See OXYPTHALIC ACID under PHTHALIC ACIDS.

On the Heat of Combination of Oxygen with other Elements, see Heat (pp. 952–961).

On the quantities of Oxygen consumed in the Imperfect Combustion of Gases and Gaseous Mixtures, see CHEMICAL ACTION (pp. 430–436).

Occurrence in the Sun.—The presence of oxygen in the sun has been discovered by H. Draper (*Sill. Am. J.* [3], xiv. 89), by the appearance of *bright* lines in the solar spectrum coinciding with those of incandescent oxygen. The brightness of these lines is attributed by Draper to the very great thickness of the incandescent gas-stratum of the sun, which may reverse the effect of the photosphere. J. C. Draper, on the other hand (*ibid.* xvi. 256), has shown, by means of a diffraction-spectrum, that the solar spectrum contains numerous very fine dark lines coinciding with the bright lines of the oxygen spectrum and extending to the ultra-violet.

Preparation.—In preparing oxygen from potassium chlorate, it is advantageous, according to J. Löwe (*Dingl. pol. J.* cxxiii. 533), to mix the chlorate with about an equal weight of recently ignited ferric oxide (*Caput mortuum*) instead of cupric oxide or manganese dioxide. Previous fusion of the chlorate is also to be recommended.

On the preparation of Oxygen, see also S. Zinno (*Chem. News*, xxxvi. 168).

On the Evolution and Absorption of Oxygen by Plants, see PLANTS.

On the Relative Affinities of Oxygen and Sulphur for Metals, see SULPHUR.

Reaction with Sodium Hyposulphite and with Cuprous Oxide.—When a solution of sodium hyposulphite, Na_2SO_3 , is added to aerated water tinted with indigo, the indigo is decolorised when a quantity of the liquid has been added sufficient to consume just half the oxygen present. The liquid thus decolorised becomes blue again under the influence of the slightest trace of free oxygen, and the gases extracted from it by ebullition or by the mercurial pump consist of nitrogen and carbon dioxide without appreciable traces of oxygen.

If an excess of a colourless solution of ammoniacal cuprous chloride is added to aerated water, the liquid becomes blue, and on titrating by means of hyposulphite the cupric oxide which has been formed, its amount is found to be equivalent to half that of the dissolved oxygen. Certain reducing agents, notably sodium hyposulphite and ammoniacal cuprous chloride in presence of oxygen dissolved in water, divide the oxygen into two equal parts, one of which acts upon the reducing agent itself, the other remaining disguised in the liquid. The oxygen which thus disappears probably unites with the water, forming hydrogen peroxide. It becomes free again on heating the liquid. Stannite of sodium, however, removes the whole of the dissolved oxygen (Schützenberger a. Risler, *Compt. rend.* lxxvi. 1214).

Estimation.—On the estimation of Free Oxygen in Water and in Blood by means of the Hyposulphite reaction above described, see BLOOD (vii. 200); also *Chem. Soc. J.* 1873, 936. Remarks thereon by König a. Mutschler (*Ber.* x. 2017; *Jahresb. f. Chem.* 1877, 1035).

On the estimation of Oxygen in Water, see also Endemann (*Amer. Chem.* v. 9), and H. Wurtz (*ibid.* 10); also *Jahresb. f. Chem.* 1874, 963; further, *Amer. Chem.* v. 237, 364.

On the estimation of the total amount of Oxygen in Commercial Copper, see COPPER (p. 561).

On the direct estimation of Oxygen in Organic Compounds, see ORGANIC ANALYSIS (p. 1445).

OXYHEMOGLOBIN. From recent experiments by Hoppe-Seyler (*Zeitschr. physiol. Chem.* i. 396), it appears that this substance, when treated in aqueous solution with palladium-hydrogen, in a vessel from which the air is excluded, is completely converted into methæmoglobin. This latter must therefore contain less oxygen than oxyhæmoglobin and cannot be a peroxyhæmoglobin, as supposed by Jäderholm (p. 920). Methæmoglobin is converted by putrefaction, in the absence of oxygen, into hæmoglobin, which by cautious treatment may be converted into oxyhæmoglobin, and more readily into carbonyl-hæmoglobin.

OXYHEPTIC ACID, $\text{C}^7\text{H}^{10}\text{O}^3$. See HEPTIC ACID (p. 1020).

OXYHEPTOIC ACID, $\text{C}^7\text{H}^{14}\text{O}^3$. See CENANTHYLIC ACID (p. 1427).

OXYISOBUTYRIC ACID. See OXYBUTYRIC ACIDS (p. 1468).

OXYISODINAPHTHYL, See NAPHTHYL-COMPOUNDS.

OXYISOLEPIDIN, $C^{25}H^{20}O^2$. See LEPIDIN (p. 1177).

OXYISOPHTHALIC ACID. See OXYPTHALIC ACID, under PHTHALIC ACIDS.

OXYISOKYLENE QUINONE. See XYLENE QUINONES.

OXYITACONIC ACID, $C^6H^3O^3 = HO.HC \begin{smallmatrix} \diagup CO^2H. \\ \diagdown CH^2CO^2H. \end{smallmatrix}$. An acid produced, together with formic acid, by the action of boiling baryta-water on aconic acid (vii. 22).

OXYKETONES. The introduction of an acid radicle into the hydroxyl-group of phenol gives rise to a body which is capable of reacting further with an acid chloride to form the ether of an oxyketone. Thus, for instance, the introduction of the benzoyl-radicle into phenol produces phenyl benzoate, and this substance reacts with benzoyl chloride and zinc chloride in such a manner as to form benzoyl-phenyl benzoate, $C^6H^5.CO.O.C^6H^4.CO(C^6H^3)$ (Doebner, *Ber.* x. 1968).

In like manner, the action of zinc chloride on a mixture of benzoyl chloride and resorcinol produces two benzoeresorcinols, $C^6H^5.CO.C^6H^3(OH)^2$ and $(C^6H^5.CO)^2C^6H^3(OH)^2$, which, by the further action of benzoyl chloride, are converted into dibenzoates (Doebner a. Stackmann, *Ber.* xi. 2268). See RESORCINOL.

OXYLEPIDINS, $C^{25}H^{20}O^2$ and $C^{26}H^{20}O^3$. See LEPIDIN (pp. 1173, 1176).

OXYLEUCATIN. A constituent of Coto bark (p. 574).

OXYMALEIC ACID. Syn. with Hydroxymaleic acid, $C^4H^3(OH)O^2$. See MALEIC ACID (p. 1256).

OXYMALONIC ACID. Syn. with Hydroxymalonic acid, $C^4H^3(OH)O^3$. See MALONIC ACID (p. 1260).

OXYMESITYLENIC ACID, $C^9H^{10}O^3$, appears to be formed, together with mesitol (p. 1282), by fusing potassium mesitylenesulphonate with potassium hydroxide (Biedermann a. Ledoux, *Ber.* viii. 57).

OXYMETHANESULPHONIC ACID, $CH^3SO^4 = CH^2(OH).SO^3H$. *Methyl-isethionic acid* (Max Müller, *Ber.* vi. 1031). This acid, metameric with methylsulphuric acid, $(OH^3)HSO^4$ or $SO^2(OCH^3)(OH)$, is obtained by distilling sulphuric anhydride (2 mol.) into a well-cooled mixture of methyl alcohol (1 mol.) with a large quantity of concentrated sulphuric acid. The resulting liquid is diluted with water, boiled for some hours and neutralised with lead carbonate, the lead is removed by hydrogen sulphide, and then filtered, and the filtrate neutralised with potassium carbonate. By repeated crystallisation, the pure *potassium salt* is obtained in large anhydrous orthorhombic crystals moderately soluble in water, insoluble in alcohol. The *barium salt* forms small limpid plates; the *ammonium salt*, small easily soluble needles. The free acid, as well as its salts, is very stable, not being decomposed by boiling with water or with concentrated acids.

Oxymethanedisulphonic acid, $CH(OH)(SO^3H)^2$, is formed by passing the vapour of sulphuric anhydride into pure methyl alcohol. The action is very violent, the liquid blackening and giving off sulphur dioxide, even when it is well cooled with a freezing mixture. When the liquid in the receiver is so far supersaturated with sulphuric anhydride as to give off thick fumes, it is to be treated in the manner above described for the preparation of oxymethanemonosulphonic acid. The product is a dark-coloured *potassium salt*, which may be freed from colouring matters by digestion with boiling alcohol of 40 per cent. and obtained by crystallisation from hot water in concentric groups of needles. The *barium salt* is produced by mixing a dilute solution (1 : 80) of the potassium salt with barium chloride, and separates after a while in small well-formed needles. Both the acid and its salts are as stable as the oxymethanemonosulphonates. The disulphonic acid may also be prepared by heating potassium oxymethanemonosulphonate for four or five hours with fuming sulphuric acid.

Oxymethanetrissulphonic acid, $C(OH)(SO^3H)^3$. *Methyl-alkoholtrisulfosäure* (Albrecht, *Liebig's Annalen*, clxi. 129). The potassium salt of this acid is obtained by dropping bromine into a warm solution of potassium methylmercaptan-trisulphonate till the liquid exhibits a faint yellowish colour :

The salt then separates in beautiful needles, which, after recrystallisation and drying, have the composition $COH(SO^3K)^3 + H^2O$. By slow crystallisation it is obtained in fine monoclinic strongly refracting prisms. It dissolves in 81 pts. of water at 21°. The *free acid*, obtained by precipitating the solution of the potassium salt with basic lead acetate, and decomposing the precipitate with hydrogen sulphide, dries up on

evaporation in a vacuum to a deliquescent crystalline mass. It does not give any colour-reaction with ferric chloride. The *ammonium salt*, $\text{COH}(\text{SO}^3\text{NH}_4)^2$, prepared by neutralisation, forms thin tabular anhydrous crystals immediately soluble in water. The *barium salt*, $[\text{COH}(\text{SO}^3)^2\text{Ba}^2 + 8\text{H}_2\text{O}]$, is precipitated by barium chloride from a hot aqueous solution of the potassium salt in nacreous laminae, dissolves in a very large quantity of water, and crystallises therefrom in small shining needles. The *copper salt* is less characteristic. A *basic mercuric salt*, $[\text{COH}(\text{SO}^3)^2\text{Hg}^2.3\text{HgO} + 15\text{H}_2\text{O}]$, is obtained by dissolving moist mercuric oxide in the free acid. The *silver salt*, $\text{COH}(\text{SO}^3\text{Ag})^2 + \text{H}_2\text{O}$, crystallises in tufts of needles, easily soluble in warm water. A *plumbiferous potassium salt*, obtained by evaporating the liquid remaining over the precipitate formed on mixing a solution of potassium oxymethanetrissulphonate with normal lead acetate, was found to have the composition $4\text{COH}(\text{SO}^3\text{K})^2 + [\text{CO}(\text{SO}^3\text{K})^2]^2\text{Pb} + 6\text{H}_2\text{O}$. A double salt of lead oxymethanetrissulphonate with lead acetate, $[\text{COH}(\text{SO}^3)^2]^2\text{Pb}^2 + (\text{C}^2\text{H}^3\text{O}^2)^2\text{Pb} + 8\text{H}_2\text{O}$, is obtained in efflorescent tabular crystals when the precipitate formed on adding basic lead acetate to the solution of the potassium salt is dissolved in dilute acetic acid, and the solution is left to evaporate. It is decomposed by boiling water, with formation of lead sulphate.

OXYMETHYLBENZOIC ACID, $\text{C}^6\text{H}^4\text{O}^2 = \text{C}^6\text{H}^4(\text{CH}^2\text{OH})(\text{COOH})$ (J. Hessert, *Ber.* x. 1445; xi. 237). This acid is formed by the action of alkalis or alkaline carbonates on phthalide, which is its anhydride,

It is much less soluble in cold water than phthalide, but dissolves easily in alcohol and ether. It melts at 118° , giving up 1 mol. water, and being reconverted into phthalide; the same change takes place also on boiling the acid with water. It is a well-defined monobasic acid, reddens litmus strongly, and dissolves with effervescence in alkaline carbonates. Its salts are all soluble in water; those of the alkaline earths dissolve in very small quantities of water and of alcohol, but are not deliquescent. The *silver salt*, $\text{C}^6\text{H}^4(\text{CH}^2\text{OH})(\text{COOAg})$, obtained by the action of the acid on recently precipitated silver oxide, crystallises from aqueous solution in small octohedrons. The *lead salt* is decomposed by water.

OXYMETHYLOXYBENZOIC ACIDS, $\text{C}^6\text{H}^2(\text{OH})(\text{CH}^2\text{OH})(\text{COOH})$. The modifications 1 : 2 : 4, 1 : 2 : 6, and 1 : 4 : 6 of these acids are obtained, as already described, by reduction of para-aldehydo-salicylic, ortho-aldehydo-salicylic, and ortho-aldehydo-para-oxybenzoic acids respectively (see ALDEHYDO-OXYBENZOIC ACIDS (p. 1465)).

OXYNAPHTHALENE, OXYNAPHTHOIC ACIDS, OXYNAPHTHOL, OXYNAPHTHAQUINONE. See NAPHTHALENE, &c.

OXYNEURINE, $\text{C}^8\text{H}^{11}\text{NO}^2$. Syn. with BETAINE (pp. 323, 380).

OXYPARACONIC ACID, $\text{C}^8\text{H}^4\text{O}^3$. The calcium salt of this acid is formed, together with calcium itatartarate, when a solution of chloritamalic acid neutralised with calcium carbonate is heated for some time to the boiling point. See CITRIC ACIDS (PYRO-), p. 518.

OXYPEUCEDANIN. See PEUCEDANIN.

OXYPHENYLACETIC ACID, $\text{C}^8\text{H}^4\text{O}^3 = \text{CH}^2(\text{OC}^2\text{H}^5).\text{COOH}$. *Phenyl-oxyacetic* or *Phenyl-glycollic acid*.—This acid, which Heintz obtained as a sodium salt by heating sodium phenate with chloroacetic acid (p. 918), is converted by heating with alcohol into an ethyl salt, $\text{CH}^2(\text{OC}^2\text{H}^5).\text{CO}^2\text{C}^2\text{H}^5$, which boils at 251° , and yields the corresponding amide when treated with aqueous ammonia. The calcium salt yields by dry distillation a liquid of high boiling point. Cold strong nitric acid converts oxyphenylacetic acid into the *dinitro-derivative*, $\text{C}^8\text{H}^3(\text{NO}^2)^2\text{O}.\text{CH}^2.\text{COOH}$. The *mononitro-derivative*, obtained by the action of sodium monochloroacetate on sodium nitrophenol (prepared from volatile nitrophenol), melts at 153° , and volatilises easily with vapour of water (P. Fritzsche, *J. pr. Chem.* [2], xix. 33).

OXYPHENYLPHthalimide

or

OXYPHthalANIL,

$\text{C}^6\text{H}^4 \begin{array}{c} \text{OH} \\ \diagup \quad \diagdown \\ \text{N} = (\text{CO}) = \text{C}^6\text{H}^4 \end{array}$ is formed by heating 1 mol. orthamidophenol and 1 mol. phthalic anhydride for some time to about 220° , and may be purified by exhausting the solidified and pulverised mass with boiling alcohol, and recrystallising the crystals which separate on cooling, several times from boiling alcohol, with addition of animal charcoal. It is thus obtained in prisms having a faint yellow colour, melting at 220° , easily soluble in alcohol and in toluene, especially when heated; it dissolves also on heating with alkalis and alkaline carbonates, forming salts of oxyphthalanilic

acid, $C^6H^4(OH).NH.CO.C^6H^4.COOH$. The sodium salt of this acid, $C^{14}H^{10}NaO^4$, crystallises from water in fine needles. The acid itself, obtained by decomposing the salt with dilute hydrochloric acid, and recrystallising the resulting precipitate from alcohol, forms prisms melting at 223° . Corresponding derivatives of paramidophenol have not been obtained (Ladenburg, *Ber.* ix. 1524).

OXYPHENYLTHIOCARBIMIDE, $C^6H^4(OH).NCS$, is obtained by boiling an alcoholic solution of orthamidophenol with carbon disulphide in a stream of hydrogen, as long as hydrogen sulphide continues to be evolved :

The product freed from alcohol by slow evaporation deposits the thiocarbimide in yellowish-grey crystalline crusts, and on recrystallising these from alcohol and boiling water, it is obtained in broad nearly colourless needles melting at 196° . It does not volatilise with aqueous vapour, but carbonises when heated above its melting point. It dissolves readily in ammonia, and crystallises therefrom unaltered.

Silver nitrate added to the ammoniacal solution throws down white flocks which do not blacken on boiling. Oxophenylthiocarbimide is decomposed by boiling aniline with formation of hydrogen sulphide, and by hydrochloric acid at 170° into carbon dioxide, hydrogen sulphide, and amidophenol (J. Dunner, *Ber.* ix. 465).

OXYPTHALIC ACID. See PHTHALIC ACIDS.

OXYPTHALYL-PARAMIDOBENZOIC ACID,

$C^6H^4 \begin{smallmatrix} CO.NH.C^6H^4.COOH \\ COOH \end{smallmatrix}$, formed by oxidation of paratolylphthalimide,

$C^6H^4(CH^3)-C^6H^3 \begin{smallmatrix} CO \\ CO \end{smallmatrix} NH$, with permanganate, is nearly insoluble in water, melts with decomposition at $275^\circ-277^\circ$, and is converted by heating with hydrochloric into paramidobenzoic acid (A. Michael, *Ber.* x. 576).

OXYPROPANE-SULPHONIC ACID, $C^3H^6(OH)(SO^3H)$ (Max Müller, *Ber.* vi. 1441). This acid admits of five modifications, three derived from normal and three from pseudopropyl alcohol, viz. :

Only one of these is however known, and is obtained by the three following processes : (1). By passing the vapour of sulphuric anhydride into normal propyl alcohol till the liquid begins to fume in the air, and treating the product in the manner already described for the preparation of oxymethanesulphonic acid (p. 1471). The salts of the acid thus obtained do not crystallise from aqueous solution, and they are so little soluble in hot absolute alcohol that only very small quantities can be crystallised therefrom; the potassium salt may however be readily crystallised in small needles by heating it with alcohol under pressure at about 140° . (2). By boiling allyl alcohol (b. p. 92°) with a concentrated solution of acid potassium sulphite, mixing the solution with a large excess of sulphuric acid, precipitating with alcohol (20 vols.), and treating the residue left on evaporating the alcoholic filtrate in the manner above mentioned: $C^3H^6O + SO^2H^2 = C^3H^6(OH)(SO^3H)$. (3). Acrolein, $CH^2=CH-CHO$, treated with excess of acid sodium sulphite, is converted into the oxydisulphonic acid, $CH^2.CH(SO^3H).CH(OH)(SO^3H)$ or $CH^2(SO^3H).CH^2-CH(OH)(SO^3H)$, which when decomposed yields sulphur dioxide, water, and an acroleinsulphonic acid, either $CH^3.CH(SO^3H).CHO$ or $CH^2(SO^3H).CH^2.CHO$, and this when heated with sodium-amalgam takes up 2 at. hydrogen, and is converted into oxypropane-sulphonic acid, $CH^3.CH(SO^3H).CH^2OH$ or $CH^2(SO^3H).CH^2.CH^2OH$.

OXYPROPYLBENZOIC ACID, $C^{10}H^{12}O^3 = C^6H^4(C^3H^6OH).COOH$ (R. Meyer, *Ber.* xi. 1283). This acid is formed, together with a small quantity of terephthalic acid, by oxidising cumic acid, $C^9H^4(C^3H^7).CO^2H$, dissolved in caustic soda with potassium permanganate. It is soluble in hot water, and separates from a strong aqueous solution in dendritic crystals, from a dilute solution in long thin prisms. It is very soluble in alcohol and ether, melts at $155^\circ-156^\circ$, and sublimes with partial decomposition. Its ammonium salt is soluble, and its neutral solution gives no reaction with ferric chloride. The copper salt is obtained first as a bright blue amorphous precipitate, which on standing becomes crystalline. The lead salt is obtained as a white amorphous precipitate, which melts in boiling water. The silver salt, $C^{10}H^{11}AgO^3$, is a white crystalline body, not easily acted on by light; and may be crystallised from hot water in beautiful, shining transparent, rhombic plates.

By oxidation with chromic acid mixture, oxypropylbenzoic acid is converted into terephthalic acid:

OXYPURPURIN. See PURPURIN.

OXYPYROTARTARIC ACID. See PYROTARTARIC ACID.

OXYSALICYLIC ACID, $\text{C}^6\text{H}^3(\text{OH})^2(\text{CO}^2\text{H})^2$ [$\text{CO}^2\text{H} : \text{OH} : \text{OH} = 1 : 2 : 5$]. See p. 289. The so-called *gentisic acid*, obtained by Hlasiwetz a. Habermann from gentisin, the colouring matter of gentian root, by the action of melting potash, and at first supposed by them to be a dioxybenzoic acid different from the four previously known (p. 860), has been shown by subsequent experiments to be identical with oxy-salicylic acid. *Pyrogentisic acid*, $\text{C}^6\text{H}^3\text{O}^2$, obtained by heating gentisic acid, and originally supposed to be a fourth modification of dihydroxybenzene, is now found to be identical with hydroquinone (Hlasiwetz a. Habermann, *Liebigs Annalen*, clxxx. 343).

OXYSUCCINYL-PARAMIDOBENZOIC ACID, $\text{C}^{11}\text{H}^{11}\text{NO}^5 = \text{C}^9\text{H}^4(\text{CO}^2\text{H})\text{NH}(\text{CO}^2\text{H})\text{CO}^2\text{H}$, is formed by the action of potassium permanganate on paratolylsuccinimide, $\text{C}^9\text{H}^4(\text{CH}^3)\text{N}(\text{CO}^2\text{H})\text{CO}$, and crystallises in yellowish needles, melting at $225^\circ\text{--}226^\circ$, sparingly soluble in cold, freely in hot water, moderately soluble in cold, very easily in hot alcohol. When boiled with hydrochloric acid, it yields paramidobenzoic acid. The *ammonium salt* is moderately soluble; the *barium salt* is less soluble, and crystallises from hot water in laminae. The *lead salt* is a white, the *copper salt* a blue precipitate, both soluble in hot water. The *silver salt*, $\text{C}^{10}\text{H}^3\text{Ag}^2\text{NO}^5$, is a white flocculent precipitate. *Orthotolylsuccinimide* does not yield an acid by oxidation (A. Michael, *Ber.* x. 576).

OXYSULPHOBENZIDE, $\text{C}^{12}\text{H}^{10}\text{SO}^4 = (\text{C}^6\text{H}^4\text{OH})^2\text{SO}^2$. This compound, produced by the action of strong sulphuric acid on crystallised phenol, was discovered in 1867 by Glutz (vi. 894), and its methyl-, ethyl-, and amyl-derivatives, also its tetrachloro-derivative, were obtained in 1870 by Annaheim (vii. 886), who has since discovered and examined a large number of other derivatives (*Ber.* vi. 1206; viii. 1059; ix. 79; xi. 1668; *Liebigs Annalen*, clxxii. 28).

Preparation.—The best yield of oxysulphobenzide is obtained by heating two parts of pure phenol and one part of fuming sulphuric acid for 3–5 hours to $189^\circ\text{--}190^\circ$.

The product is purified by pouring the warm mass slowly into cold water and triturating it to convert it into a crystalline mass. The oxysulphobenzide thus obtained amounts to 63·5 per cent. of the weight of the phenol, and the mother-liquor contains only paraphenolsulphonic acid. If more sulphuric acid be used than is indicated by the above equation, much less oxysulphobenzide, or none at all, is obtained, because sulphuric acid readily acts on this compound at a high temperature. Thus when it is heated with an excess of common sulphuric acid for an hour or two to $180^\circ\text{--}190^\circ$, paraphenolsulphonic and disulphonic acids are produced, while by treating it at the same temperature with three times its weight of fuming sulphuric acid, a mixture of di- and trisulphonic acids is formed.

The crude oxysulphobenzide is purified by boiling it with water, which leaves a red oil; the crystals separating from the filtrate are again treated in the same way, and then recrystallised, first from a small quantity of boiling alcohol, then from water, whereby the compound is obtained in perfectly white glistening needles, melting at 293° .

Crystallisation.—To obtain measurable crystals, pure oxysulphobenzide is dissolved in a beaker nearly to saturation in glacial acetic acid at the boiling heat; the solution, without filtering, is immediately placed over a water-bath heated to 100° , a second beaker is inverted over it, and the whole is covered with a cloth and left for twenty-four hours. The crystals, 2 cm. long, thus obtained are orthorhombic, and exhibit the combination $\infty P \infty . \infty P2 . 0P$. P. Axes $a : b : c = 1.2829 : 1 : 0.53419$. Sp. gr. = 1.3663 at 15° , whence molecular volume = 182.9 (Annaheim).

Oxidation.—Oxysulphobenzide is completely oxidised by potassium permanganate, yielding the potassium salt, $(\text{C}^6\text{H}^4\text{OK})^2\text{SO}^2$, together with sulphate and oxalate. Potassium-oxysulphobenzide is soluble in alcohol, yielding an alkaline solution from which hydrochloric acid separates the oxysulphobenzide in a mass of shining crystals. If the quantity of permanganate used is insufficient to oxidise the whole of the oxysulphobenzide, part of the latter remains unattacked, and the rest is completely oxidised to sulphuric, oxalic, and carbonic acids, without formation of intermediate products (Guareschi, *Gazz. chim. ital.* 1878, 246).

Tetrachloroxysulphobenzide, $\text{SO}^2[\text{C}^6\text{H}^2\text{Cl}^4(\text{OH})]^2$, is produced, together with chloranil and other quinones, by adding to a mixture of 1 pt. of oxysulphobenzide and

2 pts. of potassium chlorate, 120–150 times its weight of hydrochloric acid. The product is washed with cold and warm water and cold alcohol, the residue dissolved in boiling alcohol, and an equal volume of boiling water added; on cooling, long white needles separate out, which are purified by recrystallisation. From strong alcohol the compound crystallises in large nacreous prisms melting at 288°–289°. It is insoluble in water, sparingly soluble in cold alcohol, freely in boiling alcohol, benzene, and ether. It combines with alkalis and decomposes carbonates.

Tetrabromoxysulphobenzide, $\text{SO}_2[\text{C}^6\text{H}^2\text{Br}^2(\text{OH})]^2$, may be obtained by the action of mercuric oxide and bromine on oxysulphobenzide in presence of water, but is best prepared by dissolving oxysulphobenzide in an excess of bromine and evaporating the solution on a water-bath. It crystallises from hot alcohol in short thick monoclinic prisms melting at 278°–279°, and dissolves readily in boiling amyl alcohol, in caustic alkalis and in alkaline carbonates, forming salts which do not crystallise.

Tetradioxysulphobenzide, $\text{SO}_2[\text{C}^6\text{H}^2\text{I}^2(\text{OH})]^2$, is produced by dissolving 12·5 pts. of oxysulphobenzide and 51 of iodine in alcohol, and adding 30 of freshly prepared mercuric oxide. The product, after being washed with alcohol and ether, is boiled with water and potassium carbonate, and the solution is precipitated with hydrochloric acid. It is insoluble in water, cold alcohol, ether, benzene, carbon sulphide, and chloroform, almost insoluble in boiling alcohol and glacial acetic acid, separating from these solutions in microscopic needles melting at 260°–270°.

Methyloxysulphobenzide, $\text{SO}_2(\text{C}^6\text{H}^4\text{OCH}^3)^2$, is prepared by boiling an alcoholic solution of oxysulphobenzide, potash, and methyl iodide. It is insoluble in water and caustic alkalis, sparingly soluble in cold, and freely in boiling alcohol, crystallising on quick cooling, in thin square plates, and on slow evaporation in flat prisms, melting at 130°, and subliming when more strongly heated. On dissolving it in hot sulphuric acid, it yields a mono- and a di-sulphonic acid. The barium salt of the latter forms colourless, transparent, monoclinic crystals, resembling felspar, and consisting of $\text{C}^6\text{H}_3(\text{OCH}^3)(\text{SO}_3)^2\text{Ba} + 4\text{H}^2\text{O}$. The calcium salt contains also 4 mols. water, and crystallises in long, white glistening needles. Methyloxysulphobenzide is identical with Cahours' *sulphanisole*, obtained by the action of sulphuric acid on anisol.

Dibromomethyloxysulphobenzide, $\text{SO}_2(\text{C}^6\text{H}^3\text{BrOCH}^3)^2$, is obtained by adding the required quantity of bromine to the methyl-compound. It is insoluble in water and alkalis, sparingly soluble in cold, and readily in boiling alcohol, crystallising in beautifully white, small plates, which melt at 166°.

Dinitromethyloxysulphobenzide, $\text{SO}_2[\text{C}^6\text{H}^3(\text{NO}^2)\text{OCH}^3]^2$, is readily formed by dissolving the dry methyl-ether in fuming nitric acid. It is insoluble in water, cold alcohol, ether, and benzene, almost insoluble in boiling alcohol, and sparingly soluble in boiling glacial acetic acid, from which it crystallises in microscopic prisms melting at 214°–215°. By the action of phosphorus iodide and water, it is reduced to the corresponding diamido-compound.

Ethyloxysulphobenzide, $\text{SO}_2(\text{C}^6\text{H}^4\text{OC}^2\text{H}^5)^2$, dissolves readily only in ether and boiling alcohol, and crystallises in glistening small quadratic plates, melting at 159°.

Dibromomethyloxysulphobenzide, $\text{SO}_2[\text{C}^6\text{H}^3\text{BrOC}^2\text{H}^5]^2$, resembles the corresponding methyl-compound, and forms plates melting at 183°.

Dinitroethyloxysulphobenzide, $\text{SO}_2[\text{C}^6\text{H}^3(\text{NO}^2)\text{OC}^2\text{H}^5]^2$, crystallises from alcohol in large shining plates, or fine needles, melting at 192°. By reducing it with phosphorus iodide and water, *diamidoethyloxysulphobenzide hydriodide*, $\text{SO}_2[\text{C}^6\text{H}^3(\text{NH}^2)\text{OC}^2\text{H}^5]^2 + 2\text{HI}$, is formed, crystallising from water or alcohol in yellowish needles. From its solution alkalis precipitate the base as a crystalline powder.

Amyloxysulphobenzide, $\text{SO}_2(\text{C}^6\text{H}^4\text{OC}^3\text{H}^{11})^2$, requires a rather high temperature for its formation, and crystallises from boiling alcohol in small, brilliant, white plates, melting at 98°. Its *bromine-derivative*, $\text{SO}_2(\text{C}^6\text{H}^3\text{BrOC}^3\text{H}^{11})^2$, crystallises from hot alcohol in small white plates, melting at 100°. The *nitro-derivative*, $\text{SO}_2[\text{C}^6\text{H}^3(\text{NO}^2)\text{OC}^3\text{H}^{11}]^2$, is sparingly soluble in boiling alcohol, and forms brilliant, nacreous, six-sided plates or prisms, melting at 150°–151°. It differs from the other nitro-derivatives of oxysulphobenzide, in not being reduced by water and phosphorus iodide, or by tin and hydrochloric acid (Annahme, *Liebig's Annalen*, clxxii. 38–59).

Dinitroxysulphobenzide, $[\text{C}^6\text{H}^3(\text{NO}^2)\text{OH}]^2\text{SO}_2$, separates from a solution of oxysulphobenzide in warm nitric acid, in crystalline scales; it is insoluble in water, only slightly soluble in alcohol, ether, and benzene, and crystallises from alcohol in microscopic rhombic needles. With alkalis and alkaline earths it forms easily soluble compounds having a deep yellow-red colour. The *barium salt*, $[\text{C}^6\text{H}^3(\text{NO}^2)\text{O}]^2\text{Ba}.\text{SO}_2$, is prepared by dissolving dinitroxysulphobenzide in hot baryta-water, and separates from the solution—freed from excess of barium by carbonic

acid and evaporated—in crystalline crusts. The *sodium salt*, $[\text{C}^6\text{H}^3(\text{NO}^2)\text{ONa}]^2\text{SO}^2$, prepared in like manner, forms red-yellow crystalline crusts, and its aqueous solution gives precipitates, apparently of analogous composition, with silver, zinc, copper, and lead salts (Glutz, *loc. cit.*)

Dinitroxysulphobenzidamide, $[\text{C}^6\text{H}^3(\text{NO}^2)(\text{NH}.\text{C}^6\text{H}^3)]^2\text{SO}^2$, is formed by heating the dinitro-compound just described with 2 pts. of aniline:

It crystallises from aniline in brilliant red rhombic prisms, exhibiting the combination ∞ P. OP. On boiling it with water, alcohol, ether, or benzene, it is decomposed with reproduction of aniline (Annaheim, *Ber.* vii. 436).

Diamidoxysulphobenzide, $\text{C}^{12}\text{H}^{12}\text{N}^2\text{SO}^4 = [\text{C}^6\text{H}^3(\text{NH}^2)\text{OH}]^2\text{SO}^2$. The *hydriodide* of this base, $\text{C}^{12}\text{H}^{12}\text{N}^2\text{SO}^4.2\text{HI} + 2\text{H}^2\text{O}$, is formed by the action of phosphorus iodide on dinitroxysulphobenzide in presence of a small quantity of hot water, and separates from the solution, after removal of the phosphorus, in long colourless needles which give off their water at 110° – 115° , and dissolve readily in water and in alcohol (Glutz, *Liebig's Annalen*, cxlvii. 52; Annaheim, *Ber.* vii. 436).*

The corresponding *hydrochloride*, $[\text{C}^6\text{H}^3(\text{NH}^2)\text{OH}]^2\text{SO}^2.2\text{HCl} + 2\text{H}^2\text{O}$, obtained by reduction of the dinitro-compound with tin and hydrochloric acid, is a very similar body. The *sulphate*, $[\text{C}^6\text{H}^3(\text{NH}^2)\text{OH}]^2\text{SO}^2.\text{H}^2\text{SO}^4 + 2\text{H}^2\text{O}$, obtained by heating the hydrochloride with sulphuric acid, is slightly soluble in water and in alcohol, and crystallises from hot water in short thick prisms; it is very stable, and may be heated to 140° without decomposition. Ammonia added to the solution of this salt throws down the free base, which separates from water in large crystals.

On treating the sulphate or hydrochloride in acid aqueous solution with potassium nitrite, the liquid turns red and deposits a substance having a splendid vermilion colour, dissolving in ammonia with deep red colour, reprecipitated by acids, detonating when heated (Annaheim).

Tetranitro-oxyulphobenzide, $[\text{C}^6\text{H}^2(\text{NO}^2)_2\text{OH}]^2\text{SO}^2$, obtained by the action of red fuming nitric acid on the dry dinitro-derivative, and purified by crystallisation from hot water, is a solid straw-yellow, very bitter substance, melting at 253° , and exploding at a higher temperature. It is insoluble in most of the usual solvents, but crystallises in long needles from boiling water, the mother-liquor when mixed with hydrochloric acid yielding an additional crop. It has well-marked acid properties, and readily decomposes alkaline carbonates. It is extremely soluble in glacial acetic acid at the boiling heat, and separates almost completely on cooling in needles, in which, however, part of the remaining hydrogen is replaced by acetyl. Its *potassium salt*, $[\text{C}^6\text{H}^2(\text{NO}^2)_2\text{OK}]^2\text{SO}^2$, is sparingly soluble in cold, moderately soluble in hot water, and separates therefrom on cooling in reddish-yellow microscopic crystals, which detonate when heated. The corresponding *sodium salt* dissolves easily in water either hot or cold, and separates after a long time in minute yellow crystals. Another sodium salt, whose composition was not determined, was once obtained in hydrated efflorescent octohedral crystals 1 cm. long (Annaheim, *Ber.* xi. 1668).

Dibromodinitro-oxyulphobenzide, $[\text{C}^6\text{H}^2\text{Br}(\text{NO}^2)\text{OH}]^2\text{SO}^2$, is prepared by mixing 34 grams of dinitroxysulphobenzide (to which a little bisulphide of carbon has been added) with 32 grams of bromine, evaporating to dryness on the water-bath, washing with water, dissolving in sodium carbonate, and crystallising out the sodium salt.

Sodium dibromodinitroxysulphobenzide crystallises in small, yellowish-red needles, soluble in hot water, but with some difficulty in cold water. The free acid is separated from the solution on addition of hydrochloric acid. Dibromodinitroxysulphobenzide is insoluble in water, sparingly soluble in alcohol, but easily soluble in boiling acetic acid, from which it separates again in white needles of a faint straw colour. It melts at 284° – 285° .

Diiododinitroxysulphobenzide, $[\text{C}^6\text{H}^2\text{I}(\text{NO}^2)\text{OH}]^2\text{SO}^2$, is prepared by bringing together 50 grams of iodine dissolved in alcohol, and a mixture of 34 grams of dinitroxysulphobenzide with 21.6 grams of yellow mercuric oxide, and heating on the water-bath. After filtration and washing with water, the product is boiled with sodium carbonate and extracted two or three times with boiling water. The difficultly soluble sodium salt separates from the hot solution in fine orange-red needles.

Diiododinitroxysulphobenzide is insoluble in water and alcohol, but dissolves in boiling acetic acid. It melts at 294° – 295° . Like the previous compounds, it possesses acid properties and decomposes alkaline carbonates (Annaheim, *Ber.* ix. 660).

Tetraoxysulphobenzide, $[\text{C}^6\text{H}^2.\text{N}=\text{N}.\text{OH}]^2\text{SO}^2$, is prepared by dissolving

* Glutz assigned to this compound the formula $\text{C}^{12}\text{H}^8\text{N}^2\text{SO}^4.2\text{HI} = \text{C}^6\text{H}^4(\text{NH}^2)^2\text{SO}^4.2\text{HI}$; but the formula above given is more in accordance with its mode of formation, and is moreover supported by Annaheim's analysis.

15 pts. of the hydrochloride of diamidoxysulphobenzide in 70 pts. of alcohol, and adding 15 pts. of amyl nitrite. It forms six-sided microscopic laminae, which, when exposed to air and sunlight, are converted into a red colouring matter. It is insoluble in alcohol, but dissolves in water acidulated with hydrochloric acid; detonates violently at 120° (Annaheim, *Ber.* viii. 1059).

Constitution of Oxysulphobenzide.—Annaheim represents this substance by the formula

regarding it as formed of two benzene-nuclei directly united by the group SO^2 , and having the two hydroxyls in the para-positions with regard to that group. This view is supported: 1. By the reaction of oxysulphobenzide with sulphuric acid, whereby it is resolved into two paraphenol-monosulphonic acids, $\text{C}^6\text{H}_4\text{OH.H.SO}^3\text{H.H}^2$. 2. By the fact that the two hydroxylic hydrogen-atoms may be simultaneously replaced by alcohol radicles, and that the resulting compounds, *e.g.* sulphanisöilide, may in like manner be resolved into two molecules of one and the same compound,

3. By the fact that, as Annaheim has shown by heating oxysulphide with ethylene bromide, the two hydroxylic hydrogens cannot be replaced by the diatomic radicle ethylene, as might be expected if the two hydroxyls occupied contiguous positions (*Liebig's Annalen*, clxxii. 59).

OXYTOLUIC ACIDS. See TOLUIC ACIDS.

OXYTOLUIDINE. Syn. with AMIDOCRESOL. See TOLUIDINES.

OXYTRIMESIC ACID, $\text{C}^6\text{H}^2(\text{OH})(\text{COOH})^3$. This is the modification of phenol-tricarboxylic acid in which the three carboxyls are symmetrically disposed. See PHENOL-TRICARBOXYLIC ACID.

OXYUVITIC ACID, $\text{C}^6\text{H}^3\text{O}^5 = \text{C}^6\text{H}^2(\text{CH}^3)(\text{OH})(\text{CO}^2\text{H})^2$. This acid is formed on adding chloroform to the crude product of the action of sodium on ethyl acetate, and boiling the resulting mixture of ethers till a sample of it no longer yields an oily product with acids. On adding hydrochloric acid to the solution thus obtained, oxyuvitic acid separates in yellowish flocks; and on dissolving these in a large quantity of boiling water, and decolorising with animal charcoal, the acid is obtained in thin colourless needles. On the mode of its formation, see ACETO-ACETIC ETHERS (p. 17).

Oxyuvitic acid is but sparingly soluble in cold water, but dissolves more readily in hot water, still more in alcohol and ether. With ferric chloride it gives a red-violet, with ferrous salts a reddish coloration. It softens at 290°, and decomposes at the same time, so that its melting point cannot be determined.

The oxyuvitates of the alkali-metals are very soluble, crystallise indistinctly, and turn brown on exposure to the air. The *potassium salt* has the composition $\text{C}^6\text{H}^3\text{K}^2\text{O}^5 + \text{H}^2\text{O}$. The *barium salt*, $\text{C}^6\text{H}^3\text{BaO}^5 + 1\frac{1}{2}\text{H}^2\text{O}$, crystallises in microscopic needles, which easily turn yellowish: it is soluble in alcohol, gives off 1 mol. water at 125°, the rest at 150°. By distillation with lime, it yields a cresol boiling at 200°. The *calcium salt* has the composition $\text{C}^6\text{H}^3\text{CaO}^5 + 1\frac{1}{2}\text{H}^2\text{O}$. The *silver salt*, $\text{C}^6\text{H}^3\text{Ag}^2\text{O}^5$, separates, after long standing, as a curdy precipitate not quite insoluble in water; so likewise does the greenish *copper salt*, $\text{C}^6\text{H}^3\text{CuO}^5$. The solution of the barium salt gives with lead nitrate a white amorphous precipitate, with ferric chloride a brown-violet precipitate; none with mercuric chloride or zinc chloride (Oppenheim a. Pfaff, *Ber.* vii. 929).

The *methyl ether*, $\text{C}^6\text{H}^2(\text{OH})(\text{CH}^3)(\text{COOCH}^3)^2$, produced by heating the silver salt at 100° with methyl iodide and perfectly anhydrous ether, forms yellow trapeziform plates several mm. long, melts at 108°, and sublimes between 200° and 300°.

Reactions.—1. By oxidation of oxyuvitic acid Emmerling a. Oppenheim (*Ber.* ix. 726) have obtained, not, as was expected, oxytrimesic acid, but an acid, $\text{C}^6\text{H}^3\text{O}^5$, isomeric with Böttlinger's uvic acid, which they designate as *hydro-oxybenzoic acid* (see UVIC ACID). With chromic acid only a small product is obtained; with potassium permanganate a somewhat larger quantity, about 10 per cent. of the oxyuvitic acid employed.

2. *Fuming nitric acid*, either alone or mixed with sulphuric acid, converts oxyvitic acid into a trinitrocresol, $C^6H^3(NO^2)^3O$, which after purification forms fan-shaped groups of faintly-yellowish smooth needles melting at 106° (Emmerling a. Oppenheim, *Ber.* ix. 1094).

3. Oxyvitic acid treated with *phosphorus pentachloride* is converted into a mixture of chlorides, which when boiled with water yields, together with reproduced oxyvitic acid, an acid which separates from the sufficiently concentrated mother-liquor in long needles, and appears from the analysis of its barium salt to be an anhydride of oxyvitic acid, $[C^6H^2(OH)(CH^3)(COOH)CO]^2O$ (Oppenheim a. Pfaff, *Ber.* viii. 884).

Constitution.—Oppenheim a. Pfaff find that the cresol obtained by dry distillation of the calcium and barium salts of oxyvitic acid is *metacresol*, a result which confirms the relative position of the radicles OH and CH^3 in the acid, as represented by the formula given on p. 17.

Hence also it follows that the acid here designated as oxyvitic acid is not the true oxy- or hydroxy-acid of uvitic acid, which, according to Böttger, has the substituted radicles in the symmetrical position 1, 3, 5, or $C^6.CO^2H.H.CH^3.H$ (*see UVITIC ACID*).

OXYXYLENE, or **HYDROXYXYLENE**, $C^6H^3(CH^3)^2OH$. This is the constitution of phlorol (*q.v.*)

OXYXYLIC ACID, $C^6H^2(CH^3)^2(OH)(COOH)$. An acid formed by the action of melting potash on *pseudocumenol*, $C^6H^2(CH^3)^2OH$ (*q.v.*)

OZONE. On the formation of Ozone by the action of the silent electric discharge on oxygen, see *ELECTRICITY* (p. 727), also Giannetti a. Volta (*Ber.* ix. 84). A powerful apparatus for this purpose is described by Leeds (*Chem. News*, xl. 196). According to J. Boehe (*Ber.* vi. 439), the electrification of dry oxygen is the only method that yields pure ozone, all other methods giving rise at the same time to the formation of nitrous vapours or of hydrogen dioxide.

According to Böttger (*N. Rep. Pharm.* xxiii. 372), ozone is produced in the formation as well as in the electrolysis of water. When acidulated water is decomposed by an electric current, the ozone formed at the positive pole destroyed by addition of a small quantity of potash, and the mixed gases then exploded by contact with a flame, iodised starch-paper introduced into the cylinder which contained them is turned blue.

Experiments on the formation of ozone by combustion in the air have been made by W. Radulocoitsch (*Ber.* vii. 1454). When wax, stearin, petroleum or magnesium was burnt within a bottomless flask, and the products of combustion were made to pass through a glass tube containing strips of iodised starch paper, the formation of ozone was shown by the bluing of the paper; when however the same substances were burnt in ordinary lamps, the formation of ozone could not be detected. When a small quantity of petroleum (boiling at 30° to 100° and upwards, and of sp. gr. 0.67 to 0.68 at 22°) is placed in a capacious flask which is frequently opened and shaken, it acquires oxidising properties, and the air contained in the flask gives the ozone reaction. This occurs in a few days at the summer temperature if the vessel is exposed to the direct rays of the sun, and more slowly at a lower temperature and in diffused daylight. The slow evaporation appears to play an important part. When petroleum thus treated is shaken up with a solution of potassium iodide, iodine is liberated, and paper prepared with potassium iodide and starch-paste acquires a blue colour when exposed to the air in the flask. The altered petroleum also decolorises indigo, gives a blue colour to guaiacum extract, and exhibits the other reactions of active oxygen. When the petroleum is shaken up with water, the latter remains neutral, and when tested shows the presence of hydrogen peroxide; but, if the petroleum has remained for a long time in contact with the air, it acquires an acid reaction which it communicates to water when agitated therewith. The aqueous solution is found still to contain hydrogen peroxide, but it also reduces silver nitrate, thus indicating the presence of formic acid. Petroleum readily absorbs ozone—liberated from potassium permanganate by the action of sulphuric acid—and when agitated with water gives to it an acid reaction, whilst the solution reduces silver salts; but the petroleum is not at once capable of liberating

iodine from potassium iodide solution. If however allowed to stand for twenty-four hours, it acquires that property, and if it be then agitated with water, the solution gives the characteristic reactions of hydrogen peroxide.

Similarly, pure benzene, and the portion of light coal-oil boiling between 80° and 100°, exhibit the same power of rendering oxygen active. Pure phenol mixed with water also acquires, in contact with air, the power of turning paper blue which has been prepared with potassium iodide and starch-paste (Fadakowski, *Ber.* vi. 106). Similar observations have been made by E. Schaer (*ibid.* 406).

An apparatus constructed by O. Loew for the preparation of ozone for industrial purposes, depending on the ozonisation of oxygen by the combustion of coal-gas or other hydrogenised bodies in a rapid stream of air, is described by Ad. Ott (*Dingl. pol. J.* cxxiii. 180). The use of such an apparatus is suggested for the defuselation of brandy, or the manufacture of vinegar.

On the supposed formation of Ozone by the oxidation of Turpentine-oil and other essential oils, see Kingzett (p. 1430).

On the ozonisation of Air by moist Phosphorus, see A. R. Leeds (*Chem. News*, xl. 70; *Chem. Soc. J.* xxxvi. 881).

Bellucci (*Ber.* viii. 905; ix. 581) observed in the neighbourhood of the water-falls of Terni and Trollhättan a strong smell of ozone, which he attributes to the friction of the particles of water in the spray, and the consequent development of electricity. He finds that the spray of water containing solid substances in solution generates more ozone than that of pure water, and that the effect is still further increased if the water holds solid particles in suspension.

From experiments by Bellucci (*Ber.* vi. 756; *Compt. rend.* lxxviii. 362) it appears that the oxygen exhaled from plants in sunlight does not exhibit the properties of ozone.

Amount of Ozone in Air.—The following average results for the several months of the year 1873, obtained with Lender's ozonometer, are recorded by A. v. Löseke (*Arch. Pharm.* [3], v. 427):

	Ozone-degree	Temperature	Amount of rain
January . . .	9.35	— 0.40°	
February . . .	9.90	— 2.00	
March . . .	9.30	+ 2.30	
April . . .	8.76	+ 4.30	
May . . .	8.45	+ 6.50	
June . . .	8.66	+ 11.90	7.06 cm.
July . . .	8.30	+ 14.00	5.98
August . . .	8.32	+ 12.70	4.57
September . . .	7.86	+ 8.50	6.95
October . . .	8.55	+ 6.47	5.56
November . . .	2.26	+ 1.45	5.69
December . . .	5.60	— 1.70	1.43

The mean for the winter half-year was 8.4, for the summer half-year 7.5, and for the day-time 7.94. The proportion of ozone in a yard surrounded by moderately high buildings was about 2° lower; in dwelling-rooms and other apartments, whether the windows were closed or opened for a longer or shorter time, and whether growing plants were placed in the room or not, no ozone could be detected; neither was any connection observed between the amount of ozone and the direction of the wind (compare Houzeau, vii. 113, 114).

According to L. Fautrat (*Compt. rend.* lxxxiii. 752), the proportion of ozone in the air of forests is smaller than in the open country.

Experiments on the gradual conversion of ozone into ordinary oxygen have been made by Berthelot (*Compt. rend.* lxxxvi. 76) by means of flasks of about 260 c.c. capacity filled with oxygen ozonised by the discharge and kept at a temperature of about 12°. At the commencement of the experiment, the gas contained 2.2 per cent. of ozone; in twenty-four hours the amount was reduced to 2.1 per cent.; in five days to 1.5 per cent.; in fourteen days to 0.4 per cent.; after fifty-one days only a trace remained, and in sixty days no ozone could be detected either by the smell or by potassium iodide. Ozone has no fixed tension of dissociation, and the rate of destruction is directly proportional to the amount contained in the mixture. The dissociation did not appear to be accelerated by the presence of water, at least in the first week.

Relations of Ozone to Water.—The solubility of ozone in water, first observed by Williamson in 1845 (*Liebig's Annalen*, liv. 130), is corroborated by the experiments of Carius (*ibid.* clxxiv. 1) and of Schöne (*Ber.* vi. 1208, 1224). Rammelsberg, how-

* Not recorded before June.

ever (*ibid.* vi. 603), observes that diluted ozone is not absorbed by water at ordinary temperatures, the absorption taking place only when the gaseous mixture contains a considerable proportion of ozone. Carius, on the other hand, finds that water in contact with its own bulk of a gas containing 2 per cent. of ozone, acquires its odour and characteristic properties. Even when the gas contains only 1 per cent. of ozone, the solution produces a powerful effect on potassium iodide and starch, but diminution of the proportion of ozone leads very rapidly to an extreme weakening of the solution. Ozone, mixed with oxygen gas, obeys in fact the law of gaseous absorption which makes the quantity dissolved proportional to that fraction only of the total pressure which is due to the quantity of the gas itself contained in the mixture. Taking this law into account, Carius found, from a series of closely agreeing experiments, that the mean absorption-coefficient of water for ozone at 1° and 760 mm. pressure is 0.834. As, however, it is by no means certain that the limit of absorption was attained in these experiments, the actual absorption-coefficient may be even greater than that deduced from observation.

The following results have been obtained by Schöne (*Ber.* vi. 1208, 1224).

(1). Ozone does not oxidise water into peroxide of hydrogen. (2). Ozone is absorbed by water in considerable quantity even at the ordinary temperature. The observed maximum was 0.189 gram, or 8.81 c.c. (reduced) ozone (O³) per litre. (3). Ozone in contact with water suffers no qualitative alteration. (4). The quantity of ozone in ozonised oxygen is diminished by passing the gas through water. By collecting dry ozonised oxygen over water, about one-fourth of the ozone is removed, and the loss of ozone is greater after prolonged contact. (5). Since in the passage of ozonised oxygen through water, far more ozone disappears than is absorbed by the water during the time, and as the loss of ozone continues even when the water is saturated with it, it would seem that water has in this case the power of breaking up ozone. (6). Ozonised oxygen, left at rest in contact with water at the ordinary temperature for some days, becomes changed into ordinary oxygen. (7). The change of ozone into ordinary oxygen in the above manner is accompanied by an increase in volume. This result accords with that obtained by heat in the researches of Andrews a. Tait, and by Soret. Schöne likewise observes that ozone may remain for some time in contact with the skin without suffering decomposition.

From the numbers obtained by Carius, Schöne calculates for the absorption-coefficient of ozone at 16.5° the number 0.373, agreeing nearly with that deduced from his own experiments, viz. 0.366.

According to Carius (*loc. cit.*), the dissociation of ozone by water at 0° is very small. The aqueous solution, even when extremely dilute, exhibits the characteristic taste and smell of ozone, the smell even in a solution containing only 5 vol. ozone in 100 vol. water being so powerful that it can never be mistaken for that of a solution of nitrous acid, chlorine, chlorous acid, or hypochlorous acid. Delicate litmus-paper is quickly bleached by concentrated ozone-water, but in a more dilute solution the bleaching is preceded by a peculiar shade of colour resembling indistinct reddening by an acid. Concentrated ozone-water exhibits all the oxidising effects of gaseous ozone. A solution of thallous oxide produces, slowly in dilute, quickly in concentrated ozone-water, a brown precipitate of thallic oxide. The formation of silver peroxide, on the other hand, does not take place with certainty even in the most concentrated ozone-water, but only when silver leaf is introduced into the small space above the solution in a closed vessel where it can come in contact with the gases emitted from the liquid. Ozone-water prepared with ozonised air contains abundance of nitric acid, but no nitrous acid or hydrogen dioxide (Carius).

Decolorising Power.—Goppelsroeder (*Dingl. pol. J.* cexix. 540) publishes an observation made by Koeschlin, according to which pieces of calcio which had been dyed with indigo treated with sulphuric acid, then washed, and frozen by exposure in the moist state to a winter atmosphere, were found to be considerably altered in colour, especially on the edges. This effect is attributed by Goppelsroeder, on the ground of special experiments, to the action of atmospheric ozone. In the same manner aniline-brown on cotton was changed to a yellow-orange; fuchsine-rosa, Hofmann's blue and violet, red corallin, iodine-green, lakes from dye-woods, and even Turkey-red, were completely bleached. In the absence of water, however, this action of ozone did not take place.

Antiseptic Power.—Boillot (*Compt. rend.* lxxxi. 1258) recommends the use of ozone for the preservation of meat, milk, and other easily alterable articles of food.

Action on Blood.—According to Doziel (*N. Rep. Pharm.* xxiv. 431) the action of ozone on blood is exerted in the first instance on the red corpuscles, their colouring matter being separated, and the blood in a quarter of an hour acquiring a darker colour. Defibrinated blood, exposed in thin layers to the prolonged action of ozone,

acquires the colour of red sealing-wax, and the blood, after this alteration, no longer deposits crystals of hæmoglobin on addition of alcohol, ether, or chloroform. Defibrinated blood through which ozone was passed for a considerable time deposited flocks which, after washing with water, were indistinguishable from fibrin; by the still further prolonged action of ozone, the blood became dingy green and finally colourless. The formation of the fibrinoid substance is probably due to an alteration of hæmoglobin. Hæmatin is likewise decolorised by ozone. When blood poisoned with carbon monoxide is exposed to the action of ozone, it quickly acquires the properties of normal blood, carbon dioxide being separated at the same time. Blood containing carbon monoxide is less quickly decolorised by ozone than normal blood, and does not so quickly lose the property of depositing crystals of hæmoglobin. The alteration of the blood-corpuscles by ozone must not be confounded with that produced by carbon dioxide.

Estimation.—To estimate ozone in presence of chlorine and nitrogen tetroxide, D. Tommasi (*Chem. News*, xxix. 234) passes the gaseous mixture in the first instance immediately through a normal solution of potassium ferrocyanide, and secondly through a tube filled with platinum black or manganese dioxide to destroy the ozone, and then through the normal solution of potassium ferrocyanide.

M. Davy (*Compt. rend.* lxxxii. 157) estimates the very small amount of ozone present in the air, which varies from 0.76 to 1.3 mg. in 100 c.c. of air, by passing the air through a solution of neutral potassium arsenite and a little potassium iodide, and determining the amount of arsenious acid thereby oxidised, by means of a standard iodine-solution.

P.

PALLADIUM. Small quantities of this metal are of almost constant occurrence in refined silver; that of Commern and Mechernich on the Eifel contains 0.0053 per cent. palladium (H. Rössler, *Liebig's Annalen*, clxxx. 240). Palladium is also found, together with other platinum metals, in the ferric chloride obtained in the preparation of fine gold (Opificius, *Dingl. pol. J.* cxxiv. 414; *Jahresh. f. Chem.* 1877, 1142).

Electromotive Force in Gas-batteries.—According to E. Villari (*Pogg. Ann.* cli. 608), the electromotive force of palladium in gas-batteries is considerably greater than that of platinum electrodes, evidently in consequence of the great affinity of palladium for hydrogen; moreover, it becomes considerably greater when the (positive) electrode in contact with the oxygen is oxidised.

On the use of Palladium in facilitating oxidation, see HYDROCARBONS (p. 1065).

Coquillion (*Compt. rend.* lxxxiii. 394) recommends the use of palladium instead of platinum wire for igniting mixtures of hydrocarbons and air in gas-analysis, inasmuch as it brings about the combination of the gases without detonation.

On the Absorption of Hydrogen by Palladium and the properties of Palladium-hydrogen, see HYDROGEN (pp. 1070, 1071).

When palladium in the form of sponge or foil is heated in a flame of alcohol or coal-gas, it becomes coated with a thick spongy layer of soot, and on burning this away, the palladium remains in the form of a brittle skeleton.

Spongy palladium, which at 100° is capable of taking up several hundred times its own volume of hydrogen gas, does not act on ethylene at any temperature below a red heat; but on raising the heat to redness, carbon is deposited and hydrogen set free, the temperature at which this decomposition takes place being below that at which ethylene is decomposed by heat without the agency of palladium. The effect appears to be due to the absorption of hydrogen and its subsequent separation, these phenomena continually succeeding one another in the same manner as when copper is ignited in ammonia-gas (Wöhler, *Liebig's Annalen*, clxxxiv. 128).

Palladium may be *amalgamated* in the same way as iron (p. 1096), viz. by bringing it in contact with sodium- or ammonium-amalgam, and then dipping it into acidulated water.

The *black oxide of palladium*, PdO, obtained by ignition of the nitrate, is instantly reduced by hydrogen, even at ordinary temperatures, the reaction being attended with vivid incandescence. In like manner, as observed by Berzelius, palladium which has acquired a blue tarnish by oxidation immediately loses its blue colour when plunged into hydrogen gas at the ordinary temperature (Wöhler, *Liebig's Annalen*, clxxxiv. 60).

On *Palladium Mercaptide*, see MERCAPTIDES (p. 1276).

A soluble *palladium thiocyanate* is obtained, according to S. Kern (*Chem. News*, xxxii. 242), by mixing the aqueous solution of palladium chloride or nitrate and potassium thiocyanate. The solution of this salt is said to give no reaction with an alcoholic solution of iodine.

Palladammonium compounds.—Yellow palladammonium chloride, $\text{PdCl}_2 \cdot 2\text{NH}_3$ or $\text{Pd}(\text{NH}_3\text{Cl})_2$, treated with aqua regia, is converted into the compound

$\text{ClPd}(\text{NH}_3\text{Cl})_2$
 $\text{Pd}^*\text{Cl}^*.4\text{NH}_3$ or $\text{ClPd}(\text{NH}_3\text{Cl})_2$, which is a dark red, almost black substance, closely

resembling in appearance and solubility the double chloride of iridium and ammonium. Its formation may be represented by the equation $2(\text{PdCl}_2 \cdot 2\text{NH}_3) + \text{Cl}^2 = \text{Pd}^*\text{Cl}^*.4\text{NH}_3$. The same salt was obtained as a precipitate on treating some mother-liquors of dipalladammonium chloride, $\text{PdCl}_2 \cdot 4\text{NH}_3$, with aqua regia in presence of sal-ammoniac. It is interesting as showing that all the metals of the platinum group, except platinum itself, are capable of forming chlorides of the formula M^*Cl^* . It is easily decomposed by heat, breaking up into hydrochloric acid, sal-ammoniac, nitrogen, and metallic palladium. It is also decomposed by boiling water, with brisk evolution of nitrogen, the palladium trichloride being reduced to dichloride, a portion of which remains in combination with the undecomposed ammonia (Deville & Debray, *Compt. rend.* lxxxvii. 926).

PALMITONE, $\text{CO}(\text{C}^{15}\text{H}^{31})_2$. See KETONES (p. 1149).

PANCREATIC FERMENTS (p. 779). E. Scheffer (*Pharm. J. Trans.* [3], vi. 844) prepares pancreatin as follows: The freshly chopped pancreas of an ox is macerated for twenty-four hours with water slightly acidulated with hydrochloric acid; the acid liquid is poured off and replaced by pure water, which again is poured off after four to six hours, and mixed with the acid extract; the filtered liquid is neutralised with recently precipitated calcium carbonate, then filtered again; and this second filtrate is mixed with an equal volume of alcohol, whereby the pancreatin is thrown down in white flocks, which dissolve almost completely in water, convert starch into sugar, and decompose neutral fats, with separation of the free acids. Pancreatin is decomposed by *pepsin* dissolved in acidulated water.

v. Mering & Musculus (*Zeitschr. physiol. Chem.* i. 395), by treating starch and glycogen with pancreatic and salivary ferment, have obtained dextrin and maltose; also dextrose with pancreatic ferment.

On the action of the Organised Ferments of the Pancreas on *Carbohydrates* and *Nitrogenous Bodies*, see FERMENTS (p. 782).

By the pancreatic digestion of gelatin, Nencki (*Ber.* vii. 1593) obtained a very small quantity of indole and small quantities of tyrosine, ammonia, leucine, glycocine, and a viscid yellow body, which he calls *gelatin-peptone*.

PANDERMITE. A mineral found at Panderma, on the Black Sea, in a grey streaky gypsum bed, lying under a formation composed of alternating layers of brown clay and calcareous slate. It occurs in snow-white, fine-grained nodules and fragments enclosed in the gypsum. An analysis of the dried mineral showed it to have the following composition:

CaO	MgO	FeO	K ₂ O	H ₂ O	B ₂ O ₃
29.33	0.15	0.30	0.18	15.45	54.59 = 100.00

which may be represented by the formula $2\text{CaO} \cdot 3\text{B}_2\text{O}_3 + 3\text{H}_2\text{O}$, indicating that pandermite is nearly related to borocalcite. No chlorine, sulphuric acid, silica, or carbonic acid, could be detected in it (G. vom Rath, *Jahrb. f. Min.* 1878, 74).

PARABANIC ACID, $C^3H^2N^2O^3 = CO \begin{matrix} \swarrow NH-CO \\ \searrow NH-CO \end{matrix}$. Oxalyl-carbamide, or

Oxalyl-urea.—This compound is produced: 1. By the action of phosphorus oxychloride on oxaluric acid:

Well-dried oxaluric acid is heated to 200° in an oil-bath with three times its weight of phosphorus oxychloride as long as hydrogen chloride is given off; the residual white mass is dissolved in water; the solution filtered and evaporated to dryness; the residue pressed and dissolved in boiling alcohol; the alcoholic solution filtered and evaporated to dryness; and the oxalyl-carbamide thus obtained is purified by twice recrystallising it from boiling water (Grimaux, *Compt. rend.* lxxvii. 1548).

2. By the action of phosphorus trichloride on a mixture of oxalic acid and urea (Ponomareff, *Bull. Soc. Chim.* [2], xviii. 97):

3. By oxidising pyruvil, $C^3H^2N^2O^3$ —the diureide of pyruvic acid—with nitric acid, the pyruvil being first converted into mononitropyruvil-monoureide, $C^4H^2(NO^2)N^2O^2$, which, when distilled with 2 or 3 pts. bromine and 25 to 30 water, is resolved into bromopicrin and parabanic acid:

(Grimaux, *Compt. rend.* lxxix. 1478).

Parabanic acid separates from aqueous or alcoholic solution in shining laminae having a sour taste; it may be heated to 200° without alteration, but at higher temperatures it yields a white sublimate, gives off pungent vapours smelling of cyanic acid, and leaves a carbonaceous mass. Its solution is not clouded by calcium acetate, but when boiled with potash it gives off ammonia, and if then supersaturated with acetic acid, it gives a copious precipitate with calcium salts.

A hydrate of parabanic acid, $C^3H^2N^2O^3.H^2O$, is obtained by subjecting 1 pt. uric acid to the action of 3 pts. nitric acid of sp. gr. 1.3 at about 60°, and keeping the temperature towards the end of the process between 35° and 55° according to the energy of the reaction. On subsequently heating the solution to 70°, the hydrate separates in large crystals (Tollens a. Wagner, *Liebig's Annalen*, clxvi. 321; Tollens, *ibid.* clxxv. 227). The same hydrate was obtained by Ponomareff (*Bull. Soc. Chim.* [2], xviii. 97) by the action of phosphorus trichloride on a mixture of urea and oxalic acid. The action begins at ordinary temperatures and is accompanied by rise of temperature and evolution of hydrochloric acid, and on cooling, the hydrate is obtained as a crystalline mass which dissolves easily in water and crystallises in thin colourless prisms.

This hydrate is very stable, sustaining only a very slight decrease of weight when heated to 100°; between 150° and 160°, however, the water is slowly driven off. The reddish aqueous solution of the residual dry mass no longer yields large crystals of the hydrate, but the well-known broad needles of the anhydrous compound. The hydrate dissolves in water more readily than the anhydrous compound, and is thereby distinguished from oxaluric acid, with which it is isomeric (Tollens a. Wagner).

Salts. The *diargentic salt* of parabanic acid, obtained by precipitation, was described by Liebig a. Wöhler (iv. 339). The *mono-argentic salt* and the *alkali-salts* have been obtained by Menshutkin (*Liebig's Annalen*, clxxii. 73). On account of the ready convertibility of parabanic into oxaluric acid, the preparation of these salts succeeds only under peculiar conditions. The *ammonium salt* is obtained as a white bulky crystalline precipitate on adding alcoholic ammonia to a solution of parabanic acid in absolute alcohol. Gaseous ammonia is but slowly absorbed by parabanic acid. The salt is very easily decomposable, and in aqueous solution is converted, even at ordinary temperatures, and more quickly during evaporation by heat, into ammonium oxalurate. When heated for six or eight hours to 100° in a sealed tube with alcoholic ammonia (absolute alcohol saturated at ordinary temperature with ammonia gas), it is converted into oxaluramide. The same result is obtained by merely

heating parabanic acid with alcoholic ammonia, just as aniline parabanate is converted into phenyl-oxaluramide (iv. 339). The *potassium salt* is obtained as a light white precipitate on adding rather less than the theoretical quantity of *potassium ethylate* (solution of potassium in absolute alcohol) to a solution of parabanic acid in absolute alcohol. The presence of water (or potassium hydrate) gives rise to the formation of oxalurate; excess of potassium ethylate produces oxalate. Potassium parabanate is insoluble in alcohol; water converts it into oxalurate. The *sodium salt* is prepared like the potassium salt, and exhibits similar properties. The *diargentic salt* is obtained as a crystalline precipitate having the composition $C^8N^2Ag^2O^3 + H^2O$, on adding silver nitrate to a solution of parabanic acid or of ammonium parabanate. [Liebig a. Wöhler obtained it anhydrous by precipitating the aqueous acid with silver nitrate; Strecker obtained it as a hemihydrate, $2C^8N^2Ag^2O^3 + H^2O$, on mixing the aqueous acid with silver nitrate and a little ammonia (iv. 339).] The *mono-argentic salt*, $C^8N^2HAgO^3$, is obtained as a crystalline precipitate on adding silver nitrate (1 mol.) to a recently prepared solution of potassium parabanate, treating the resulting precipitate, after washing, with a quantity of nitric acid not sufficient to dissolve the whole of it, and mixing the warm solution with ammonia; also by mixing the aqueous solutions of 2 mols. parabanic acid with 3 mols. silver nitrate, removing the diargentic salt formed at the same time by filtration, precipitating the warm mother-liquor with ammonia, and purifying the precipitate as above. The salt thus produced is sometimes anhydrous, sometimes contains 1 mol. H^2O ; in the latter case it is isomorphous with silver oxalurate, from which, however, it differs by being less soluble in water, and by being converted into the diargentic salt when its solution in nitric acid is mixed with silver nitrate and ammonia (Menschutkin).

Methyl-parabanic Acid, $C^8N^2H(CH^3)O^3$, is best prepared by heating methyl-uric acid with 5 or 6 pts. of nitric acid, sp. gr. 1.30, till the liquid is no longer coloured by ammonia. The excess of acid is driven off by heat, and the residue diluted with a little water is exhausted with ether, which on evaporation leaves the methyl-parabanic acid as a residue which soon crystallises in translucent prisms, to be purified by pressure and recrystallisation. The same compound is formed by the prolonged action of boiling nitric acid on methyl-alloxan (H. Hill, *Ber.* ix. 370).

Dimethyl-parabanic Acid, $C^8N^2(CH^3)^2O^3 = CO \begin{matrix} \diagup N(CH^3)-CO \\ \diagdown N(CH^3)-CO \end{matrix}$ (also called *cholesthrophane*, i. 926; iv. 340), is produced by heating the dry silver salt to 100° with methyl iodide, also by the action of chlorine or nitric acid upon caffeine. It crystallises from hot alcohol in prisms melting at 155.5° ; it also sublimates and distills at $275^\circ-277^\circ$, apparently without decomposition. Alcoholic ammonia converts it into dimethyl-oxaluramide, which melts with decomposition at 225° , and dissolves but sparingly in alcohol even at the boiling heat:

Dimethyl-parabanic acid is not attacked by acids, but is completely decomposed by alkalis (Menschutkin, *Liebig's Annalen*, clxxviii. 201).

Constitution of Parabanic acid.—The conversion of parabanic acid into oxaluric acid by assumption of water, and its synthesis from oxalic acid and urea (p. 1483), prove beyond doubt that it is an anhydride intermediate in composition between the two last-named substances, or, in other words, an anhydride of oxaluric acid,

$CO \begin{matrix} \diagup NH^2-CO.OH \\ \diagdown NH-CO \end{matrix}$. These considerations however do not suffice for the complete establishment of its constitution; for oxaluric may lose a molecule of water in several different ways, leading to as many different constitutional formulæ, of which two at least may be regarded as equally well entitled to represent the constitution of parabanic acid, viz.

The first of these, which is the usually accepted formula of the acid, differs from all the rest in having its two hydrogen-atoms symmetrically attached to the two nitrogen-atoms, and its correctness may be tested by an examination of the products of decomposition of dimethyl-parabanic acid under the influence of acids. For, if each of the

two methyl-groups in this compound is attached to a nitrogen-atom as above represented, it must be resolved by assumption of the elements of water into oxalic acid, carbon dioxide, and methylamine,

whereas the unsymmetrical formula, $\text{CO} \begin{array}{c} \diagup \text{N}(\text{CH}_3)^2 \\ \diagdown \text{N}(\text{C}^2\text{O}^2) \end{array}$, would require the formation of a mixture of ammonia and dimethylamine, and all the other possible formulæ would imply the formation either of pure ammonia or of a mixture of ammonia and methylamine. Now it has been shown by A. Calm (*Ber.* xii. 624) that dimethyl-parabanic acid heated to 200° with hydrochloric acid is actually resolved into CO^2 , oxalic acid and pure methylamine: hence the first of the two formulæ above given for parabanic acid may be regarded as established.

PARABUXINE. See BUXINE (p. 365).

PARACAMPHORIC ACID. See MESOCAMPHORIC ACID (p. 1286).

PARACONIC ACID, $\text{C}^3\text{H}^3\text{O}^4$. This acid, isomeric with citraconic, itaconic, and mesaconic acids, is formed by abstraction of HCl from itamonochloropyrotartaric acid (vi. 760), and may be regarded as an anhydride of itamalic acid, $\text{C}^3\text{H}^3\text{O}^5$:

(Swarts, *Bull. Acad. royal Belgique* [2], xxxiii. No. 1 [1872]; *Jahresb. f. Chem.* 1873, 585).

PARACOTOÏN. A constituent of Coto-bark (p. 573).

PARACRYLIC ACID. See DIACRYLIC ACID (p. 46).

PARACYANOCARBONIC ACID. See CYANOCARBONIC COMPOUNDS, POLYMERIC (p. 618).

PARA-DERIVATIVES, AROMATIC. *Paraldehydosalicyclic acid.* See BENZOIC ACIDS, ALDEHYDO-OXY- (p. 288).

Parabenzoyl-benzoic acid. See p. 310.

Parabenzoyl-benzyl Chloride, Parabenzoyl-benzylene Dichloride and Parabenzoyl-benzetyl Trichloride. See TOLYL-PHENYL KETONES (p. 1155).

Parabenzoyl-toluene, $\text{C}^6\text{H}_5\text{CH}^2\text{H.H.C}^7\text{H}^5\text{O.H}^2$, obtained by distilling a mixture of calcium paratoluate and benzoate, and fractionating the product, is a slightly coloured fragrant oil, boiling at 310° - 312° , and gradually crystallising when left at rest. By oxidation with chromic acid it is converted into parabenzoyl-benzoic acid (Radziszewski, *Ber.* vi. 810).

Parabromacetanilide, $\text{C}^6\text{H}_5\text{NH}(\text{C}^2\text{H}^3\text{O}).\text{H.H.Br.H}^2$, prepared by treating parabromaniline with excess of acetyl chloride, washing the product with water, and recrystallising from alcohol, forms large many-faced prisms, sometimes perfectly transparent and colourless with a vitreous lustre, sometimes opaque and white with nacreous lustre. It is moderately soluble in alcohol, nearly insoluble in cold water, slightly in hot water. Melts at 165.4° (Körner, *Gazz. chim. ital.* 1874, 329).

Parabromaniline, $\text{C}^6\text{H}_5\text{NH}^2.\text{H.H.Br.H}^2$. See BENZENES (BROMAMIDO-), p. 193. This base is resolved by distillation into [1 : 2 : 4] dibromaniline, melting at 79.5° , and tribromaniline, $\text{C}^6\text{H}_3\text{NH}^2.\text{Br.H.Br.H.Br.}$, melting at 117° (E. Büchner, *Ber.* viii. 361).

Parabromobenzyl Compounds. *Parabromobenzyl alcohol,* $\text{C}^6\text{H}_4\text{Br.CH}^2\text{OH}$, is most easily prepared by boiling parabromobenzyl bromide with water for some days, in a flask with reversed condenser. It is also obtained by heating parabromobenzyl acetate to 150° , with aqueous ammonia. It forms long, colourless, elastic, flat needles, having a fine nacreous lustre and unpleasant odour, melting at 69° , and dissolving easily in boiling water, alcohol, ether, benzene, and carbon disulphide.

The *acetate*, formed by heating the bromide with sodium acetate in alcohol, decomposes when distilled, and has not yet been obtained pure.

The *cyanide*, $\text{C}^6\text{H}_4\text{Br.CH}^2\text{CN}$, is obtained by boiling the bromide with alcoholic solution of potassium cyanide. It is a crystalline body of strong disagreeable odour,

melting at 46° , and dissolving easily in alcohol, ether, benzene, glacial acetic acid, and carbon bisulphide, but not in water.

The *thiocyanate*, $C^6H^4Br.CH^2SCN$, formed by boiling the bromide with potassium thiocyanate, crystallises in needles, melting at 25° , and dissolving very easily in alcohol.

Parabromophatoluic acid, $C^6H^4Br.CH^2.COOH$, formed by heating the above cyanide to 100° with hydrochloric acid in sealed tubes, crystallises in long white needles, which melt at 114.5° . It decomposes carbonates very slowly, but dissolves readily in ammonia and soda-ley, forming salts. By oxidation with chromic acid it is converted into parabromobenzoic acid. The ammonium salt forms precipitates with mercuric, mercurous, ferrous and lead salts, but not with salts of aluminium, chromium, zinc, cobalt, nickel, or magnesium.

Parabromobenzyl bromide reacts with ammonia at ordinary temperatures, forming triparabromobenzylamine, $(C^6H^4Br.CH^2)^3N$, and the corresponding hydrobromide, $(C^6H^4Br.CH^2)^3N.HBr$. The base crystallises from alcohol in needles melting at 78° – 79° ; the hydrobromide is deposited from the alcoholic liquid in which it is formed, in white nacreous scales melting at 270° , insoluble in water and in alcohol, but easily soluble in ether (Jackson a. Lowery, *Ber.* ix. 1209).

Parabromometabromobenzoic acid, $C^6CO^2H.H.Br.Br.H^2$. See BENZOIC ACIDS, DIBROMO- (p. 261).

Parabromorthonitraniline, $C^6.NH^2.NO^2.H.Br.H^2$. See BENZENES, NITROBROMAMIDO- (p. 200).

Parabromoparanitrodiphenyl, $C^{12}H^8Br(NO^2)$, m. p. 173° ; b. p. above 360° . See DIPHENYL (p. 661).

Parabutenylanisole, $C^{11}H^{14}O = C^6H^4(OCH^3).CH=CH.CH^2.CH^3$. This appears to be the compound formed, with separation of CO^2 , by heating methyl-paraoxy-phenylangelic acid, $C^{11}H^{14}O^3$ (Perkin, p. 505).

Parachloracetanilide, $C^6.NH(C^2H^3O).H.H.Cl.H^2$, obtained by the action of acetyl chloride on parachloraniline, crystallises from acetic acid in long needles melting at 172.5° . Treated with a mixture of nitric and sulphuric acids, it yields a nitro-derivative convertible by sodium carbonate into parachlororthonitraniline, $C^6.NH^2.NO^2.H.Cl.H^2$ (p. 202), (Beilstein a. Kurbatow, *Ber.* vii. 1760).

Parachloramidotoluene. See TOLUIDINES.

Parachlorobenzamide and Anilide. See BENZOIC ACIDS, CHLORO- (p. 262).

Paracyananiline, $C^6.NH^2.H.H.CN.H^2$, is formed by heating para-uramidobenzoic acid: $C^7H^5N^2O^3 = C^7H^5N^2 + CO^2 + H^2O$, and crystallises in small white shining prisms melting at 86° (Griess, *Ber.* viii. 860).

Paradiphenyl-benzene. See DIPHENYL-BENZENE (p. 665).

Paradiphenyl-carboxylic acid or *Paraphenyl-benzoic acid*, $C^6.CO^2H.H.H.C^6H^5.H^2$ (p. 667).

Paradinitrophenyl-nitranilines, $NH(C^6H^4NO^2)[C^6H^3(NO^2)^2]$. See BENZENES, NITROBROMAMIDO- (p. 199).

Parabromosalicylic acid and Aldehyde. See TOLUIC (HYDROXY-) ACID and ALDEHYDE.

Parahydrazoxydiidobenzene. See PARAZOXYDIIDOBEENZENE (p. 1487).

Para-iodoacetanilide, $C^6.NH(C^2H^3O).H.H.I.H^2$, is formed as a dark crystalline precipitate by heating acetanilide with 1 mol. iodine chloride. It dissolves easily in hot water, and crystallises therefrom in white rhombic plates; dissolves also in alcohol and in glacial acetic acid; melts at 181.5° . On boiling it with hydrochloric acid and treating the resulting salt with ammonia, para-iodaniline melting at 60° is obtained.

Para-iodoacetanilide is decomposed by strong nitric acid, with separation of iodine; but when its solution in glacial acetic acid is treated with nitric acid, para-iodo-nitranilide, $C^6H^3I(NO^2)(NH^2)$, is formed, which crystallises from alcohol in orange-yellow needles melting at 122° , slightly soluble in water, more freely in alcohol and glacial acetic acid. It does not unite with hydrochloric acid (Michael a. Norton, *Ber.* xi. 107).

Para-iodobenzyl Compounds (Mabery a. Jackson, *Ber.* xi. 55–58).—*Para-iodobenzyl bromide*, $C^6H^4I.CH^2Br = C^6CH^2Br.H.H.I.H^2$, formed by the action of bromine on para-iodotoluene at temperatures above 115° , crystallises in white flat needles, having an aromatic odour, and melting at 78.75° . It sublimes in needles, and dissolves in hot alcohol, ether, benzene, and carbon bisulphide, but not in water.

Para-iodobenzyl alcohol, $C^6H^4I.CH^2OH$, produced by boiling the bromide with

water, forms white silky scales of unpleasant odour, melting at $71\cdot75^\circ$, and dissolving easily in alcohol, ether, benzene, and carbon bisulphide; sparingly in water.

Para-iodobenzyl cyanide, $C^6H^4I.CH^2CN$, crystallises from alcoholic solution in white pearly laminae, which melt at $50\cdot5^\circ$, and resemble the preceding compounds in solubility.

Para-iodoaliphatic acid, $C^6H^4I.CH^2.COOH$, obtained by heating the nitril at 100° with fuming hydrochloric acid, forms white pointed plates, of agreeable odour, melting at 135° , and subliming at a somewhat higher temperature. By oxidation with chromic acid it is converted into para-iodobenzoic acid. Its *silver salt* crystallises from solution in boiling water in brilliant plates, easily soluble in dilute nitric acid. The *barium* and *calcium salts* form easily soluble white needles. The *zinc* and *magnesium salts* are crystalline, and sparingly soluble. Precipitates are produced by an ammoniacal solution of the acid in solutions of cupric sulphate, lead acetate, mercurous nitrate, aluminic and ferric chlorides, and nickel nitrate.

Para-iodobenzylamines.—The bromide, when heated with alcoholic ammonia, yields a bulky precipitate, which is resolved by crystallisation into the two following bodies:—

1. *Tri-para-iodobenzylamine*, $(C^6H^4I.CH^2)^3N$, the less soluble product, crystallises in white needles, melting at $114\cdot5^\circ$, and dissolving easily in ether, benzene, and carbon bisulphide. It forms with platonic chloride yellow needles of the salt, $[(C^6H^4I.CH^2)^3NH]^+PtCl_6^-$.

2. *Di-para-iodobenzylamine*, $(C^6H^4I.CH^2)^2NH$, the more soluble product, forms white needles, melting at 76° . It forms with hydrochloric acid a salt, crystallising in thick white plates, of very high melting-point, easily soluble in carbon bisulphide and glacial acetic acid. The platinochloride, $[(C^6H^4I.CH^2)^2NH]^+PtCl_6^-$, forms pale-yellow crystals.

Para-iodobenzyl thiocyanate, $C^6H^4I.CH^2.SCN$, formed by the action of the bromide on potassium thiocyanate, crystallises in long white plates of pleasant odour, melting at 40° . It dissolves easily in ether, benzene, carbon bisulphide, and glacial acetic acid; sparingly in alcohol.

Paraldehydosalicylic acid, $C^6.CO^2H.OH.H.H.CO.H.H$. See BENZOIC ACIDS (ALDEHYDO-OXY), p. 288.

Paralyl-anisöl, or *Anethöl*, $C^6.OCH^3.H.H.C^3H^5.H^2$, is formed, with evolution of CO^2 , by the action of heat on methylparaoxyphenylcrotonic acid, $C^6.OCH^3.H.H.C^3H^4(CO^2H).H^2$ (Perkin, p. 505).

Para-nitraniline, $C^6.NH^2.H.H.NO^2.H^2$. See BENZENES (NITRAMIDO-), p. 198.

Paraoxybenzoic acid and *Aldehyde* (pp. 285, 304, 1459, 1465).

Paraoxybenzyl Alcohol, $C^6.OH.H.H.CH^2OH.H^2$. See OXYBENZYL ALCOHOLS (p. 1468).

Parapicrylnitranilines and *Parapicrylmetapicrylamine*. See BENZENES (NITRAMIDO-), p. 199.

Parasulphamine-benzoic or *Parasulphobenzamic acid*, $C^6H^4(SO^2NH^2)COOH$. See BENZOIC ACIDS (SULPHO-), p. 294.

Parasulphobenzim. See PHENYL SULPHIDE.

Parasulphobenzicarboxylic acid, $C^6H^4(SO^2)(C^6H^4)(CO^2H)$. See SULPHONES.

Parasulphobenzoic acid, $C^6.CO^2H.H.H.SO^2H.H^2$. See BENZOIC ACIDS (SULPHO-), p. 293.

Parathiobenzoate, *Tolylic*, $C^7H^5O.S.C^7H^7$. See THIOBENZOIC ACID.

Paratolyl. See TOLYL.

Paravinyl-anisöl, $C^6H^4(OCH^3)(C^2H^3)$, is produced, with evolution of CO^2 , by the action of heat on methylparaoxyphenylacrylic acid (p. 504).

Para-xylene. See XYLENE.

Paraoxydiiodobenzene, $C^6H^2I^2ON^2 = \begin{matrix} C^6H^4I-N \\ | \\ C^6H^4I-N \end{matrix} > O$, is formed by heating

10 pts. pariodonitrobenzene, m. p. $171^\circ-172^\circ$ (vi. 269), with 16 pts. potassium hydroxide and 100 pts. alcohol. It crystallises in light yellow plates and scales, melts at 199° to $199\cdot5^\circ$, is insoluble in cold alcohol, slightly soluble in hot alcohol, also in glacial acetic acid and in ether, easily in benzene, nitrobenzene, and carbon sulphide. Heated for an hour to 100° in a sealed tube with alcoholic ammonium sulphide,

it is converted into parahydrazodiiodobenzene, $\begin{matrix} C^6H^4I-NH \\ | \\ C^6H^4I-NH \end{matrix}$, which crystallises

in white or slightly yellow laminæ or flat needles, easily soluble in alcohol, glacial acetic acid, benzene, and nitrobenzene; melts at a temperature above 100° . By boiling with hydrochloric acid it is decomposed, with separation of iodine. Its alcoholic solution, treated with ferric chloride or boiled with animal charcoal, yields parazodi-

iodobenzene, $\begin{array}{c} \text{C}^6\text{H}_4\text{I}-\text{N} \\ || \\ \text{C}^6\text{H}_4\text{I}-\text{N} \end{array}$, which crystallises in reddish scales, slightly soluble in

alcohol and glacial acetic acid, easily in hot benzene, nitrobenzene, and carbon sulphide, melts at 237° , and volatilises at higher temperatures, leaving a trace of charcoal. The same compound is obtained by dissolving parazoxydiiodobenzene in strong sulphuric acid, and separates on cooling in brown needles having a steel-blue lustre, while immersed in the liquid (Gabriel, *Ber.* ix. 1405). On the corresponding *meta*-compounds, see p. 1287.

PARADIGITOGENIN. One of the numerous substances obtainable, according to Schmiedeberg (*Pharm. J. Trans.* [3], v. 741), from Digitalis.

PARADIPIC ACID, $\text{C}^6\text{H}^{10}\text{O}_4$, and **PARADIPIMALIC ACID**, $\text{C}^6\text{H}^{10}\text{O}^8$. See ACRYLIC ACID (pp. 46, 47).

PARAFFINS, $\text{C}^n\text{H}^{2n+2}$. On Paraffins from Petroleum, see PETROLEUM.

The several paraffins, Methane, Ethane, Propane, Butane, Pentane, Hexane, and Octane, are described in their alphabetical places.

On heptane, C^7H^{16} , from Pennsylvanian petroleum and the alcohols derived from it, see p. 1024.

Heptane from *Pinus sabiniana*. This tree, which is indigenous in California, and is known locally as the *Nut Pine* or *Digger Pine*, yields, when incisions are made in its bark, a terebinthinate from which, by distillation, an oily hydrocarbon is obtained, known in San Francisco as an article of commerce under the names of abietene, erasine, aurantine, theoline, &c., and used as a substitute for benzolin or petroleum-benzene for removing grease-spots, paint-stains, &c., from clothing. It is a nearly colourless, mobile liquid having a strong aromatic odour, recalling that of orange-oil, and differs greatly in most of its physical properties from the terpenes obtained from most coniferous trees, boiling, after rectification, at 101° . and having a sp. gr. of 0.694 at 16.5° , whereas oil of turpentine boils at 160° , and has a sp. gr. of 0.840 at about the same temperature (W. Wenzell, *Pharm. J. Trans.* March 30, 1872).

This hydrocarbon has been further and very carefully examined by T. E. Thorpe (*Chem. Soc. J.* xxxv. 296), who has shown that it consists of normal heptane, $\text{CH}^3(\text{CH}^2)^5\text{CH}^3$. It affords the first instance of a paraffin playing the part of turpentine-oil in the vegetable kingdom, the only natural sources of heptane hitherto known being petroleum, and some of the fossil-fish oils obtained from Greenland, Switzerland, and other places.

The crude oil when distilled began to boil a little below 100° , the greater part distilling below 101° . The residual portion darkened slightly, and left on evaporation a small quantity of brown resinoid matter having in a very high degree the peculiar smell of the oil, indicating that the odour of the crude oil might be due in great part to the resin in solution; and this proved to be the case, for on agitating the oil with strong sulphuric acid, the acid became brown, and the liquid when again distilled was found to have lost the smell of orange oil.

The pure oil boils at 98.42° under a pressure of 760 mm. Its sp. gr. in the state of vapour is by experiment 49.94; by calculation 50.07 ($\text{H}=1$); in the liquid state 0.70057 at 0° . Its rate of expansion by heat is represented by the formula:

$$1 + 0.00121023 t + 0.0000011331 t^2 + 0.00000001174 t^3,$$

where t is the temperature reckoned from 0° .

The volume at 0° being 1, that at the boiling point is 1.14111: hence the sp. gr. at this temperature is 0.61393, which gives for heptane the specific volume 162.54. Kopp's values ($\text{C}=11$; $\text{H}=5.5$) gave the number 165.

The refractive index of the heptane for the line D, determined by the method of minimum deviation is 1.3879. Its specific refractive energy, $\frac{\mu-1}{d}$, where d is the density of the liquid at 17.6° , is 0.565; whence the molecular refractive energy is 56.4, a value agreeing closely with the computed number 55.8 deduced from Landolt's data, $\text{C}=5$, $\text{H}=1.3$.

The heptane is slightly active to polarised light, producing in a column 200 mm. long a deviation of $6^{\circ} 9'$.

On the viscosity and surface-tension of the liquid, see the original paper (pp. 302-308).

A comparison of the sp. gr. and boiling point of the heptane from *Pinus sabiniana*, with those of normal heptane from petroleum and of heptane obtained by heating azelaic acid with caustic baryta, yields the following results:

	Normal Heptane from Petroleum	Heptane from Azelaic acid	Heptane from <i>P. Sabiniana</i>
Boiling point . . .	98°-98.6°	98°-99°	98°-42°
	(bar. 750.3 mm.)		
Sp. gr. at 0° . . .	0.7301	0.7000	0.70057

With the exception of the higher sp. gr. of the petroleum heptane, which is at present unaccountable, these values point to the conclusion that the heptanes from these three sources are identical.

Solid Paraffins. Occurrence in Lava.—A lava from Paternò, at the foot of Etna, was found by O. Silvestri (*Gazz. chim. ital.* 1877, 1) to contain a petroleum (1 per cent. of the rock) yielding 42.79 per cent. of solid paraffin, together with 17.97 per cent. of a liquid hydrocarbon boiling at 280°, 31.95 per cent. of another boiling at 280°-409°, together with 2.90 per cent. asphalt, 12 ash, and 4.39 sulphur.

Purification.—Fordred (*Monit. scient.* [3], iii. 826) purifies crude paraffin by melting it, leaving the mechanical impurities to settle down to the bottom of the liquid mass, and then transferring it to small vessels to cool. The cakes are next warmed again till they become kneadable, and in this state the paraffin is finally washed with a solution of 10 pts. soft soap in 90 water, and heated to about 38° C. The colouring matters, and any oils that may be present, are transferred by this treatment to the soap-water, and the solid paraffin comes out purified and bleached.

An apparatus for decolorising paraffin by means of pulverised animal charcoal is described by L. Rahmdohr (*Dingl. pol. J.* ccxvi. 244).

On the Estimation of Paraffin in Stearin-candles, see Donath (*Dingl. pol. J.* ccviii. 305; *Chem. Soc. J.* xxviii. 1058).

Specific Gravity.—The sp. gr. of paraffin in the solid and fused states has been determined by Albrecht (*Dingl. ccxviii.* 280), with the following results:

	Melting point	Specific gravity		
		at 17°	at 55°	at 60°-65°
Solar oil and Paraffin . . .	38°	0.872	0.779	—
Secunda Paraffin . . .	43	0.883	0.788	—
Secunda Press-paraffin . . .	43	0.889	0.785	—
Secunda Paraffin . . .	46	0.887	—	0.781
Prima Press-paraffin . . .	47	0.900	—	0.775
" . . .	51	0.908	—	0.775
Hard Paraffin " . . .	56	0.912	—	0.777

These numbers show that paraffins expand considerably in melting. Albrecht also observed that solutions of paraffin in mineral oils have lower specific gravities than either the oils and the paraffins separately, so that in selecting for technical purposes lubricating oils of as great a density as possible, it is best to take paraffin oils from which the greater part of the solid paraffin has crystallised out.

Oxidation.—When paraffin is exposed for some time at 120° to a stream of air or oxygen, an absorption of that gas takes place. The same action takes place with coal, and may explain the increase of weight often observed when coal is dried in heated air (*Jaznowitsch, Ber.* viii. 768).

G. Pouchet (*Compt. rend.* lxxix. 320) finds that paraffin (m. p. not stated), treated with fuming nitric acid at a temperature not exceeding 110°, till it assumes a buttery consistence, yields a product from which water extracts butyric, valeric, caproic, cœnanthylie, caprylic, capric, and suberic acids, together with nitrated fatty acids, chiefly nitrocapyrylic and nitrocapric. When a mixture of sulphuric and nitric acids is used, the product yields to water nothing but suberic acid, and a peculiar deliquescent crystalline acid soluble in water and alcohol, while the portion insoluble in water consists of a solid acid called by Pouchet *paraffinic acid*, which, when purified by saponification, &c., has the composition $C^{24}H^{46}O_2$, whence it may be inferred that the particular paraffin operated on consisted of $C^{24}H^{50}$. Paraffinic acid is described as a whitish-yellow solid, smelling like wax, easily decomposed by heat, and burning with a bright smoky flame; insoluble in water, moderately soluble in dilute, easily in strong alcohol, also in ether, chloroform, benzene, and petroleum, and separating from the alcoholic solution by slow evaporation in nacereous laminæ. Nitric acid converts

it into suberic acid and nitro-derivatives of fatty acids. Heated with potash lime, it yields paraffins, solid and liquid, together with olefines.

Gill a. Meusel, by oxidising paraffin (m. p. 66°) with chromic acid mixture, obtained cerotic acid (vi. 421). This acid was not observed by Pouchet amongst the products of oxidation with nitric acid.

NITROPARAFFINS.

Nitromethane, $\text{CH}^{\text{N}}\text{NO}^2$. This compound, already described in vol. vii. p. 893, has been further examined by Preibisch (*J. pr. Chem.* [2], vii. 480; viii. 309). In preparing it by heating potassium monochloracetate with potassium nitrite (Kolbe's method), the result is the same whether the solutions are concentrated or dilute, the only difference being that in the latter case the liquid does not froth so much. Among the secondary products ammonium carbonate was found, the presence of which caused the blackening of the liquid and the loss of nitromethane.

Dry ammonia does not act on nitromethane, but aqueous ammonia dissolves it, the liquid soon darkening, and carbon separating out. When a little water is added to a mixture of alcoholic ammonia and nitromethane, and the solution is evaporated under the exsiccator, a small quantity of fine brownish needles is obtained, which soon undergo complete decomposition, even if kept in a closed tube. Nitromethane, heated with iron-filings, acetic acid, and water, is converted into methylamine.

The sodium-compound, $\text{CH}^{\text{N}}\text{NaNO}^2$, is conveniently prepared by precipitating an alcoholic solution of nitromethane with alcoholic soda, and washing the precipitate once with alcohol on the filter-pump. In the moist state it soon turns yellow, and it is therefore advisable to use only a small quantity of nitromethane for each operation. With an alcoholic turmeric solution it produces a deep-red colour. Sodium-nitromethane acts violently on acid chlorides, but no definite compounds could be obtained; neither was an isomeride of nitrotoluene formed by acting on it with bromobenzene. Chlorine and bromine do not act on nitromethane, even in sunshine, whereas by leaving it in contact with a mixture of nitric acid and sulphuric acid for some weeks, a body was formed exploding most violently on distillation. When nitromethane is mixed with bleaching powder and a little water, a brisk evolution of gas sets in, and chloronitromethane, $\text{CH}^{\text{N}}\text{ClNO}^2$, distils over. This compound boils at 98° and has a very pungent and irritating smell. The corresponding bromine-compound could not be obtained in the pure state. Nitromethane is not acted upon by phosphorus pentoxide, or by concentrated sulphuric acid; but, on heating it gently with fuming sulphuric acid, a violent reaction sets in, carbon monoxide and sulphur dioxide being given off, and hydroxylamine sulphate produced: $\text{CH}^{\text{N}}\text{NO}^2 = \text{CO} + \text{NH}^{\text{O}}\text{O}$ (p. 1074). Heated with hydrochloric acid (sp. gr. 1.14), best in a sealed tube at 150° , it yields hydroxylamine and formic acid, $\text{CH}^{\text{N}}\text{NO}^2 + \text{H}^{\text{O}} = \text{NH}^{\text{O}}\text{O} + \text{CH}^{\text{O}}\text{O}$ (Meyer a. Locher, *Ber.* viii. 219). By heating with an alcoholic solution of caustic soda, nitromethane is converted into the sodium salt of methazonic acid, $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{NO}^2$ (p. 1301). On mono-bromonitromethane, formed by the action of bromine on sodium-nitromethane, and dibromonitromethane, produced from it by the action of bromine and potash-ley, see Tscherniak (vii. 894).

Nitroethane, $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{NO}^2$. This compound, gently heated with fuming sulphuric acid, is converted into ethylene-disulphonic acid, $\text{C}^{\text{H}}\text{H}^{\text{N}}(\text{SO}^{\text{H}}\text{H})^2$, (p. 755). Hydrochloric acid, of sp. gr. 1.14, acts upon it in the same manner as on nitromethane, yielding hydroxylamine and acetic acid. According to Werner (*Jen. Zeitschr.* [2], iii. 2nd Suppl. 70), the same reaction is also produced by sulphurous acid.

When potassium nitro-ethane, $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{K}(\text{NO}^2)$, is added to solution of diazobenzene nitrate (obtained by adding nitraniline to a dilute solution of potassium nitrite, and filtering from a yellow insoluble compound formed at the same time), a yellow acid body is precipitated having the composition $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{N}^{\text{O}}\text{O}^4 = \text{C}^{\text{H}}\text{H}^{\text{N}}\text{NO}^2.\text{N}^2.\text{C}^{\text{N}}\text{H}^{\text{N}}\text{NO}^2$. This body forms, when pure, a yellow powder soluble with red colour in alkalis, and easily soluble in hot alcohol. The sodium salt is sparingly soluble in water; its solution gives coloured precipitates with silver, copper, and lead salts. When treated with tin and hydrochloric acid, the acid yields a body which forms with stannic chloride a crystalline compound agreeing in composition with the formula $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{N}^{\text{O}}\text{O}^4.\text{SnCl}^4$. The formation of this body may perhaps be represented by the equation $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{N}^{\text{O}}\text{O}^4 + \text{H}^{\text{N}}\text{H}^{\text{N}} + 2\text{HCl} = 4\text{H}^{\text{O}} + \text{C}^{\text{N}}\text{H}^{\text{N}}\text{N}^{\text{O}}\text{O}^4\text{Cl}^2$ (Hallmann, *Ber.* ix. 389).

When diazobromobenzene nitrate (obtained by adding potassium nitrite to a solution of parabromaniline in nitric acid) is mixed with potassium-nitroethane, a precipitate is formed, having the composition $\text{C}^{\text{N}}\text{H}^{\text{N}}\text{Br}.\text{N}^2.\text{C}^{\text{N}}\text{H}^{\text{N}}(\text{NO}^2)\text{K}$. This salt separates from alcoholic solution in shining brick-red crystals soluble in ether, chloroform, &c., melting with decomposition at 135° – 138° . Its solution gives with cupric sulphate a greenish-yellow precipitate, with lead acetate a light red precipitate, and with silver

nitrate a precipitate of a deep orange colour soon turning black (H. Wald, *Ber.* ix. 393).

On *Bromo- and Dibromonitroethane*, see vii. 805.

Dinitroethane, $C^2H^4(NO^2)^2 = CH^3.CH(NO^2)^2$ (E. ter Meer, *Ber.* viii. 793, 1080). The potassium-derivative of this compound is formed by the action of potassium nitrite and alcoholic potash on monobromonitroethane:

It is best prepared by dissolving 21 grams of monobromonitroethane in twice its weight of alcohol, and adding first a solution of 12 grams potassium nitrite in the same weight of water, and then gradually 45 pts. of alcoholic potash (1 : 5). After standing for one to two hours, the crystals which have separated out are first washed with alcohol and ether, and then with water to remove the potassium bromide. On adding a dilute acid to the potassium compound, dinitroethane separates out as a colourless, very refractive liquid, having a peculiar sweet taste, and a faint alcoholic smell. It boils at 185° – 186° (cor.), and has, at 23.5° , the sp. gr. 1.3503. It is a tolerably strong acid, which even decomposes carbonates, though not readily. The *potassium salt* forms yellow glistening monoclinic crystals, $a : b : c = 0.58124 : 1 : 0.99016$. It is sparingly soluble in cold water, readily in hot water, and insoluble in absolute alcohol; when exposed to light it acquires an orange colour. The *sodium salt* is a very similar body, but dissolves more freely in water and alcohol. The *barium salt* crystallises in yellow needles or small plates; and the very explosive *silver salt*, $CH^3.C(NO^2)^2Ag$, forms small yellow plates having a metallic lustre and dissolving but sparingly in water.

The aqueous solution of the potassium salt is not precipitated by calcium, barium, strontium, aluminium, cobalt, or ferrous salts. Ferric chloride forms a reddish-brown precipitate; lead acetate a pure yellow crystalline precipitate; basic lead acetate a bulky yellow precipitate; copper sulphate a pale blue; and mercuric chloride a light brown precipitate. Mercurous nitrate produces a greyish-black precipitate, soon changing into colourless crystals.

By reduction with *tin* and *hydrochloric acid*, dinitroethane ought to yield aldehyde and hydroxylamine, seeing that dinitropropane, as shown by Meyer (*infra*), yields by reduction hydroxylamine and acetone. But only a trace of aldehyde was actually obtained, the products being acetic acid, ammonia, and hydroxylamine. This is easily explained on the supposition that the aldehyde in the nascent state is oxidised by hydroxylamine, and this was confirmed by experiment. On passing the vapour of aldehyde mixed with carbon dioxide into a boiling solution of pure hydroxylamine hydrochloride containing a little freshly prepared spongy platinum, the hydroxylamine was soon reduced to ammonia. The reactions which take place in the reduction of dinitroethane may therefore be represented by the following equations:

Monobromodinitroethane, $CH^3.CBr(NO^2)^2$, is produced on adding bromine-water to an aqueous solution of potassium-dinitroethane, and separates as a heavy colourless oil having a highly pungent odour. It decomposes when distilled alone, but volatilises undecomposed with steam. By *potash* either in aqueous or alcoholic solution, and even by *potassium carbonate*, it is decomposed, with evolution of oxygen and reproduction of potassium dinitroethane:

Nitro-allylethane, $C^3H^4(C^2H^5).NO^2$, appears to be formed on adding allyl iodide to a solution of nitroethane in a quantity of alcoholic potash sufficient for the production of potassium-nitroethane. A brisk reaction then takes place, attended with separation of potassium iodide, and the filtrate, when mixed with water, deposits an oil which cannot be distilled without decomposition. This oil, reduced with zinc and hydrochloric acid, yields a liquid amine which boils at 85° , dissolves in water and in alcohol, is separated from the aqueous solution by potash, reacts strongly with carbon disulphide, but does not form with it a crystallisable compound. The platinum-chloride of this amine crystallises from water in yellow laminae, and gives by analysis a quantity of platinum, indicating that the formula of the amine is $C^3H^9.NH^2$. Hence it is probable that the oily nitro-compound from which the amine is formed is nitro-allylethane, $C^3H^9.NO^2$ (H. Gal, *Compt. rend.* lxxvi. 1354).

Nitropropanes. Normal nitropropane, $CH^3.CH^2.CH^2(NO^2)$, formed by the action of propyl iodide on silver nitrite (vii. 895), boils, according to Cahours (*Compt. rend.* lxxvii. 749), at 125° – 128° , and burns with a yellowish flame. By *nascent*

hydrogen it is converted into propylamine; by *alcoholic soda* into the sodium salt, $C^3H^5Na(NO^2)$, which crystallises in laminae slightly soluble in alcohol.

Normal nitropropane is decomposed by dilute *hydrochloric acid* in the same manner as nitroethane (p. 1490), yielding hydroxylamine and propionic acid. Isonitropropane, on the other hand, is converted by hydrochloric acid into a black-brown greasy substance containing a large quantity of ammonium chloride (Meyer a. Locher, *Ber.* viii. 219).

On *Bromonitropropanes*, see Meyer a. Tscherniak (vii. 896).

Dinitropropane, $C^3H^5(NO^2)^2$. Of this compound two modifications are known, distinguished as α and β .

α -*Dinitropropane*, $CH^3.CH^2.CH(NO^2)^2$, is obtained by treating 27 pts. of normal monobromonitropropane, $CH^3.CH^2.CHBrNO^2$, with 27 pts. alcohol and 28 pts. of an aqueous solution of potassium nitrite (1 : 1), and immediately adding 54 pts. of alcoholic potash (5 : 1), and separating the resulting potassium α -dinitropropane, $CH^3.CH^2.C(NO^2)^2K$, from the potassium bromide which is deposited at the same time, by recrystallisation from hot water. This salt forms light yellow explosive laminae, resembling those of dinitroethane, easily soluble in hot water, insoluble in absolute alcohol and in ether. On adding it (either pure or in the crude state mixed with potassium bromide) to dilute sulphuric acid, α -dinitropropane is obtained as a colourless, nearly scentless oil, having a density of 1.258 at 22.5°, remaining liquid at -17°, and boiling at 189° (corr. 192.5°). It forms coloured precipitates with salts of the heavy metals. The *silver salt*, $CH^3.CH^2.C(NO^2)^2Ag$, forms greenish-yellow explosive laminae (E. ter Meer, *Ber.* viii. 793 and 1081).

β -*Dinitropropane*, $CH^3.C(NO^2)^2.CH^3$, is obtained by oxidation of propyl-pseudonitrole, $CH^3.C(NO)(NO^2).CH^3$. For this purpose 2 pts. of dry finely pulverised propyl-pseudonitrole are drenched with 16 parts of glacial acetic acid, and $\frac{4}{3}$ pts. chromic acid are added, the liquid being at the same time gently heated, so that the reaction-temperature may not exceed 76°. When the action is complete, the mixture is poured into water, the acetic acid neutralised with aqueous alkali, and the product of the reaction separated either by extraction with ether or by distillation with steam. This same compound is produced in small quantity in the decomposition of propyl-pseudonitrole by heat. After distillation with steam and drying over calcium chloride, it forms dazzling-white crystals melting at 53°; it boils without decomposition at 185.5°. The crystals sublime below their melting point; volatilise easily with vapour of water; deliquesce in alcohol, ether, and glacial acetic acid; dissolve but sparingly in water, and not at all in aqueous alkalis (Meyer a. Locher, *Ber.* vii. 1613).

Nitrobutanes. Normal nitrobutane, $CH^3.CH^2.CH^2.CH^2(NO^2)$, prepared by the action of silver nitrate on well-cooled normal butyl iodide, is a colourless liquid, lighter than water, distilling without decomposition at 151°-152°, soluble in caustic potash. It is easily converted into butylamine by the action of tin and hydrochloric acid; resolved by heating with hydrochloric acid to 140° into hydroxylamine hydrochloride and normal butyric acid; converted by nitrous acid into normal butylnitrolic acid.

Normal monobromonitrobutane, $CH^3.CH^2.CH^2-CHBr(NO^2)$, prepared by the action of bromine on normal potassium-nitrobutane, is a heavy oil, boiling at 180°-181°. The *dibromonitrobutane* obtained by the action of bromine on a mixture of normal nitrobutane and caustic potash, is a heavy, yellow oil, insoluble in caustic potash, boiling at 203°-204° (J. Züblin, *Ber.* x. 2083).

Normal dinitrobutane, $C^4H^7CH(NO^2)^2$, is prepared by slowly adding dilute sulphuric acid to a mixture of potassium nitrite and normal monobromonitrobutane dissolved in excess of caustic potash, until a blue colour is produced. Caustic potash is then added, the resulting potassium dinitrobutane acidified with sulphuric acid, and the dinitrobutane extracted with ether. It is a yellow oil, boiling at 190°, but decomposed by distillation. The potassium salt forms brilliant golden scales, soluble in water and in alcohol. The aqueous solution gives with silver nitrate a precipitate of silver-dinitrobutane, which can be obtained by recrystallisation in large scales, appearing yellow by transmitted and bluish violet by reflected light.

Normal monobromodinitrobutane, $C^4H^7.CBr(NO^2)^2$, obtained by acting on potassium dinitrobutane with bromine-water, is an oily liquid, decomposed by distillation (Züblin, *loc. cit.*)

Isonitrobutane, $(CH^3)^2CH.CH^2(NO^2)$, which Demole obtained by the action of silver nitrite on isobutyl iodide, has been already described (vii. 897). *Isobromonitrobutane*, $(CH^3)^2CH.CHBr(NO^2)$, is a heavy oil, boiling at 173°-175°, and otherwise resembling its isomeride.

Isodinitrobutane, $(\text{CH}^3)^2\text{CH}.\text{CH}(\text{NO}^2)^2$, is a yellowish oil decomposing when distilled. Its potassium and silver salts crystallise in yellow shining needles. *Isobromodinitrobutane*, $(\text{CH}^3)^2\text{CH}.\text{CBr}(\text{NO}^2)^2$, is obtained by the action of bromine-water on an aqueous solution of potassium-isodinitrobutane, and purified by treatment with sulphurous acid to remove free bromine, washing with caustic soda, and distillation in a current of steam. It is a colourless vitreous body, resembling camphor in appearance, having a pungent odour, and melting at 38° . Its potassium salt, treated with diazobenzene nitrate, yields *isonitrobutyl-azophenyl*, $\text{C}^6\text{H}^5.\text{N}=\text{N}.\text{CH}(\text{NO}^2)\text{CH}(\text{CH}^3)^2$, as a yellowish oil, dissolving with yellow-red colour in alkalis (Züblin).

Secondary Nitrobutane, $\text{CH}^3.\text{CH}^2.\text{CH}(\text{NO}^2).\text{CH}^3$, is prepared by the action of secondary butyl iodide (120 pts.) on silver nitrite (150 pts.), the latter being mixed with an equal weight of previously ignited sand. The reaction is attended with considerable rise of temperature; normal butylene is given off; and the residual mass consists of a mixture of secondary nitrobutane and butyl nitrite, which are but imperfectly separable by fractional distillation. The nitrobutane (not quite pure) thus obtained is a colourless oil having a peculiar odour, boiling at about 140° , and converted by repeated agitation with potash and potassium nitrite into butyl-pseudonitrole, $\text{CH}^3.\text{CH}^2.\text{C}(\text{NO})(\text{NO}^2).\text{CH}^3$ (V. Meyer a. Locher, *Ber.* vii. 1506).

Tertiary nitrobutane, $(\text{CH}^3)^3.\text{C}(\text{NO}^2)$, is formed in small quantity, together with butyl nitrite and oxides of nitrogen, by the action of silver nitrite on tertiary butyl iodide. It is a colourless liquid, smelling like peppermint and boiling between 110° and 130° . Like nitrobenzene, it has no acid properties, the carbon-atom to which the NO^2 -group is attached not being also combined with a hydrogen-atom. Accordingly it does not yield a bromo-derivative when treated with bromine and potash; neither is it converted into a pseudonitrole by treatment with dilute sulphuric acid, potassium nitrite, and potash (Tscherniak, *Liebig's Annalen*, clxxx. 155).

Nitrolic Acids and Pseudonitroles.

(1). The nitrolic acids, $\text{C}^n\text{H}^{2n}\text{N}^2\text{O}^3$, may be represented by either of the two following constitutional formulæ, in which R stands for $\text{C}^n\text{H}^{2n+1}$, n having any integral value from 0 upwards:

The first of these formulæ agrees best with the modes of formation of the nitrolic acids, the second with their decomposition by heat and by sulphuric acid.

Nitrolic acids are produced: 1. By the action of nitrous acid, or better of potassium nitrite and sulphuric acid, on the sodium derivatives of primary nitro-paraffins, or on solutions of these nitro-compounds in caustic potash or soda:

2. By the action of the dibrominated nitroparaffins on hydroxylamine:

(2). Pseudonitroles, $\text{C}^n\text{H}^{2n+1}.\text{C}(\text{NO})(\text{NO}^2).\text{C}^n\text{H}^{2n+1}$, are formed by the action of potassium nitrite on secondary nitro-paraffins, thus:

Methyl-nitrolic Acid, $\text{CH}^3\text{N}^2\text{O}^3 = \text{H}(\text{NO}^2)\text{C}=\text{N.OH}$. This acid is very unstable in aqueous solution, so that its preparation requires special precautions. The following method is given by Tscherniak (*Ber.* viii. 114): Nitromethane (15 grams) is treated with a quantity of water just sufficient to dissolve it, and the solution is mixed with a moderately dilute solution of potassium nitrite (8 grams) and cooled to 0° by addition of a large quantity of ice. A mixture of sulphuric acid (4 grams) with a large quantity of water is also cooled by ice, and slowly poured into the first liquid, to which, thus diluted, weak aqueous potash is first added till it turns red, and then again dilute sulphuric acid till the colour disappears. To remove any free nitrous acid, the solution is shaken with a little precipitated chalk, after which the nitrolic acid is dissolved out by ether, and the solution evaporated over sulphuric acid.

Methylnitrolic acid thus obtained forms large brittle crystals resembling the ethyl-compound; from a dilute ethereal solution it separates in long needles. It decomposes slowly at ordinary temperatures, rapidly at 64° , into formic acid, nitrogen, and nitrogen tetroxide:

By boiling with dilute sulphuric acid, it is resolved into formic acid and nitrogen monoxide:

Ethylnitrolic Acid, $\text{C}^2\text{H}^4\text{N}^2\text{O}^3 = \text{CH}^3(\text{NO}^2)\text{C}=\text{N}.\text{OH}$ (V. Meyer a. Locher, *Ber.* vi. 1494; Meyer, *ibid.* vii. 425). The preparation of this compound by the action of potassium nitrite and sulphuric acid on an alkaline solution of nitroethane has been already described (vii. 564). It is essential that the nitroethane be first dissolved in the alkali; for if the nitroethane and sulphuric acid be added simultaneously to a solution of potassium nitrite, no ethylnitrolic acid will be produced.

Ethylnitrolic acid crystallises in light yellow, transparent, highly lustrous prisms, very much like saltpetre; by slow evaporation of the aqueous or ethereal solution it is easily obtained in crystals an inch long. According to Kenngott's measurements, they belong to the orthorhombic system, exhibiting the combination $\infty\text{P}.\infty\bar{\text{P}}.\infty\bar{\text{P}}.\infty$. The angle of the brachydiagonal prismatic edge is approximately $108^\circ 30'$; that of the terminal edge of the transverse dome $47^\circ 30'$. The acid has a strong sweet taste and acid reaction. It dissolves readily in all the ordinary solvents, and its difference of solubility in cold and slightly warm water is so great that a solution saturated merely at the heat of the hand deposits an abundant crop of crystals a few minutes after the hand has been removed.

The ethylnitrolates of sodium, potassium, ammonium, and barium dissolve in water, with a deep red colour, but have not been obtained in the pure state. Water is required for their formation, inasmuch as nitroethane dissolves in an ethereal solution of ammonia without coloration, but on adding a trace of water, the liquid assumes a deep red colour. The action of alkalis on ethylnitrolic acid is so sensitive that this acid might be used as an indicator in alkalimetry. The ethylnitrolates of the heavy metals are coloured unstable precipitates, very easily changing into nitrites. The lead salt has a brilliant orange colour, and the silver salt is egg-yellow.

Ethylnitrolic acid, heated to $80^\circ\text{--}81^\circ$, melts and suffers rapid decomposition, giving off nitrogen tetroxide and free nitrogen, and leaving glacial acetic acid:

The same decomposition goes on slowly at the common temperature, and quickly on boiling with an alkali. In these decompositions a small quantity of a white solid, containing nitrogen and melting at 61° , is always formed.

Nascent hydrogen obtained from tin and hydrochloric acid or sodium-amalgam, converts the acid into acetic acid, nitrous acid, and ammonia—

Strong *sulphuric acid*, when employed in excess in order to moderate the reaction, decomposes it into acetic acid and nitrogen monoxide: $\text{C}^2\text{H}^4\text{N}^2\text{O}^3 = \text{C}^2\text{H}^4\text{O}^2 + \text{N}^2\text{O}$.

These decompositions are most readily explained on the supposition that ethyl-nitrolic acid contains the radicle acetyl, as represented by the second of the two general formulæ on p. 93, *e.g.*

(Victor Meyer, *Ber.* vii. 425).

Propylnitrolic Acid, $\text{C}^3\text{H}^6\text{N}^2\text{O}^3 = \text{CH}^3.\text{CH}^2(\text{NO}^2)\text{C}=\text{N}.\text{OH}$, may be prepared either by passing nitrous acid into a solution of nitropropane in potash, and adding sulphuric acid, or by the action of dibromonitropropane on hydroxylamine. Hydroxylamine hydrochloride (7 pts.), dissolved in a small quantity of water, is decomposed with the exact quantity of baryta-water required, and dibromonitropropane (2 pts.) prepared from primary nitropropane is added to the mixture; the mass, after being left to itself two days at the ordinary temperature and frequently shaken, is acidulated with sulphuric acid and agitated with ether; the resulting ethereal solution is purified by mixing it with soda-ley, acidulating with sulphuric acid, and exhausting with ether; and the propyl-nitrolic acid which remains after the evaporation of the ether is finally purified by once recrystallising it from the same solvent (Meyer a. Lecco, *Ber.* ix. 395).

Propylnitrolic acid crystallises in light yellow prisms having a sweet and biting taste, easily soluble in water, alcohol, and ether, coloured deep red by alkalis, melting at 60° , and decomposing at higher temperatures with violent evolution of red vapours. By *sodium-amalgam* and *water* it is resolved into ammonia, nitrous acid, and probably also propionic acid; by strong *sulphuric acid* into propionic acid and nitrogen monoxide. When left to itself in a sealed tube it begins to decompose in four or five weeks; on subsequently opening the tube, red fumes escape with vio-

lence, and the residual liquid is found to consist of propionic acid. The metallic *propylnitrolates* quickly decompose in the same manner as the ethylnitrolates, yielding nitrites (V. Meyer, *Liebig's Annalen*, clxxv. 114).

Propylpseudonitrole, $\text{CH}_3\text{C}(\text{NO})(\text{NO}^2)\text{CH}_3$. When an alkaline solution or secondary nitropropane is treated with potassium nitrite and sulphuric acid, the liquid assumes a fine deep blue colour, and propylpseudonitrole is separated in the form of a white sandy powder. This compound, isomeric with propylnitrolic acid, is insoluble in water, alkalis and acids, not very freely soluble in cold alcohol or chloroform, but readily in the hot liquids, forming blue solutions from which it crystallises on cooling. By slow evaporation from the chloroform solution it is obtained in large colourless glassy monoclinic crystals, having the axial ratio $a : b : c = 1.2911 : 1 : 0.6672$. It melts at 76° to a deep blue liquid, which solidifies on rapid cooling to a colourless mass, but when further heated, is converted, with brisk evolution of gas, into an oil which no longer solidifies. When suspended in water it is not acted upon by sodium-amalgam in presence either of acid or of alkali, but in alcoholic solution it is decomposed by sodium-amalgam, with decolorisation, and formation of sodium nitrite and a white flocculent sodium-compound. When gently heated with strong sulphuric acid, it gives off a large quantity of a gas which extinguishes flame. It is partially decomposed by boiling water, and when heated with aqueous alkalis it gives off nitrogen, and forms a nitrate. By oxidation with chromic acid it is converted into dinitropropane, $\text{CH}_3\text{C}(\text{NO}^2)_2\text{CH}_3$ (p. 1492). (Meyer, *Liebig's Annalen*, clxxv. 120).

Butylnitrolic Acid, $\text{C}_4\text{H}_7\text{N}_2\text{O}_3 = \text{C}^3\text{H}^7(\text{NO}^2)\text{C}=\text{N.OH}$, obtained by the action of potassium nitrite and sulphuric acid on an alkaline solution of primary nitrobutane, is not crystallisable, but remains as a syrup on evaporation of its ethereal solution. It forms red alkaline solutions, and yields with silver nitrate an orange-coloured precipitate which quickly decomposes with formation of nitrite. By strong acid, it is resolved into isobutyric acid and nitrogen monoxide (Demole, *Ber.* vii. 790).

Butylpseudonitrole, $\text{C}_4\text{H}_9\text{C}(\text{NO})(\text{NO}^2)\text{CH}_3$, is obtained by repeatedly agitating secondary nitrobutane with potassium nitrite and potash-ley as long as it continues to dissolve, removing the oil (isobutyl nitrite) which floats on the surface of the liquid, and mixing the alcoholic solution with dilute sulphuric acid, whereby the pseudonitrole is separated as a blue liquid solidifying on cooling to a nearly colourless mass which may be purified by triturating it with dilute potash-ley, then washing it with water, and dried by aid of heat. Butylpseudonitrole resembles the corresponding propyl-compound in its relations to solvents, and in being white in the solid, blue in the liquid state, but differs from it by melting at a lower temperature, namely, at 58° (Meyer, *Ber.* vii. 1506).

The modes of formation and the colour-reactions of the nitrolic acids and pseudonitroles may be utilised as a means of distinguishing between primary, secondary and tertiary alcohols of the series $\text{C}^n\text{H}^{2n+1}\text{OH}$. Since the formation of nitrolic acids is determined by the presence of the group CH_2NO^2 , and that of pseudonitroles by the group CH.NO^2 , and consequently the tertiary nitro-derivatives of the fatty series cannot give rise either to nitrolic acids or to pseudonitroles, it follows that the three classes of alcohols may be distinguished by the following reactions. A quantity of dry silver nitrite, mixed with an equal weight of previously ignited sand, is introduced into a small distillation-flask fitted with a side-tube; the hydriodic ether of the alcohol under examination is then added; the mixture, after the reaction has begun, is distilled over an open flame without a condenser; and the distillate, received in a test-tube, is shaken up with potassium nitrite and potash-ley, and then acidulated with dilute sulphuric acid. If no coloration of the mass ensues, the alcohol-radicle present is a tertiary, whereas a red coloration indicates the presence of a primary, and a blue coloration that of a secondary radicle. The reaction may be recognised with great distinctness with the use of not more than 0.3 to 0.5 grm. of the alcoholic iodide (Meyer a. Locher, *Ber.* vii. 1510).

PARAGLOBULIN. See PROTEIDS.

PARAGUAY TEA or **MATÉ**. This substance, the produce of the *Ilex paraguayensis* or *Ilex Maté* of South America, where a decoction of it constitutes a favourite drink, has been examined by H. Byasson (*Pharm. J. Trans.* [3], viii. 605). The variety examined was the greenish-yellow powder, which is prepared by the natives from the roasted and coarsely-powdered leaves. The analysis was

made by mixing the maté with lime and successively exhausting the mixture with chloroform and alcohol. 100 grams gave:—

Caffeine	1.85
Glutinous substance. &c.	3.87
Complex glucoside	2.38
Resin	0.63
Inorganic salts, including iron	3.92
Malic acid	not estimated.

Exhausted with boiling water, the tea gave 24 per cent. dry extract, and 3.92 per cent. of ash in the extract, calculated on the maté taken. The ash contained potassium carbonate and much sulphuric acid. The tests for tannin and caffeic acid gave negative results. The amount of caffeine is comparable with that in the kinds of tea and coffee richest in that alkaloid.

PARAHYDROCYANALDINE, $C^6H^{12}N^4$. The crystalline forms of this compound, and of its isomeride hydrocyanaldine (i. 108), have been examined by C. Haushofer (*Zeitschr. Kryst.* i. 620). Hydrocyanaldine crystallises in the monoclinic system; $a : b : c = 2.8727 : 1 : 3.8596$; angle $ac = 52^\circ 28'$. The crystals, which are for the most part well developed on all sides, exhibit the combination $\infty P. 0P. \infty P \infty. + P \infty. - \frac{1}{2}P \infty$. The orthopinacoid faces exhibit striation, parallel to the combination-edge with $-\frac{1}{2}P \infty$. The crystals do not exhibit any distinct cleavage. They are permanent in the air, and melt at 115° .

Parahydrocyanaldine forms orthorhombic crystals having the axial ratio $a : b : c = 0.6639 : 1 : 1.8741$. Observed combination $\infty P. \infty P \infty. P \infty. 0P$; prismatic in the direction of ∞P ; more rarely tabular in that of $\infty P \infty$. Melting point 230° – 232° .

PARAISOBUTYRIC ALDEHYDE, $C^{12}H^{24}O^3$. This polymeric compound, which Barbaglia obtained by the action of chlorine on isobutyric aldehyde (vii. 228), is likewise produced by the action of bromine or iodine. Bromine acts best in the form of vapour mixed with air. Cyanogen has no effect (Barbaglia, *Ber.* vi. 1064). The same polymeric modification is produced by the action of phosphorus pentachloride on isobutyric aldehyde, its formation in this case being probably due to the small quantity of hydrochloric acid formed from the pentachloride by the action of moisture, for strong sulphuric acid and gaseous hydrogen chloride likewise bring about the polymerisation; on bringing the substances together great heat is evolved, and the liquid solidifies on cooling to a crystalline pulp of slender needles (Dementschenko, *ibid.* 1176). It melts at 60° , resolidifies at 50° – 51° , and is not altered by heating to 200° in a sealed tube for 15 hours, or by dry chlorine, bromine, or iodine (Barbaglia). Boils at 194° . Crystallises in needles from water, and on sublimation (Dementschenko).

PARALACTIC ACID. See LACTIC ACIDS (p. 1160).

PARALBUMIN. See PROTEIDS.

PARALDOL. See ALDOL (p. 54).

PARAMORIN. See MORIN (p. 1336).

PARA-NUTS. These nuts contain crystallised vitellin. See PROTEIDS.

PARARABIN. See ARABIN (p. 119).

PARICINE, $C^{16}H^{18}N^2O$. This alkaloid, occurring together with quinamine in the bark of *Cinchona succirubra* from Darjeeling, may be separated from all the cinchona-alkaloids with which it may be associated in a saline solution, by means of sodium carbonate, which throws it down before any of the rest (Hesse, *Ber.* x. 2152).

PARIGENIN and PARILLIN. Substances allied to SAPONIN (q. v.)

PASSYITE. A white earthy silicious mineral, occurring in layers or kidney-shaped masses at the border of the red clays and argillaceous sands which overlie the chalk in the Department of the Seine inférieure, frequently also enveloping flints. Analysis by Marchand (*Ann. Chim. Phys.* [5], i. 392):

H ² O	SiO ²	CaCO ³	MgCO ³	Fe ² O ³ , Al ² O ³
1.1	84.5	15.0	trace	— = 100.6
0.3	89.2	10.4	trace	trace = 99.9
—	88.9	11.4	trace	— = 100.3

PASTINACA. The volatile oil of the fruit of the parsnip (*Pastinaca sativa*) contains the normal butyric ether of normal octyl alcohol.

PASTINACINE. A volatile alkaloid, existing, according to Wittstein (iv. 357), in the seeds of the parsnep, and, according to A. R. Porter (*Pharm. J. Trans.* [3], vii. 174), in the root of *Sium latifolium*.

PATCHOULI CAMPHOR, $C^{15}H^{26}O$. This substance, first examined by Gall (vi. 902), who assigned to it the formula $C^{15}H^{26}O$, has been further investigated by J. de Montgolfier (*Compt. rend.* lxxxiv. 88; *Ber.* x. 234). It forms regular hexagonal crystals, some almost spherical from the rounding of the faces. They are always composed of a prism and a pyramidal summit, and do not exhibit hemihedry. The inclination of the faces to each other is 120° , and to the summit $120^\circ 24'$. They have no rotatory power for polarised light; but the liquid camphor is lævogyrate; $[\alpha]_D = -118^\circ$. The rotatory power remains constant when the camphor is dissolved in alcohol of 95 per cent., but diminishes considerably on dilution. If e be the proportion by weight of substance in solution:

$$(\alpha)_D = -124^\circ 5' + 21 e.$$

The dispersion is nearly the same as that of quartz or of sugar; $[\alpha]_D = -10^\circ 37'$ and $\alpha_y = -11^\circ 48'$. The crystals melt at 52° and remain liquid for a long time.

The corresponding hydrocarbon, *Patchoulin*, $C^{15}H^{24}$, is easily prepared from the camphor by the action of acids, but the best method is to heat the camphor to 100° for some hours with a mixture of glacial acetic acid and acetic anhydride. The upper layer consists of the hydrocarbon. It boils at 252° – 255° under 743 mm. pressure. It has no smell when pure, but oxidises easily and then acquires a resinous odour. Its density is 0.946 at 0° , and 0.937 at 13.5° . It turns the plane of polarised light strongly to the left; -7.45° for the line D, and -8.48° for the transition tint. Its dispersion is therefore equal to that of quartz, and its molecular rotatory power is $(\alpha) = -42^\circ 10'$. It does not combine with hydrochloric acid, and is destroyed by nitric acid. It most resembles essence of cubebs, but differs from it in not combining with hydrochloric acid.

PATTERSONITE. A variety of margarite accompanying corundum from Unionville, Pennsylvania. Sp. gr. = 2.81. Analysed by Genth (*Jahresb. f. Chem.* 1873, 1158):

SiO_2	Al_2O_3	Fe_2O_3	FeO	MgO	Na_2O	K_2O	Loss by ignition
29.90	27.59	3.12	9.17	17.10	0.58	2.33	11.51 = 101.30

PAYTINE, $C^{21}H^{20}N_2O.H^2O$, See CINCHONA-BASES (p. 497).

PECTEN. The muscular tissue of *Pecten irradians*, a mollusc found on the eastern coasts of the United States of America, and much prized as an article of food, has been found by N. H. Chittenden (*Sill. Am. J.* [3], x. 26) to contain considerable quantities of glycogen and glycocine. An analysis of the eatable portion gave:

	I	II
Water	79.60	80.25 p. c.
Solid parts	20.40	19.75
Ash	1.28	1.24
Nitrogenous Substance	15.68	15.04
Fat	0.33	0.32
Non-nitrogenous Substance	3.13	3.15

PECTOUS SUBSTANCES. E. Reichardt (*Arch. Pharm.* [3], x. 116) from a comparison of the earlier researches on the bodies of this group (iv. 363–370) infers that their composition differs but very slightly from that of the carbohydrates, and that the differences shown in some cases by the analyses may be attributed to impurities. Referring also to Scheibler's investigations on arabin and arabinose, and his own on pararabin (p. 119), he concludes that it is not advisable to place these bodies in a distinct group, but that they should be regarded as gelatinising carbohydrates, nearly related to the gums.

M. Giraud, on the other hand (*Compt. rend.* lxxx. 477), divides the mucilaginous or gummy substances of the vegetable kingdom into three groups: to the first of which belongs gum tragacanth, which is characterised by the presence of a body capable of yielding pectous substances; to the second, those which contain no pectous substances, and are rendered insoluble in water even by very dilute acids: an example of these bodies is afforded by quince-mucilage; and to the third group, those kinds of gum which are free from pectin, are not precipitated by dilute acids, but when heated therewith are converted into dextrin and sugar. All these substances are converted by heating with dilute acids into a crystallisable, non-fermentable sugar, which, therefore, is different from glucose. Gum tragacanth dissolves very slowly in cold water, but when treated with boiling water for twenty-four hours becomes perfectly

soluble and is converted into pectin. Gum-tragacanth, digested on the water-bath for three hours with acid of 1 per cent., is partly ($\frac{1}{10}$) converted into sugar, the greater portion, however, being converted into pectin. It therefore contains more than half its weight of a pectous substance, probably Frémy's pectose. By treating gum-tragacanth with 1 per cent. hydrochloric acid, precipitating with baryta, and decomposing the precipitate with hydrochloric acid, 60 per cent. of the weight of tragacanth employed is obtained as pectic acid, agreeing in its properties with that which Frémy prepared from fruits. A quantitative analysis of gum-tragacanth gave:

Water	20	p. c.
Pectous Substances	60	„
Soluble Gum	8 to 10	„
Cellulose	3	„
Starch	2 to 3	„
Mineral Substances	3	„
Nitrogenous Bodies	traces	„

PELAGOSITE. G. Tschermak (*Jahrb. f. Min.* 1878, 751) examined numerous specimens of limestone and dolomite from the Mediterranean coast, which were covered with a grey, shining, varnish-like substance, formed where the waves act upon the rock. No organised structure was observed, but a chemical examination proved it to consist mostly of calcium carbonate. The finest specimens of this substance came from the island of Pelagosa, in the Adriatic: whence its name. Descloizeaux a. Vélain observed this peculiar incrustation on feldspathic rocks in Corsica, on the coast of Oran, and on the basaltic lavas on the coast of Réunion.

PELARGONIC ACID, $C^8H^{17}.CO^2H$. This acid is found, together with its nitroso-derivative, $C^8H^{16}(NO)^2O^2$, amongst the products of the action of fuming nitric acid on *stearolic acid* (q.v.)

PELHAMINE. A black mass, resembling serpentine, occurring to the thickness of a foot in the asbestos mine of Pelham, Massachusetts; analysed by C. U. Shepard (*Sill. Am. J.* [3], xii. 231):

SiO ²	Al ² O ³	FeO	MgO	H ² O	Sp. gr.
38.40	2.80	15.52	39.88	3.40 = 100	2.9 to 3.2

PELLETIERINE. The alkaloid of the pomegranate. To obtain it, the bark of the tree is roughly powdered and mixed with milk of lime to a thick paste, which is washed with water; the liquid is shaken with chloroform, which dissolves the pelletierine; the chloroform solution is then treated with a dilute acid; and the solution of a salt of the alkaloid thus obtained is evaporated in a vacuum over sulphuric acid. To obtain the free base, the solution of one of its salts is treated with potassium carbonate and shaken with chloroform. The chloroform solution on evaporation leaves the alkaloid as a colourless oily mass, boiling at about 180°, and very soluble in water, alcohol, or ether, and especially in chloroform. It has an alkaline reaction, and precipitates most of the metals from their salts. It is precipitated by barium chloride, the precipitate being soluble in excess of the reagent. A precipitate is also formed by bromine water in excess; by Nessler's reagent; by iodide of potassium and cadmium, and by phosphomolybdic acid. The sulphate, nitrate, and hydrochloride of pelletierine are crystalline and extremely hygroscopic (Tanret, *Compt. rend.* lxxvi. 1270).

PENNINE. This mineral from the Zillerthal, where it occurs in transparent plates, sometimes uniaxial, sometimes biaxial, has been described by J. Rumpf and analysed by van Warvecke (*Min. Mitth.* 1873, 33). P. Groth (*Zeitschr. Kryst. i.* 509) refers the greenish mass (regarded by Delesse as pyrosclerite) which often occurs, together with nuclei of felspar, in the granular limestone near Markirch in Alsace, to Kennigott's pseudophite (iv. 744), and regards this latter, together with a greenish steatitic mineral, occurring in the primitive limestone of Flaben near Bodweis, and of Ckyn in Bohemia, as dense varieties of pennine.

Analyses.—1. From the Zillerthal (van Warvecke). 2. Pseudophite from Moravia (v. Hauer, *Wien. Akad. Ber.* xvi. 170). 3. Greenish mineral from Flaben (v. Drasche, *Jahrb. f. Min.* 1873, 1204). 4. A similar mineral from Ckyn (Genth, *ibid.*, 1874, 653).

SiO ²	Al ² O ³	Fe ² O ³	FeO	MgO	CaO	H ² O
1. 34.24	12.62	1.64	3.35	34.86	0.30	14.14 = 101.15
2. 33.42	13.42	—	2.58	34.04	—	14.68 = 93.14
3. 34.63	17.13	—	1.61	33.38	—	13.93 = 100.68
4. 35.31	18.28	1.26	0.83	31.61	—	13.26 = 100.55

PENTABROMACETONE, C^5HBr^5O . When phlorobromin, C^9HBr^9O (a product of the action of bromine on phloroglucinol), is dissolved in warm alcohol, and the solution, after standing for several hours, is mixed with a large quantity of cold water, an oil is precipitated, together with slender needles, which, after being pressed and recrystallised from alcohol or chloroform, have the composition of pentabromacetone. The compound thus prepared melts at 76° , and is crystallographically identical with that which is obtained directly from acetone, forming orthorhombic prisms having the axial ratio $a : b : c = 0.6182 : 1 : 0.6928$, and exhibiting the faces $P, \infty P_2, \infty P_\infty$. Pentabromacetone is converted by ammonia, either aqueous or alcoholic, into dibromacetamide (Benedikt, *Liebig's Annalen*, clxxxix. 165).

PENTA-, TETRA-, and HEXBROMANTHRACENE. *Tetrabromanthracene* (vi. 178), exposed to the vapour of bromine for some days, is converted into *tetrabromanthracene tetrabromide*, $C^{14}H^6Br^4$, which crystallises from a hot saturated solution in carbon bisulphide in distinct, colourless prisms melting, with decomposition, at about 212° ; and this compound, heated to 230° till it ceases to give off bromine and hydrogen bromide, yields *pentabromanthracene*, $C^{14}H^5Br^5$, a pulverulent yellow substance which melts at 212° , dissolves sparingly in alcohol and ether, easily in benzene, toluene, and carbon sulphide, and is converted by oxidation with chromic acid into *tribromanthraquinone*, a body subliming in broad needles and melting at 365° .

Hexbromanthracene, $C^{14}H^4Br^6$, is formed, with violent reaction, when tetrabromanthracene tetrabromide is heated with alcoholic soda. It is but sparingly soluble in all solvents, and crystallises from petroleum (b. p. 130° – 160°) in golden-yellow silky needles, which may be sublimed, but do not melt even at 370° . By oxidation with chromic acid it is converted into *tetrabromanthraquinone*, $C^{14}H^4Br^4O^2$, which may be purified and crystallised in small needles from solution in carbon sulphide, but separates from all other solvents in the form of powder (Hammerschlag, *Ber.* x. 1212).

PENTABROMAZONAPHTHALENE. See AZONAPHTHALENE, under NAPHTHALENE.

PENTACETYL-GALACTOSE, $C^6H^7(C^2H^3O)^5O^6$. See GALACTOSE, under SUGARS.

PENTACETYL-SULPHOTANNIC ACID, $C^{12}H^4(C^2H^3O^2)^3(SO^2H)SO^3$. See TANNIC ACIDS.

PENTACHLOROBUTYLENE, $C^4H^3Cl^5$, is formed, together with other chlorinated compounds, by the action of chlorine on tertiary butyl alcohol (p. 360).

PENTACHLORONAPHTHALENE. See NAPHTHALENE.

PENTAMETHYLETHOL, or *Dimethyl-katabutyl Carbinol*, $C(CH^3)^3.C(CH^3)^2OH$. See HEPTYL ALCOHOLS (p. 1026).

PENTANES, C^5H^{12} . *Boiling Points.*—Normal pentane, $CH^3.(CH^2)^3.CH^3$, boils at 38° , isopentane, $CH^3.CH^2.CH(CH^3)^2$, at 30° , tetramethyl-ethane, $C(CH^3)^4$ at 9.5° (A. Naumann, *Ber.* vii. 173).

Isopentane (amyl hydride) in aqueous solution (1 c.c. to 2 litres of water) mixed with half its volume of chromic acid mixture (500 pts. water, 5 crystallised chromic anhydride, and 1 potassium dichromate) and left for five weeks at a temperature of 15° – 20° , was found to be converted into valeric acid (Berthelot, *Compt. rend.* lxxix. 1435).

Pentane from petroleum, and inactive isopentyl chloride, are converted by *chromyl chloride*, CrO^2Cl^2 , into chlormethyl-isopropyl ketone, $CH^3Cl.CO.CH(CH^3)^2$ (Etard; see KETONES, p. 1148).

PENTAPHENYLCHLORETHANE, $C(C^6H^5)^3.CCl(C^6H^5)^2$, is formed, together with diphenyl, by the action of monobromobenzene on carbon tetrachloride, the two substances being dissolved in ether, and sodium introduced into the solution, and may be extracted from the crude product by distilling off the ether and boiling the residue with alcohol. It melts between 120° and 125° , boils above 340° , and yields a nitro-derivative when treated with nitric acid (Guareschi, *Gazz. chim. ital.* 1877, 409).

PENTATHIONIC ACID. See SULPHUR, OXYGEN-ACIDS OF.

PENTIC ACID, $3C^5H^8O^2 + H^2O$, and **PENTENIC ACID**, $3C^5H^8O^3 + H^2O$. The compounds so-called by Demarçay (not true acids) are formed by the action of 1 and 2 mol. bromine respectively on 1 mol. ethylic ethylacetacetate, in the same manner as the homologous compounds hexic and hexenic acids are formed from ethylic acetovalerate (p. 1501). Ethylic methylacetacetate, treated with bromine in like

manner, yields tetric acid, $3\text{C}^4\text{H}^4\text{O}^2 + \text{H}^2\text{O}$, and tetronic acid, $3\text{C}^4\text{H}^4\text{O}^3 + \text{H}^2\text{O}$. Tetric acid, m. p. 150° , and pentic acid, m. p. 189° – 190° , crystallise readily, and their aqueous solutions are reddened by ferric chloride. The reaction, indeed, appears to be general for compounds of this series (Demarçay, *Bull. Soc. Chim.* [2], xxvii. 483).

PENTINE, C^5H^8 . *Valerylène*.—This hydrocarbon is known in three modifications, viz.:

(1). $(\text{CH}^3)^2\text{C}=\text{C}=\text{CH}^2$. This is the compound which Reboul obtained by heating amylene bromide with alcoholic potash (v. 981):

It has a sp. gr. of 0.700; boils at 45° ; does not form compounds with silver or copper.

(2). *Propyl-acetylene*, $\text{CH}^3.\text{CH}^2.\text{CH}^2.\text{C}\equiv\text{CH}$, is formed in like manner by abstraction of 2HCl from propyl-methyl ketonic chloride, $\text{C}^3\text{H}^7.\text{CCl}^2.\text{CH}^3$. It boils at 50° , and yields metallic derivatives with silver and copper (Friedel).

(3). *Isopropyl-acetylene*, $(\text{CH}^3)^2\text{CH}.\text{C}\equiv\text{CH}$. Produced: *a.* By converting valeraldehyde, $(\text{CH}^3)^2\text{CH}.\text{CH}^2.\text{CHO}$, into the corresponding chloride, $(\text{CH}^3)^2\text{CH}.\text{CH}^2.\text{CHCl}^2$, by means of phosphorus pentachloride, and removing 2HCl from this chloride by the action of potash (Bruylants, *Ber.* vii. 759). *B.* By the action of alcoholic potash on the chloride of isopropylethylene, $(\text{CH}^3)^2\text{CH}.\text{CHCl}.\text{CH}^2\text{Cl}$ (Eltehoff, *Ber.* x. 707). It boils at 35° ; gives with ammoniacal copper solution a yellow precipitate; with ammoniacal silver solution, on heating, an amorphous white precipitate, which is lighter than water and is but little affected by light. When treated with a solution of iodine in potassium iodide, it takes up 2 at. iodine, and is converted into isopropyl-acetylene di-iodide, $(\text{CH}^3)^2\text{CH}.\text{CI}=\text{CHI}$, which boils without decomposition at 140° , is but very slightly affected by light, and is reconverted by sodium ethylate into isopropylacetylene. Sodium dissolves in isopropylacetylene, with evolution of hydrogen and formation of a compound which crystallises in large plates, but falls to powder in contact with the air, and is reconverted by water into isopropylacetylene (Eltehoff).

PENTIOIC ACIDS, $\text{C}^5\text{H}^{10}\text{O}^2 = \text{C}^4\text{H}^9.\text{COOH}$. 1. **Normal Pentic Acid**, $\text{CH}^3.(\text{CH}^2)^3.\text{COOH}$. This acid, which Lieben a. Rossi obtained by oxidation of normal pentyl alcohol (vii. 1197), is also produced by heating normal hexoic (caproic) acid, $\text{CH}^3.(\text{CH}^2)^4.\text{CO}^2\text{H}$, in a water-bath with 1 mol. bromine, whereby it is converted into α -bromocaproic acid, $\text{CH}^3.(\text{CH}^2)^3.\text{CHBr}.\text{CO}^2\text{H}$; then adding sodium carbonate to permanent alkaline reaction; decomposing with sulphuric acid; dissolving out the resulting α -hydroxycaproic or normal leucic acid, $\text{CH}^3.(\text{CH}^2)^3.\text{CHOH}.\text{CO}^2\text{H}$, with ether; then expelling the ether, oxidising with chromic acid mixture, $[\text{C}^6\text{H}^{12}\text{O}^3 + \text{O}^2 = \text{C}^6\text{H}^{10}\text{O}^2 + \text{CO}^2 + \text{H}^2\text{O}]$, and distilling. The volatile acid contained in the distillate exhibits all the properties of the normal pentic acid described by Lieben a. Rossi (Erlenmeyer, *Ber.* ix. 1840).

Normal Ethyl Pentoate, $\text{CH}^3.(\text{CH}^2)^3.\text{COOC}^2\text{H}^5$, boils, under a pressure of 736.5 mm. reduced to 0° , at 114.6° (corr.). Its sp. gr., referred to water at equal temperatures, is 0.894 at 0° , 0.8765 at 20° , and 0.8616 at 40° (Lieben a. Rossi, *Liebig's Annalen*, clxv. 117).

2. **Isopentic, Isopropyl-acetic, Isobutyl-formic, Valeric, or Valerianic Acid**, $(\text{CH}^3)^2\text{CH}.\text{CH}^2.\text{COOH}$. This acid has been found by O. Jacobsen in geranium-oil (*Liebig's Annalen*, clvii. 232).

Preparation.—According to O. Ficin (Arch. Pharm. [3], iii. 219), dilute valeric acid may be formed by a continuous oxidation-process similar to that adopted for vinegar making (i. 8), the acidifier being filled with chopped valerian-root, and dilute fusel-oil repeatedly passed through it, the temperature being kept between 30° and 40° . The process, however, is mentioned as being merely of scientific interest, and not advantageous in practice. On the formation of valeric acid by oxidation of paraffin, see p. 1489.

For the preparation of pure valeric acid, H. Lescœur (*Bull. Soc. Chim.* [2], xxvii. 104) takes advantage of its property to form acid salts with potash and soda. A molecule of the neutral salt is mixed with 2 mol. of valeric acid; the acid salt is left to crystallise in the cold; the crystals are dried; and the acid separated from them by distillation. The pure acid begins to pass over a little above 200° , and the distillation should be stopped when the temperature rises to 300° .

According to Balbiano (*Gazz. chim. ital.* 1876, 229, 402), valeric acid, prepared from inactive amyl alcohol, boils at 174.1° under a pressure of 724 mm. (compare Erlenmeyer a. Hell, vii. 1199).

According to C. Schacht (*Arch. Pharm.* [3], ii. 97), *bismuth valerate* has the composition $\text{C}^5\text{H}^9\text{BiO}^4 = (\text{C}^5\text{H}^9\text{O}^2)^4.\text{Bi}^3(\text{OH})^3$.

On the sp. gr. of valeric acid and its ethers at different temperatures, see Pierre a. Puchot (vii. 1200).

Ethylic Acetovalerate, $C^2H^{16}O^2 = CH^3.CO.CH(C^2H^7).CO.O.C^2H^5$ (Demarçay, *Compt. rend.* lxxxiii. 449; *Bull. Soc. Chim.* [2], xxvii. 483). This acid is formed by the action of isopropyl iodide on ethylic acetosodacetate:

It boils at $200^\circ-202^\circ$ under a pressure of 758 mm.; colours ferric chloride pale violet. Bromine acts strongly on it; the action requires to be moderated by cooling. On adding 1 mol. bromine to 1 mol. of the ether, treating the oily product with alcoholic potash, and then adding hydrochloric acid, a body separates, which appears under the microscope to consist of elongated rectangular plates, and has the composition $3C^2H^5O^2 + H^2O$. This compound, called by Demarçay hexic acid, melts at $123^\circ-124^\circ$, boils with slight decomposition at about 263° , is slightly soluble in cold, moderately soluble in boiling water, easily in alcohol, ether, and chloroform, and separates from the ethereal solution in crystals several centimeters long. It is not a true acid, as it does not form salts, and the product obtained by treating it with phosphorus pentachloride is not decomposed by water.

1 mol. acetovaleric ether and 2 mols. bromine yield the compound $3C^2H^5O^2 + H^2O$, called hexenic acid, which is difficult to purify, melts at 187° , and boils with decomposition at $270^\circ-280^\circ$, yielding an oily distillate reconvertible by water into the original compound. The so-called hexenic acid is sparingly soluble in cold, freely in boiling water, also in alcohol and ether, very slightly soluble in chloroform.

Methyl-ethylacetic Acid, $(CH^3)(C^2H^5)CH.COOH$. The preparation of the ethylic ether of this acid by distilling ethylic methyl-ethylacetacetate with sodium ethyl has already been described (p. 15). The acid obtained from it boils at 173° , and resembles ordinary optically active valeric acid in every respect excepting that it forms an amorphous barium salt (Saur, *Ber.* vii. 1037).

Trimethylacetic Acid, $(CH^3)^3C.COOH$, also called *Pivalic Acid*. This acid, which Butlerow obtained by saponification of katabutyl cyanide, $(CH^3)^3C.CN$ (vii. 1182), is also produced by oxidation of methyl-katabutyl ketone (pinacolin), $(CH^3)^3C.CO.CH^3$ (p. 1148), with chromic acid mixture (Friedel a. Silva, *Compt. rend.* lxxvii. 48). When separated from its sodium salt by sulphuric acid, it forms a crystalline mass which gradually becomes granular. The crystals belong to the regular system, as they do not exhibit double refraction. The acid dissolves in 46 pts. of water at 20° . It melts, according to Butlerow, at $34^\circ-35^\circ$; according to Friedel a. Silva at 30° after repeated partial fusion. It is separated from its salts even by acetic acid. The *potassium salt* is deliquescent. The *sodium salt*, $C^3H^9O^2Na + 2H^2O$, gives off its water of crystallisation on exposure to dry air, and, as well as the potassium salt, forms after fusion a laminar mass like the acetates (Friedel a. Silva); according to Butlerow, the sodium salt crystallises in flat prisms, very soluble in alcohol. The *barium salt*, $(C^3H^9O^2)^2Ba + 5H^2O$, and the *calcium salt*, $(C^3H^9O^2)^2Ca + 4H^2O$, form silky very soluble needles. The *silver salt* is obtained by precipitation in small laminæ. The *copper salt*, $(C^3H^9O^2)^2Cu + H^2O$, is obtained by decomposing a soluble trimethylacetate with copper sulphate, as a heavy crystalline green precipitate, requiring more than 500 pts. water to dissolve it. The solution when evaporated leaves blue scales, consisting of a basic salt, which is also obtained by prolonged washing of the normal salt. The latter is obtained in the state of greatest purity by the action of free trimethylacetic acid on cupric carbonate. It gives off its water in a vacuum at ordinary temperatures. It may be freed from basic salt by solution in alcohol of 95 per cent., from which it crystallises in dark bluish-green prisms apparently having the composition $(C^3H^9O^2)Cu + H^2O + \frac{1}{2}C^2H^5O$; it is likewise soluble in ether. It sublimes when heated (Friedel a. Silva). The *zinc salt* is a white crystalline powder, unctuous to the touch, slightly soluble in water (Butlerow).

Friedel a. Silva resrepresent pinacolin and its product of oxidation (pivalic acid) by the following formulæ:

But pinacolin being formed by the action of zinc-methyl on trimethyl-acetyl chloride, has much more probably the constitution of methyl-katabutyl ketone assigned to it by Butlerow (p. 1148), and may therefore be expected to be converted by oxidation into trimethyl-acetic acid. And, in fact, the only important difference between Butlerow's acid and the pivalic acid of Friedel a. Silva consists in the lower melting

point of the latter, which, as they observe, may have been due to a slight admixture of acetic acid, inasmuch as the lowest melting fractions yielded a silver salt, the percentage of silver in which was somewhat too high for the formula $C^5H^9O^2Ag$.

PENTOIC ALDEHYDE, $C^5H^{10}O$. See VALERAL.

PENTYL ALCOHOLS, $C^5H^{12}O = C^5H^{11}.OH$. These compounds have hitherto been described as *amyl alcohols* (i. 203; vi. 106–114; vii. 62; viii. 75–78); but it is better to designate them generally as *pentyl alcohols*, a term which indicates their place in the series of alcohols $C^nH^{2n+1}OH$, and restrict the term *amyl alcohol* to the one which has long been known by that name, viz., isopentyl carbinol, $(CH^3)_2CH.CH^2.CH^2OH$, the first discovered of the group. The following are the most recent additions to our knowledge of these bodies.

According to Wischnegradsky (*Liebig's Annalen*, exc. 328), the *amyl alcohol* of fermentation is a mixture of isopentyl alcohol (isobutyl-carbinol) with small quantities of normal pentyl alcohol and methyl-ethyl carbinol, which he regards as the optically active constituent.

The following dextrorotatory amylic ethers have been prepared by J. A. le Bel (*Bull. Soc. Chim.* [2], xxi. 542) from laevorotatory *amyl alcohol*:

Chloride.	B.-p. 97°–99°	$[\alpha]_D = +1.24$
Bromide.	„ 117°–120°	$[\alpha]_D = +3.75$
Iodide.	„ 144°–145°	$[\alpha]_D = +5.34$ to 5.12

Methyl-amyl and amylene from active *amyl alcohol* are inactive.

Methyl-isopropyl Carbinol, $CH^3.CHOH.CH(CH^3)_2$ (Winogradoff, *Liebig's Annalen*, exci. 125). This secondary alcohol is formed by acting on zinc-methyl with bromoacetyl-bromide, and treating the product with water. To avoid explosions, it is best to pour the acid bromide (1 mol.) into the zinc-methyl (3 mols.) through a tap-funnel, the neck of which dips into the liquid. The mixture, after being left to itself for some weeks, is mixed with water and hydrochloric acid and distilled; and the chief product (50 per cent. of the theoretical quantity) which passes over between 110° and 120°, is treated first with anhydrous baryta, and then with sodium, in order to remove the last portions of water and bromine.

On the mechanism of the reaction, see the original paper, and *Chem. Soc. J.* xxxiv. 485.

Methyl-isopropyl carbinol thus obtained is a liquid having a faint odour, easily soluble in water, boiling at 113°, and not solidifying at –33°. Its specific gravity is 0.8308 at 0°, and 0.8219 at 19°. With *bromine* it yields an amylene. By *phosphorus pentachloride*, and by gaseous *hydrogen iodide* with aid of heat, it is converted into tertiary pentyl chloride and iodide (*infra*).

Dimethyl-ethyl Carbinol, $(CH^3)_2(C^2H^5)COH$. In the preparation of this tertiary alcohol by distilling 5 grams of commercial amylene with sulphuric acid (2 vols. H^2SO^4 to 1 vol. water), Butlerow (*Ber.* x. 81) obtained two grams of the pure alcohol (comp. p. 81). It melts at –12°, and boils at 102°–104°. The corresponding *chloride* boils at 86°, the *bromide* between 108° and 109°, the *iodide* between 127° and 128° (Wischnegradsky, *Liebig's Annalen*, exc. 331).

PENTYL-GLYCOLS or PENTYLENE ALCOHOLS. Three of these compounds are known, and have been already described (i. 208, and pp. 81 and 82 of this volume), viz.:

Trimethyl glycol, $(CH^3)_2COH.CHOH.CH^3$	B.-p. 177°
Methyl-ethyl glycol, $(C^2H^5).CHOH.CHOH.CH^3$	187.5°
Isopropethylene glycol, $CH(CH^3)_2.CHOH.CH^2OH$	206°

PENTYLENES, C^5H^{10} . *Amylenes*.—Three of these hydrocarbons have already been described (p. 79), viz.:

Isopropylethylene, $H^2C=CH[CH(CH^3)_2]$.
 Methyl-ethyl-ethylene, $H^2C=C(CH^3)(C^2H^5)$.
 Trimethyl-ethylene, $(CH^3)_3C=CH(CH^3)$.

(1). According to Wischnegradsky (*Ber.* x. 81; *Liebig's Annalen*, exc. 328), Flavitzky's amylene, boiling at 25°, is a mixture of two isomeric hydrocarbons: for when the iodide obtained from ordinary *amyl alcohol* (rot. power = +2.9°) is treated with alcoholic potash, a hydrocarbon is formed, having a variable boiling point (23°–27°), and from this, on agitation with sulphuric acid, a third hydrocarbon is dissolved, while an amylene boiling at 21°–22° (regarded by Wischnegradsky as *isopropylethylene*) remains behind. The same hydrocarbon (boiling at 21.5°–22°, and behaving similarly with sulphuric acid) is also formed from the comparatively inactive

amyl iodide (rot. power = +0.3 (which is obtained, together with ethyl iodide, by the action of hydriodic acid on amyl-ethyl oxide). (2). Ordinary (commercial) amylene, obtained by the action of zinc chloride on ordinary amyl alcohol, appears to contain three pentylenes, viz., trimethyl-ethylene, unsymmetrical methyl-ethyl-ethylene, $\text{H}^{\text{c}}\text{C}=\text{C}(\text{CH}^{\text{s}})(\text{C}^{\text{c}}\text{H}^{\text{s}})$, and normal propyl-ethylene. The pentylene prepared from ordinary amyl chloride contains two isomerides, viz., unsymmetrical methyl-ethylene and isopropyl-ethylene.

The presence of isopropyl-ethylene in the amylene boiling at 25° is further confirmed by the experiments of Eltekoff (*Ber.* x. 707), from which it appears that the bromide of this amylene, when treated with alcoholic potash, yields, together with ethyl-valeryl oxide (b.p. 111° – 114°), a pentine or valerylene, $\text{C}^{\text{c}}\text{H}^{\text{s}}$, having the constitution of isopropyl-acetylene, $\text{HC}\equiv\text{C}-\text{CH}(\text{CH}^{\text{s}})^2$ (p. 1500).

Oxidation.—The products obtained by the action of various oxidising agents on amylene have been examined by F. Zeidler (*Liebig's Annalen*, clxxxvi. 245). (1). *Amylene*, b.p. 35° (from optically active amyl alcohol, with stannic chloride), yielded with potassium permanganate in neutral or alkaline solution: carbonic, formic, acetic, and succinic acid; with permanganate in sulphuric acid solution: carbonic, butyric, propionic, acetic, oxalic acids; with potassium dichromate and sulphuric acid: carbonic, butyric, acetic, and propionic acids; with chromic acid: carbonic acid, acetic acid, a higher fatty acid, and succinic acid; with potassium iodate in acid solution: carbonic and acetic acid. (2). *Amylene*, b.p. 22° – 23° (from the hydriodic ether of optically active amyl alcohol with alcoholic soda), yielded with potassium permanganate in neutral or alkaline solution: carbonic, acetic, butyric, propionic (?), oxalic, and succinic acids; in acid solution: carbonic, acetic, higher fatty acids, a small quantity of succinic and a large quantity of oxalic acid; with potassium dichromate and sulphuric acid, or with chromic acid: carbonic, acetic, propionic, and butyric acids; with potassium iodate: carbonic and acetic acids; with nitric acid: carbonic acid, acetic acid, and a nitro-derivative. (3). *Amylene*, b.p. 33° , from ethyl-amyl oxide with phosphoric anhydride, yielded with potassium permanganate in neutral acid or alkaline solution: carbonic, acetic, and oxalic acids; with potassium dichromate and sulphuric acid or with chromic acid: carbonic, acetic, and propionic acids; with potassium iodate or nitric acid: carbonic and acetic acids.

PEPPER. The amounts of moisture, ash, and nitrates (reckoned as nitric acid), also of alcoholic and aqueous extract in the kinds of pepper most frequently met with in commerce, have been determined by A. Wynter Blyth (*Chem. News*, xxxii. 140) with the following results:

	Moisture	Soluble ash	Total ash	Nitric acid	Alcoholic extract	Aqueous extract
Penang . . .	9.531	2.212	4.189	0.0447	7.650	18.335 p.c.
Tellicherry . .	12.908	3.380	5.770	0.0886	7.896	16.500 "
Sumatra . . .	10.103	2.626	4.316	0.0656	6.450	17.500 "
Malabar . . .	10.548	3.453	5.195	0.0386	6.375	20.375 "
Trang . . .	11.664	2.538	4.775	0.1187	6.300	18.175 "

The ash of Tellicherry pepper was found to have the following composition:

K ² O	Na ² O	MgO	CaO	Fe	P ² O ⁵	SO ²	Cl	CO ²	Sand
24.38	3.23	13.00	11.60	0.30	8.47	9.61	7.57	14.00	6.53 = 98.69

H. Pocklington (*Pharm. J. Trans.* [3], v. 681) found in three sorts of commercial pepper from 50 to 60 per cent. of foreign substances, consisting of arrow-root, rice-starch, wheat-flour, pea-flour, and oatmeal.

On the adulterations of pepper, see also Landrin (*Monit. Scient.* vi. 883).

PEPPERMINT OIL. According to J. Moss (*Pharm. J. Trans.* [3], v. 566), Japanese peppermint-oil begins to boil at 206° , the temperature then remaining constant for some time, and ultimately rising to 218° . The oil did not deposit any crystals when cooled. The camphor or steareptene of Japanese peppermint-oil melts at 30° , resolidifies at 37.5° , and boils at 215° ; compare Oppenheim (iii. 880). According to J. Mackay (*Pharm. J. Trans.* [3], v. 825), 1 pt. of the Japanese oil dissolves readily at ordinary temperatures in 8 pts. of rectified spirit. The liquid oil easily dissolves the camphor, and deposits it in crystals when cooled. Peppermint-camphor distilled with zinc chloride yields menthene, $\text{C}^{10}\text{H}^{18}$ (Beckett a. Wright, p. 1274).

According to C. Jehn (*Arch. Pharm.* [3], iii. 29), peppermint-oil in contact with

chloral hydrate gradually assumes a dark cherry-red colour, which is easily transferred to ether, alcohol, and chloroform, is not destroyed by boiling, but becomes darker on addition of a small quantity of sulphuric acid; and on subsequent addition of chloroform, acquires a shade more inclining to dark violet. This reaction is not exhibited by other volatile oils. Danin von Wassowicz (*ibid.* xi. 510) has examined the action of chloral hydrate on seven varieties of peppermint-oil, viz.: 1. French; 2. English (Mitcham); 3. American; 4. German; 5. From *Mentha piperita*, cultivated in Galicia; 6. An older English sample diluted with an equal volume of alcohol; 7. A viscid, dark-yellow American oil. 1, 2, 5, 6, and 7 exhibited no coloration after five minutes; 3 after the same time was coloured light violet; 4, yellowish-brown. After the lapse of an hour, only 2, 5, and 6 remained uncoloured. When heated, all the varieties became coloured, and coloration was likewise immediately produced, when an impure chloral hydrate containing hydrochloric acid was used as the reagent.

According to E. B. Shuttleworth (*Dingl. pol. J.* ccviii. 464; *Amer. J. Pharm.* 1872, xlv. 171), American peppermint-oil is sometimes adulterated with alcohol and castor oil.

According to M. A. Frebault (*Pharm. J. Trans.* [3], iv. 977), peppermint-oil treated with picric, sulphuric, hydrochloric, or nitric acid, especially the first, yields a green substance which exhibits red fluorescence, and agrees in many of its reactions with chlorophyll.

PEPSIN. E. Scheffer (*Pharm. J. Trans.* [3], ii. 761, 783, 843) prepares pepsin by macerating the mucous membrane of pigs' stomachs for several days with water containing hydrochloric acid, and mixing the liquid, after it has been strained and left to clarify for 24 hours, with an equal volume of a saturated solution of common salt; the pepsin which rises to the surface is skimmed off after a few hours, then pressed and dried without application of heat. The stiff, hard, straw- to brown-yellow substance thus obtained contains a certain quantity of mucus and small quantities of calcium phosphate and sodium chloride, which however do not interfere with its action. Sweetened pepsin is prepared by mixing recently pressed pepsin with pulverised milk-sugar, and drying the mixture by exposure to the air. The milk-sugar by its antiseptic properties may perhaps conduce to the preservation of the pepsin. The aqueous solution of pepsin quickly decomposes. The digestive power of pepsin may be tested by noting the time required for dissolution, under its influence, of a given quantity of coagulated white of egg at a given temperature. The last portions of albumin require for their disappearance a proportionately longer time, even when the pepsin is present in excess. 1 grain of purified pepsin in 4 ounces of salt water dissolved 400 grains of albumin in 18 hours at 24°.

According to H. Seldon (*Pharm. J. Trans.* [3], iv. 89), the yield of pepsin by Scheffer's method is considerably increased if the digestion of the mucous membrane with dilute hydrochloric acid be performed at 37°. Scheffer's pepsin is contaminated with syntonin, and perhaps also with other proteids. Durable preparations may be obtained by trituration with milk-sugar or solution in glycerin.

Various kinds of pepsin are described by E. Rennard (*Russ. Zeitschr. Pharm.* 1874, 577; *Jahresb. f. Chem.* 1874, 944).

Volumetric Estimation.—Pepsin may be estimated volumetrically by means of fibrin which has been coloured through and through with an ammoniacal solution of carmine. This coloured fibrin may be preserved in glycerin, and when required for experiment, must be carefully freed from glycerin by rinsing with water, cut up with scissors, and drenched with a five-fold quantity of hydrochloric acid. In this manner a crimson, translucent, gelatinous mass is obtained, which must be divided into portions of equal size, best on bibulous paper, which absorbs the excess of acid. On drenching these separate portions of coloured fibrin with pepsin-solutions of various strength, red liquids are obtained, the coloration being deeper and quicker as the pepsin-solution is stronger, so that it is easy to distinguish strong from weak solutions of pepsin, and possible to apply the method for quantitative estimation (P. Grützner, *Zeitschr. anal. Chem.* 1874, 106).

PEPTONES. See **PROTEIDS**.

PERBROMETHANE or **HEXBROMETHANE**, C^2Br^6 , is formed, together with other products, by heating mucobromic acid (vii. 828) with bromine and water to 120°–130° in sealed tubes:

It crystallises from carbon sulphide in thick colourless prisms, which are insoluble in alcohol and decompose at 200°–210° (Delbrück, *Liebigs Annalen*, clxv. 253).

PERBROMIC ACID, BrHO^4 . Muir in 1874 described the formation of this acid by agitating bromine with aqueous perchloric acid (p. 351). Subsequent experiments however failed to yield the same result, so that the conditions under which the formation of this acid takes place cannot yet be considered as satisfactorily established (Muir, *Chem. Soc. J.* 1876, xxx. 469). The formation of perbromic acid by the action of bromine on perchloric acid was previously announced by Kämmerer in 1863 (iv. 374); his results have however been called in question by R. W. E. Macivor (*Chem. News*, xxxiii. 35).

PERBROMOBENZENE, C^6Br^6 . On the formation of this compound from benzene, and on its properties, see BENZENE-DERIVATIVES (p. 170). According to E. Wall (*Ber.* ix. 1649), bodies of the fatty series, when subjected to exhaustive bromination with iodised bromine, yield in the first instance perbromomethane, which by prolonged heating to its boiling point, or to 300° in a sealed tube, is converted into perbromobenzene.

PERBROMOMETHYLMERCAPTAN, $\text{CSBr}^4 = \text{CBr}^3\text{SBr}$, is formed in small quantity when carbon disulphide mixed with bromine and a little iodine is left under water for a few minutes, and remains after the carbon sulphide and bromine have been distilled off on the water-bath, as a yellowish liquid, which smells like perchloromethylmercaptan (*infra*), distils at 150° , and acts on potassium sulphide even more violently than the chlorine-compound, forming methylmercaptantrisulphonate and bromide of potassium (Rathke, *Liebig's Annalen*, clxvii. 195).

PERBROMOPHENOL, $\text{C}^6\text{Br}^5\text{OH}$ (m. p. 225°), formed from phenol by the action of iodised bromine, is converted by heating with PBr^5 into perbromobenzene (Gessner, *Ber.* ix. 1505; Ruoff, *ibid.* x. 1234).

PERCHLORETHANE, $\text{Cl}^3\text{C.CCl}^3$. This body is formed: α . Together with perchloromethane, by heating propane or propyl chloride (b. p. 46.5°) with iodine chloride to 100° – 200° in a sealed tube, which is frequently opened to allow the resulting hydrogen chloride to escape, and then filled with chlorine gas (Krafft a. Merz, *Ber.* viii. 1296; see p. 1066). β . By the action of iodine trichloride on propionic acid: $\text{C}^2\text{H}^3\text{CO}^2\text{H} + 4\text{ICl}^3 = \text{C}^2\text{Cl}^4 + \text{CO}^2 + 6\text{HCl} + 2\text{I}^2$ (Krafft, *Ber.* ix. 1085). γ . Together with perchlorobenzene, by exhaustive chlorination of diphenyl-trichlorethane, $(\text{C}^6\text{H}^5)^2\text{CH.Cl}^3$ (Ruoff, p. 1066). δ . Together with perchloromethane and perchlorobenzene, by heating chrysene with antimony pentachloride (Ruoff, *Ber.* x. 1234).

Perchlorethane melts at 179° (Geuther a. Brockhoff, *J. pr. Chem.* [2], vii. 108).

Reaction with Sodium Ethylate.—When perchlorethane (1 mol.), dissolved in ether, is heated with sodium ethylate free from alcohol (6 mol.) in a reflux apparatus, to the upper end of which is attached a glass tube dipping 250 cm. deep into mercury, a reaction commences at about 110° , after the greater part of the ether has distilled off, attended with evolution of a combustible gas; and afterwards a liquid distils over, consisting of alcohol, perchlorethylene, C^2Cl^4 , trichlorethoxyethylene, $\text{CCl}^2 = \text{CCl}(\text{OC}^2\text{H}^5)$, and triethylic dichloracetate, $\text{CHCl}^2\text{C}(\text{OC}^2\text{H}^5)^2$, the last two products being due to the reaction between sodium ethylate and perchlorethylene (p. 754). The residue of the distillation contains unaltered sodium ethylate, sodium acetate, sodium ethylglyoxylate, $\text{CH}^2(\text{OC}^2\text{H}^5)\text{CO}^2\text{Na}$, a small quantity of sodium oxalate, and two resinous compounds, one of which separates on treatment with water, while the other is precipitated on addition of hydrochloric acid. In this reaction the perchlorethane probably first acts on the sodium ethylate, forming sodium acetate, perchlorethylene, and ethane, according to the equation:

and the perchlorethylene then acts further on the sodium ethylate in the manner above indicated (Geuther a. Brockhoff, *J. pr. Chem.* [2], vii. 101).

PERCHLORETHYLENE, C^2Cl^4 . *Carbon dichloride*.—This compound is formed, together with perchloromethane, by heating perchloropropane to 300° ; $\text{C}^3\text{Cl}^8 = \text{C}^2\text{Cl}^4 + \text{CCl}^4$ (Krafft a. Merz, *Ber.* viii. 1045). It may be prepared by heating perchlorethane, mixed with twice its weight of aniline to 170° (Bourgoir, p. 754).

On the reaction of perchlorethylene with sodium ethylate, and on perchlorethylene dibromide or dibromotetrachlorethane, see also p. 754.

PERCHLORIC ACID. According to T. Fairley (*Brit. Assoc. Reports*, 1874, 58), hypochlorous acid and its salts are converted into perchloric acid and perchlorates by passing ozonised air through their solutions.

On the Perchlorates of Potassium and Bismuth, see p. 450.

PERCHLOROBENZENE, C^6Cl^6 , is formed in the exhaustive chlorination of various hydrocarbons of the aromatic series with chlorine containing iodine (p. 1066);

also in the chlorination, by similar means, of secondary hexyl iodide (from mannite) (Krafft, *Ber.* ix. 1085); and, together with perchloromethane and perchlorethane, by heating chrysene with antimony pentachloride (Ruoff, *Ber.* x. 1234).

PERCHLORODIPHENYL, $\text{C}^{12}\text{Cl}^{10}$, is formed by exhaustive chlorination of diphenyl (Ruoff); also of diphenol, benzidine (diamidodiphenyl), and carbazol or diphenylimide, $\text{NH}(\text{C}^6\text{H}^4)^2$ (Zetter, *Ber.* x. 1233).

PERCHLOROMESOL. This name is given by Krafft to a chloride of carbon, C^4Cl^6 , which is commonly produced, together with the perchlorinated derivatives of methane, ethane, and benzene, in the perchlorination of fatty bodies. It is insoluble in water, but, dissolves in alcohol, and crystallises therefrom in thin shining prisms, melting at 390° . It boils, with decomposition and evolution of chlorine, at 283° – 284° (mercury column wholly in the vapour; bar. 377 mm.)

PERCHLOROMETHANE, CCl^4 . *Carbon Tetrachloride*.—This compound is formed, together with carbon dioxide, by the action of iodine trichloride on trichloroacetic acid (Krafft, *Ber.* ix. 1085); also, together with perchlorethane or perchlorobenzene, or both, by the action of iodine trichloride or of chlorine and iodine on various hydrocarbons (p. 1066); and, together with perchlorethylene, C^2Cl^4 , by the decomposition of perchloropropane at 300° (p. 1505). The action of perchloromethane on sodium ethylate is not very definite, yielding merely two brown compounds together with sodium carbonate and a little oxalate.

PERCHLOROMETHYL-MERCAPTAN, $\text{CCl}^3\text{S} = \text{CCl}^3\text{SCl}$, is formed, as already described (vii. 266), together with trichloromethylsulphurous chloride, by the action of dry chlorine on carbon disulphide. It is an oily liquid boiling at 147° (corr.), and having a sp. gr. of 1.712 at 12.8° (referred to water at 0°). Heated to 160° with zinc chloride, it deposits a considerable quantity of sulphur in crystals, and yields zinc chloride, perchloromethane, carbon disulphide, and a small quantity of thiocarbonyl chloride, CSCl^2 . On *potassium cyanide* it acts violently, with great rise of temperature and carbonisation. It does not act on *mercuric cyanide* at ordinary temperatures, but when the mass was heated to 150° , it charred and burst the tubes.

PERCHLORONAPHTHALENE. See NAPHTHALENE (p. 1350).

PERCHLOROPROPANE, C^3Cl^3 , is obtained: 1. By heating trichlorohydrin, $\text{C}^3\text{H}^3\text{Cl}^3$, to 200° with iodine chloride (Krafft a. Merz, *Ber.* viii. 1045). 2. Together with perchloromethane by heating isobutane to 240° with iodine chloride, $\text{C}^4\text{H}^{10} + 11\text{Cl}^2 = \text{C}^3\text{Cl}^3 + \text{CCl}^4 + 10\text{HCl}$ (Krafft a. Merz, *loc. cit.*). 3. Together with perchlorethane and perchloromethane, by the action of iodine trichloride on isobutyric acid (Krafft, *ibid.* ix. 1076). Perchloropropane is resolved at 250° into perchlorethane and perchloromethane (Krafft a. Merz).

PERCHLOROTRIPHENYLAMINE, $(\text{C}^6\text{Cl}^5)^3\text{N}$. See PHENYLAMINES.

PEREIRO BARK. The bark of Pao Pereiro (*Geissospermum Vellozii*, Peckolt, *G. laeve*, Baillon) also called *Pinguiciba* and *Canudo amargosa*, is employed in Brazil as a febrifuge. It contains at least two alkaloids which have been extracted by O. Hesse (*Ber.* x. 2162). One of these, called geissospermine, crystallises in small white prisms terminated by domes, dissolves very sparingly in water and in ether, easily in alcohol and in dilute acids, and is precipitated from the acid solutions by ammonia and caustic soda in white amorphous flocks which soon become crystalline. The hydrochloric acid solution forms with *platimic chloride* a pale yellow amorphous precipitate, with *aureic chloride* a brown-yellow precipitate without reduction of metal. Geissospermine dissolves in strong nitric acid with purple-red colour, becoming yellow on heating; with strong sulphuric acid it forms a colourless solution gradually becoming pale yellow; sulphuric acid containing molybdic acid immediately dissolves it with blue colour. Crystallised geissospermine has the composition $\text{C}^{19}\text{H}^{24}\text{N}^2\text{O}^2 \cdot \text{H}^2\text{O}$, and gives off its water at 130° . Its *platinochloride* has the formula $(\text{C}^{19}\text{H}^{24}\text{N}^2\text{O}^2 \cdot \text{HCl})^2 + \text{PtCl}^4$.

A second alkaloid of Pereiro bark, called *Pereirine*, is an amorphous powder easily soluble in alcohol, coloured blood-red by strong nitric acid, violet-red by pure sulphuric acid.

PERICLASE. This mineral from the Predazzite of Monte Somma, of which it forms from 9 to 41 per cent., has been analysed by A. Cossa (*Gazz. chim. ital.* 1877, 398) with the following results:

MgO	FeO	Sp. gr. = 3.642.
95.39	4.56 = 99.95	
95.78	4.13 = 99.91	

Cossa has prepared isotropic laminae of periclase by fusing magnesium sulphate with

sodium chloride in a platinum crucible for four hours, and leaving the fused mass to cool slowly. When a little ferrous sulphate was added, larger laminæ were formed containing 0.96 per cent. FeO.

PERIODIC ACID. See IODINE, OXYGEN ACIDS OF (p. 1095).

PERMANGANATES. On *Potassium Permanganate*, see p. 1267. On the rapid oxidation of Essential Oils and other Organic Substances by a mixture of this salt with strong sulphuric acid, see ORTS (p. 1430).

Silver Permanganate is prepared by dissolving 158 pts. potassium permanganate with aid of heat, in 500 pts. water, and adding a solution of 170 pts. silver nitrate in 200 water, whereupon the silver permanganate separates in fine black, metallicallly lustrous crystals, half an inch long, which may be purified by recrystallisation from hot water, washing with cold water, and drying (Martenson, *Russ. Zeitschr. Pharm.* 1873, 66).

Zinc Permanganate is prepared for pharmaceutical purposes by dissolving 127 pts. of the silver salt just described in hot water, stirring in 68 pts. of zinc chloride made as neutral as possible (best prepared from zinc sulphate and barium chloride), and filtering the liquid through gun-cotton. The filtrate is then evaporated on the water-bath to a viscid consistence and left to cool, whereupon it solidifies to a crystalline mass. Zinc permanganate thus prepared is a black-brown metallicallly lustrous salt, very soluble in water, and deliquescent in damp air. When heated in a glass tube it gives off a purple vapour, and leaves a porous residue having the lustre of steel. When it is heated on platinum foil, the foil becomes coated with a ring-shaped deposit having a fine blue and yellow colour (Martenson, *loc. cit.*)

PEROWSKITE, CaO.TiO_2 . Hesseberg observed that this mineral, though belonging to the regular system, is bi-refractive, and attributed this anomaly to an internal transformation of the substance (vii. 899). The monometric character of the crystals has been confirmed by the measurements of N. v. Kokscharow (*Jahrb. f. Min.* 1876, 741; 1878, 88), and Des Cloizeaux (*ibid.* 749). According to v. Kokscharow, the mineral is optically biaxial, not uniaxial as stated by Hesseberg. Most of the Russian perowskites are not simple crystals, but penetration-twins. Des Cloizeaux, who has measured crystals of perowskite from Zermatt, attributes their optical characters to twin-formation and to the enclosure of bi-refractive lamellæ of foreign substances.

A. Knop (*Jahrb. f. Min.* 1877, 647) finds that the mineral from the Kaiserstuhl range, hitherto described as perowskite, contains niobic as well as titanitic acid, and designates it as *dysanalite*. The following is the result of his analysis, after deduction of silica:

TiO_2	Nb_2O_5	Cerium oxides	CaO	FeO	MnO	Na_2O
41.47	23.23	5.72	19.77	5.81	0.43	3.57 = 100.

with traces of magnesia, potash, and fluorine, and small quantities of alumina. The sp. gr. of the mineral was found to be 4.13, which is perhaps too low; in consequence of the admixture of quartz and augite. The analysis leads to the formula $6\text{RTiO}_3.\text{RNb}_2\text{O}_6$, and shows that dysanalite is a titanoniobate intermediate between perowskite, which is a pure titanate, and koppite (p. 1158), which is a pure niobate.

PERPHENYL-MELAMINE, $\text{C}^{30}\text{H}^{30}\text{N}^6 = \text{C}^3(\text{C}^6\text{H}^5)^3\text{N}^6$, is formed by the action of cyanogen chloride on diphenylamine (p. 909).

PERSICIN. See PYRETHRUM.

PERTHIOCYANIC ACID, $\text{C}^2\text{H}^2\text{N}^2\text{S}^3$, according to R. W. Atkinson, $\text{C}^3\text{HN}^3\text{S}^3$, according to Ponomareff (p. 608). Ponomareff finds by further experiments (*Compt. rend.* lxxx. 1398) that perthiocyanic acid, heated with ammonia to a temperature not exceeding 100° (in his former experiments the heat was raised to 150° – 160°), yields a compound, $\text{C}^3\text{H}^3\text{N}^3\text{S}^3$, which he designates as thiammeline, together with thio-melaneurenic acid, $\text{C}^3\text{H}^4\text{N}^4\text{S}^3$. Thiammeline is a white sandy powder which dissolves in 145 pts. of boiling water, and when heated with potash gives off ammonia and yields cyanate and thiocyanate of potassium. Hot strong hydrochloric acid resolves it into hydrogen sulphide, sal-ammoniac, and cyanuric acid. Nitric acid oxidises it to ammeline nitrate. Heated with ammonia, it yields a body having the properties of melamine. Thiammeline dissolves in acids and alkalis, and forms precipitates with the salts of the heavy metals.

Acetyl-perthiocyanic Acid, $\text{C}^2\text{H}(\text{C}^2\text{H}^3\text{O})\text{N}^2\text{S}^3$ (p. 609).

PERU BALSAM. According to Baillon (*Pharm. J. Trans.* [3], iv. 385), Peru and Tolu balsams are the produce of the same tree, and the differences between them arise merely from the modes of preparation (comp. BALSAMS, i. 496, 498).

For testing the purity of Peru balsam, the *Apothekerzeitung* recommends the determination of its specific gravity. The pure balsam has a sp. gr. of 1.14–1.16; mean 1.15. Peru balsam, which sinks in a solution of 1 pt. common salt in 5 pts. water (sp. gr. 1.125), may be regarded as pure (*Vierteljahrsschrift, pr. Pharm.* xxii. 99). Werner (*ibid.* 295) regards this method as inexact, and gives the preference to that which is recommended in the *Pharmacopœia Germanica*—namely, mixing the balsam with strong nitric acid and washing with water, pure balsam thus treated yielding a brittle mass, whereas adulterated balsam leaves an unctuous residue.

PETROCENE. This name is given by Hemilian (*Ber.* ix. 1604) to a hydrocarbon, $C^{22}H^{42}$, which may be separated from the highest-boiling portions of American petroleum. It crystallises from boiling benzene in yellow shining laminae, is nearly insoluble in alcohol and ether, melts above 300° , sublimes when cautiously heated. By dilute nitric acid and chromic acid it is oxidised to a brown powder which is insoluble in the ordinary solvents, and sublimes with decomposition. With strong nitric acid and with bromine it yields substitution-products, and with sulphuric acid a sulphonic acid which forms insoluble lead and barium salts.

PETROLEUM. *Occurrence and Formation.*—O. Silvestri (*Gazz. chim. ital.* x. 1) found in the cavities of a prehistoric doleritic lava, 22 kilometers S.S.E. of the central cone of Etna, a petroleum-like substance, forming about 1 per cent. of the rock-mass, perfectly fluid at 20° , but hardening partially at 17° . The sp. gr. of the lava in its original state was 2.797; after the extraction of the petroleum by ether, 2.849. An analysis of the crude petroleum gave:

C	H	S	O
82.49	11.61	3.33	2.57 = 100.

Proximate analyses yielded:

	Per cent.
Light Hydrocarbons of sp. gr. 0.860 (at 24°) and boiling at 79° – 80°	0.74
Hydrocarbons of sp. gr. 0.925 to 0.9408 (at 24°) and boiling at 190° – 280°	17.23
Hydrocarbons of sp. gr. 0.946 to 0.9604 (at 24°) and boiling at 280° – 400°	31.95
Paraffin melting at 52°	19.90
„ „ 57.2°	22.89
Asphalt	2.90
Sulphur crystallising in monoclinic prisms	4.30
„ „ rhombic pyramids	0.09

The hydrocarbons were found to be paraffins, C^nH^{2n+2} , the value of n ranging from 13 to 18; their formation is attributed by Silvestri to the covering of organic structures by the liquid lava, the organic matter being thereby subjected to a kind of dry distillation, the products of which condensed in the already viscid upper portion of the lava-stream and made it porous.

The formation of petroleum beneath the earth's surface is also generally attributed to the decomposition of organic remains. Mendelejeff, however (*Ber.* x. 229), objects to this view, chiefly on the ground that mineral oils are found in tertiary strata in the Caucasus, and in Devonian and Silurian strata in Pennsylvania, and must have been formed in underlying and still older strata where but few organic remains could have existed. He supposes that, as a consequence of the condensation of the earth's substance from vapours, the interior must consist to a great extent of metals (iron predominating) in combination with carbon; and that water, acting on these carbides at high pressures and temperatures, produced metallic oxides and hydrocarbons, which latter, rising in the state of vapour, became condensed in the superincumbent strata, especially in porous sandstones.

Composition. Properties. Uses. American petroleum, as shown by the analyses of Pelouze a. Cahours (iv. 385), consists mainly of *paraffins*, C^nH^{2n+2} , from $C^{14}H^{30}$ to $C^{22}H^{42}$. By fractional distillation, sometimes with the aid of steam, ordinary or superheated, and purification of the distillates with caustic potash, a number of commercial products are obtained which are applied to various purposes, the lighter oils chiefly as solvents for resins, &c., the heavier for burning in lamps and as fuel for steam-boilers. The following account of them is taken mainly from Dammer's 'Kurzes Handwörterbuch der Chemie:'

Rhigolene, b. p. 30° , used as an anæsthetic.

Petroleum-ether (Kerosolene, Rhigolene, Sherwood-oil): distils at 45°–60°: clear, colourless oil having only a faint odour of petroleum; b. p. 50°–60°; sp. gr. 0·665; absorbs oxygen from the air and becomes heavier (0·670–0·675); extremely inflammable; used as a remedy for rheumatic pains and as a local anæsthetic.

Petroleum-ether, II. (Gasoline, Canadol): distillate between 60° and 70°; has a sp. gr. of 0·665; second distillate between 70° and 90°.

Petroleum-benzin: distillate between 70° and 120°; has a sp. gr. of 0·680 to 0·700; dissolves in alcohol and ether; boils at 60°–80°; absorbs oxygen and becomes heavier; dissolves fats, caoutchouc, asphalt, and turpentine; less easily colophony, mastic, and dammar resin; kills all small animal organisms, and is used externally as a remedy for itch and other skin diseases, internally for gastric pains; also for the extraction of oil, the preservation of anatomical preparations, the carburation of illuminating gas, and for the preparation of lacquers and varnishes. *Ligroin* is a similar distillate used for feeding the so-called 'Ligroin or Wonder-lamps.'

Artificial Turpentine-oil, Petroleum-spirit, Polishing Oil: distillate between 120°–170°; obtained also with superheated steam; sp. gr. 0·740–0·745; does not dissolve resins; used for diluting linseed-oil varnish and for cleaning printers' type.

Illuminating Oil, Petroleum, Kerosene, Paraffin Oil, Refined Petroleum, has a large and increasing consumption for lamps, also for warming greenhouses, &c.; sp. gr. 0·78 to 0·81; flashing point (in the open vessel) 90°–110° F.; igniting point 110°–130° F.; includes all the intermediate distillates from crude petroleum, ranging from sp. gr. 0·76 to 0·83. The finest-quality of illuminating oil is produced from distillates ranging only from 0·775 to 0·790; this, when treated by aeration, is the water-white high-test oil used largely by the higher classes in America. It has a very high flashing point (120°–140° F. in the open vessel), as it contains none of the lighter parts of the crude oil.

Lubricating Oil.—Sp. gr. 0·850 to 0·915; of a pale amber colour; coming largely into use as an efficient lubricant in combination with rape, olive, or lard oil. The best qualities have a sp. gr. of about 0·895, the heavier oils from 0·900 to 0·915 containing solid paraffin.

The residues of the distillation are utilised for gas-making.

The present production of petroleum in the United States only, exceeds 50,000 barrels or 2,500,000 American gallons *daily*. The quantity exported thence during the year 1879 exceeded 400,000,000 gallons. See Martius (*Dingl. pol. J.* cxxxv. 504; *Jahresb. f. Chem.* 1877, 1218).

Russian Petroleum from the Caucasus (K. Linenko, *Dingl. pol. J.* ccxxvii. 78, 161). The district surrounding Baku, a city on the borders of the Caspian Sea, is the seat of the petroleum industry of the Caucasus. The regular extraction of this oil commenced in 1872, and 65,000 tons of kerosene from 200,000 tons of crude petroleum is the annual production at the present time. The crude oil of this district comes from springs not more than from 90 to 120 meters deep, and has a sp. gr. of 0·860 to 0·875; it yields only 33 to 35 per cent. of oil for lighting purposes; the remaining naphtha-residue has lately come into request for raising steam in the steam-ships of the Lower Volga and the Caspian Sea.

The refined oil of Baku is distinguished from the American by its greater density at 14°, the former being 0·820, the latter 0·800.

The following table (p. 1510) shows the results of comparative experiments on the Russian and American oils. Three kinds of Russian oil were experimented on. The 3rd kind is the heavy kerosene, manufactured for Persian consumption; the 2nd is an ordinary commercial variety; while No. 1 is prepared only in small quantities. No. 2 is a clear and slightly fluorescent liquid with a not disagreeable odour. The American varieties tested were of two kinds—1st, the ordinary variety, of a yellow colour; and 2nd, the high-test, which also goes by the name of *Australöl* and *Oleophin*. The numbers show that the hydrocarbons in the Russian oil are more volatile than those in the American. None of them were obtained quite pure.

The mineral oils of Buxière-la-Grue and of Cordesse, in Alsace, have been examined by J. Joffre (*Bull. Soc. Chim.* [2], xix. 547). They differ from American petroleum in being partly absorbed by fuming sulphuric acid, and converted by nitric acid into nitro-products. About 50 per cent. of these oils consists of paraffin-oils, and is not attacked by these reagents; the hydrocarbons, C¹²H¹⁸ and C¹⁴H²², were isolated by fractional distillation. The portions of these mineral oils which are absorbed by sulphuric acid consist of olefines, CⁿH²ⁿ, or of hydrocarbons containing a still smaller proportion of hydrogen. They do not contain either benzene or naphthalene.

Egyptian petroleum differs from the American by its much greater density

Comparison of Russian and American Petroleum.

and by not containing the lighter oils or the ordinary burning oil of sp. gr. 0·8. It yields however an excellent lubricating oil, and in its crude state is well adapted for heating steam boilers, its use involving but little risk of fire (F. Weil, *Monit. scient.* cccxvi. 432).

Sulphur in Petroleum. According to H. Vohl (*Dingl. pol. J.* cccvi. 47) all kinds of petroleum contain sulphur, and may be purified therefrom by treatment with acids and alkalis. The impurity is most easily detected by heating the petroleum with metallic sodium. If sulphur is present, the bright metal soon becomes covered with a yellow crust of sodium sulphide, which may be dissolved off by water and tested. The quantity of the sulphur may be estimated by distilling the petroleum over red-hot lime, and subsequently weighing the sulphur as barium sulphate. Vohl found in different kinds of petroleum from 0·300 to 3·114 per cent. of sulphuric acid.

On the use of the heavier petroleum oils, *Vulcan oil, Opal oil, &c.*, as lubricators, see OILS (p. 1429); also J. J. Coleman (*Dingl. pol. J.* ccx. 195; *Jahresb. f. Chem.* 1873, 1094).

Use of Petroleum for Illumination.—Experiments on the comparative cost of a given amount of light from petroleum oil, colza-oil, and coal-gas have lately been made by Messrs. B. and T. H. Redwood (*Chemist and Druggist*, Dec. 15, 1879, p. 540). The following table exhibits the mean results for 1000 ‘candle-hours,’ that is to say, for the amount of light which would be obtained by burning a standard sperm candle for 1000 hours.

Cost of 1000 ‘Candle-hours.’

From petroleum-oil at per gallon					From colza-oil at per gallon			From coal-gas at per 1000 cubic feet		
9d.	1s.	1s. 3d.	1s. 6d.		3s.	3s. 6d.	4s.	3s.	3s. 6d.	4s.
7½d.	9¾d.	11¼d.	1s. 3d.		2s. 4d.	2s. 8d.	3s. 0¾d.	1s. 3d.	1s. 5½d.	1s. 8d.

These numbers show that, taking petroleum-oil at 1s. per gallon, and colza-oil at 3s. 6d. per gallon, the cost of a given amount of light is more than three times greater for the latter than for the former; and that, taking petroleum at 1s. per gallon and coal-gas at 3s. 6d. per 1000 cubic feet, a given amount of light from the former costs only about half what it does when obtained from the latter, while there is the additional advantage that properly purified petroleum-oil in burning does not produce sulphur-compounds.

Flashing Point of Petroleum.—This term is used to denote the temperature at which any sample of petroleum or its products begins to give off inflammable vapours. The more volatile kinds give off such vapours even at ordinary temperatures, and these vapours when mixed with air form explosive mixtures: hence the use of such oils for burning in lamps is attended with great danger. To prevent accidents from this cause, it was enacted by the American Petroleum Act, and by the British Petroleum Act of 1871, that no petroleum-oil should be used for burning in lamps which gives off inflammable vapours at any temperature below 100° F. (or 38° C.) when tested in an open cup described in the Schedule of the Act. The great increase in the consumption of the article between the years 1871 and 1877, however, necessitated the adoption of a system of testing less liable to variation in the hands of different operators. This question having been referred to Professor Abel, he proposed the use of a *closed* vessel to be heated by hot water, with a standard flashing-point of 73° F., which was found to be the equivalent of 100° on the open cup system.* This proposal, being favourably reported on by the Petroleum Trade Association, was eventually adopted as the basis of the new Petroleum Act of 1879.

The testing apparatus above mentioned consists of a small closed oil-cup fitting into a water-bath. On the top of the cup is a brass slide, and a minute oil-lamp with a jet. A thermometer is also fixed with its bulb in the oil cup. The operator watches the thermometer, and at intervals draws out the brass slide, thus causing a jet of flame to dip into the oil-cup. The ‘flashing point,’ or temperature at which the petroleum begins to give off an inflammable vapour, is thereby ascertained. This apparatus is accurately described and figured in the schedules of the new Act. (See also *Chemist and Druggist*, Dec. 15, 1879, p. 541; *Chem. News*, xl. 305).

* It will be observed that the standard is not *lowered* by this alteration, but simply adjusted to the new system. More than 1000 samples were tried on the two systems, the variations ranging from 25° to 29° F.; hence 27° was adopted as the mean variation, making the standard 73° instead of 100°.

Gas from Petroleum.—The value of petroleum and coal-tar for the production of gas has been studied by A. Wagner (*Dingl.* cxxvi. 250). Experimenting with a petroleum which began to boil at 150°, he found that when the vapours given off below 288° were passed through a red-hot porcelain tube filled with lumps of pumice-stone, the petroleum was resolved into $\frac{1}{3}$ gas, $\frac{1}{3}$ condensed products, and $\frac{1}{3}$ residue left in the retort. The gas consisted of 5.0 vol. p. c. acetylene, 35.96 heavy, and 59 light hydrocarbons. Wagner is of opinion that the first product of the decomposition of the petroleum at high temperatures is ethylene, which is partly decomposed according to the equation $C^2H^4 = CH^4 + C$, and that the methane thus produced is further decomposed, yielding acetylene and hydrogen: $2CH^4 = C^2H^2 + 3H^2$. Petroleum-ether yields a larger quantity of gas than crude petroleum. 1 gram of petroleum yielded 0.876 lit. gas; 1 gram of petroleum-ether gave 0.916 lit. gas.

Wagner rejects as worthless all projects for making gas by distilling petroleum mixed with wood, peat, charcoal, &c., because the dry distillation of these solid substances always produces water, which in evaporating carries the petroleum along with it, before the petroleum can be converted into gas. The only rational way of converting petroleum into gas is to heat it by itself, and in this operation a high temperature of the retorts is an indispensable condition.

Petroleum gas when burnt alone requires burners with small apertures; it is very well adapted for heightening the illuminating power of gas of inferior quality. The production of an illuminating power of 136 kilos. of stearin requires a quantity of gas obtained from 1 cwt. of petroleum or from 2.6 cwt. of Boghead coal.

The composition of the gas emitted from certain petroleum springs in West Pennsylvania has been determined by S. P. Sadtler (*Amer. Chem.* vii. 97):

	Burns Gas-well	Leechburgh Gas-well	Harrey well	Cherry-tree well
Carbon dioxide	0.34	0.35	0.66	2.28
Carbon monoxide	traces	0.26	traces	—
Olefines	—	0.56	—	—
Methane	75.44	89.65	80.11	60.27
Hydrogen	6.10	4.79	13.50	22.50
Ethane	18.12	4.39	5.72	6.80
Propane	traces	traces	traces	—
Oxygen	—	—	—	0.83
Nitrogen	—	—	—	7.32

See also GASES (p. 858).

PETZITE. See TELLURIUM MINERALS.

PEUCEDANIN, $C^{16}H^{16}O^4$, and **OROSELONE**, $C^{14}H^{12}O^4$ (iv. 216, 386). The composition and mutual relations of these bodies have been further examined by Hlasiwetz a. Weidel (*Liebig's Annalen*, clxxiv. 67). By decomposing an alcoholic solution of peucedanin with hot aqueous hydrochloric acid, and by passing dry hydrochloric acid gas over peucedanin, they obtained oroselone, the reaction in the latter case being attended with the evolution of a gas (probably methyl chloride) which burned with a green-edged flame:

Angelic acid, which was stated by Wagner to be formed in the decomposition of oroselone with potash, was not obtained by Hlasiwetz a. Weidel, either in the reaction just mentioned, or by decomposing oroselone with alcoholic potash.

Oroselone fused with potash yields resorcinol and acetic acid:

Peucedanin fused with potash yields only a small quantity of resorcinol.

Oroselone is readily attacked by *acetyl chloride* and *valeryl chloride*, yielding monoacetyl-oroselone, $C^{14}H^{11}(C^2H^3O)O^4$, and monovaleryl-oroselone, $C^{14}H^{11}(C^4H^7O)O^4$, respectively. The former crystallises in slender colourless needles, melting at 123°; the latter forms large rhombic prisms melting at 95°–97°, and is not identical with athamantin (i. 430). Monovaleryl-oroselone is decomposed by gaseous hydrogen chloride into valeryl chloride and oroselone.

The relation between peucedanin and oroselone may perhaps be represented by the following formulæ:

Oroselone may be regarded as an aldehydic compound, and peucedanin as a corresponding ketone analogous thereto.

PHACOLITE. This variety of chabasite, originally found at Leipa in Bohemia (i. 844), occurs also in a basaltic conglomerate in the neighbourhood of Giessen. Six analyses by Burkhart and Hammerschlag gave as a mean result:

SiO ²	Al ² O ³	Fe ² O ³	CaO	K ² O	Na ² O	H ² O (?)	H ² O (?)
46.82	19.29	0.14	10.29	0.14	0.70	14.98	7.38

(?) Given off up to 300°.

(?) Above 300°.

(A. Streng, *Jahrb. f. Min.* 1877, 725).

Seebachite from Richmond in Victoria (vii. 1077) is regarded by G. vom Rath (*ibid.* 1876, 63) as identical with phacolite; he finds that it belongs to the rhombohedral system, has a density of 2.135, and gives by analysis:

SiO ²	Al ² O ³	CaO	K ² O	Na ² O	H ² O
46.08	21.09	5.75	1.77	4.52	21.08 = 100.29

leading to the formula,

which requires 46.71 SiO², 20.00 Al²O³, 5.46 CaO, 2.29 K²O, 4.52 Na²O, and 21.02 H²O. An analysis of seebachite by Lepsius (*Jahresb. f. Chem.* 1874, 1264) gave 44.77 SiO², 22.10 Al²O³, 7.51 CaO, 3.18 Na²O, and 22.07 H²O = 99.63.

PHÆACTINITE. A radiate transformation product of hornblende, forming one of the constituents of the isenite of Nassau (see ISENITE, p. 1126).

PHARMACOLITE. Native calcium arsenate (iv. 387). According to measurements by A. Schrauf (*Jahrb. f. Min.* 1873, 646) the crystals are monoclinic, having the axial ratio $a : b : c = 0.613727 : 1 : 0.362226$, and the angle $ac = 96^\circ 46\frac{3}{4}'$.

Picropharmacolite, hitherto regarded as a pharmacolite, appears from analyses by A. Frenzel (*ibid.* 1873, 786) to be a distinct mineral species. The microcrystalline, probably monoclinic, mineral occurs in white groups rarely coloured blue by copper, on copper pyrites, gneiss, and even on the timbering of the 'hohe Birke' and 'Kröner' mines at Freiberg.

A. Analysis. B. Values calculated from the formula $5\text{CaO} \cdot 2\text{As}^2\text{O}^5 + 12\text{H}^2\text{O}$:

As ² O ⁵	CaO	MgO	H ² O
A. 46.93 (?)	25.77	3.73	24.01 (?) = 100.44
B. 48.11	29.29	—	22.60 = 100

(?) A check analysis gave 48.14 per cent.

(?) 13 per cent. given off at 100°.

PHENAMYLAMINE, or *Amido-amyli-benzene*, $\text{C}^6\text{H}^4(\text{C}^5\text{H}^{11})\text{NH}^2$. A base isomeric with amylaniline, and produced therefrom by intramolecular atomic interchange. See BENZENES (AMYLAMIDO-), p. 206.

PHENANTHRENE, $\text{C}^{14}\text{H}^{10} = \begin{array}{c} \text{C}^6\text{H}^4-\text{CH} \\ | \quad | \\ \text{C}^6\text{H}^4-\text{CH} \end{array}$. *Diphenylene-ethylene*.—This hydro-

carbon, isomeric with anthracene, has already been described in connection with the latter (vii. 84; viii. 95), but many important observations relating to it have lately been published.

Phenanthrene is one of the constituents of the substance called 'idryl,' obtained by the dry distillation of an Idrian quicksilver ore (p. 1084).

Ostermayer (*Ber.* vii. 1089) prepares phenanthrene by subjecting crude anthracene to slow fractional distillation, collecting the portion which passes over between 320° and 350°, boiling it with a large quantity of alcohol, and leaving the solution to crystallise. The first crystallisation must be rejected, as it consists chiefly of anthracene; but the product obtained from the mother-liquor consists, after two recrystallisations from alcohol, of nearly pure phenanthrene melting at 98°–100°. Phenanthrene obtained by treating the dibromide (vii. 85) with alcoholic potash, melts at 96°, and the same melting point is exhibited by phenanthrene obtained by heating phenanthraquinone with zinc-dust.

On the purification of phenanthrene, see also Hayduck (*Liebig's Annalen*, clxvii. 177; *Ber.* vi. 532; *Jahresb. f. Chem.* 1873, 394).

Action of Chlorine.—By exhaustive chlorination with chlorine and iodine (p. 1066), phenanthrene is decomposed like anthracene, yielding perchlorobenzene and perchloromethane, the formation of these bodies being perhaps preceded by that of perchlorophenanthrene (Ruoff, *Ber.* 1048).

Phenanthrene Dibromide and Bromophenanthrene (Hayduck, *Liebig's Annalen*, clxvii. 180). The dibromide, $\text{C}^{14}\text{H}^{10}\text{Br}^2$, which Fittig and Ostermayer obtained

by dropping bromine into an ethereal solution of phenanthrene (vii. 85), may also be prepared by dissolving the calculated quantities of phenanthrene and bromine in carbon sulphide, and slowly mixing the solutions after cooling them with ice, and separates after a few hours in well-defined flat four-sided prisms which, after washing with a little cold carbon sulphide, and pressing between paper, are nearly white. It slowly decomposes when kept, turning brown and giving off hydrogen bromide; melts at 98° with brisk effervescence and evolution of hydrogen bromide, and is converted into monobromophenanthrene. Solution of silver nitrate added to the cold alcoholic solution forms a precipitate of silver bromide. Heating with alcohol produces immediate decomposition. According to Anschütz (*Ber.* xi. 1217), the dibromide treated with nitric acid in acetic acid solution, appears to yield a nitro-product. Dissolved in alcohol and treated with potassium cyanide, it yields phenanthrene.

Monobromophenanthrene, $C^{14}H^9Br$, is formed, as above described, by the action of heat on the dibromide, also by heating that compound with water. To prepare it, the dibromide is heated on a water-bath as long as hydrogen bromide continues to escape, and the residue is dissolved in hot strong alcohol, from which it separates as an oil which quickly solidifies to a crystalline mass. From weaker solutions it crystallises in thin white prisms, which melt at 63° , and dissolve readily in glacial acetic acid and carbon sulphide. The alcoholic solution exhibits a slight fluorescence. Bromophenanthrene may be sublimed without decomposition; it does not give off bromine when heated for several hours with alcoholic potash, but when heated with sodium amalgam in alcoholic solution it yields sodium bromide and phenanthrene.

The carbon sulphide from which phenanthrene dibromide, prepared as above, has crystallised out, still retains bromine-compounds which remain as a soft brown mass on distilling off the solvent. Cold ether decomposes this brown substance into an easily soluble oily compound and a yellowish powder which remains undissolved. The oily compound, which retained its dark colour even after repeated attempts at purification, gave by analysis 31.5 per cent. bromine, answering to the formula of monobromophenanthrene. It was not altered by boiling with alcoholic potash, or apparently by sodium-amalgam in alcoholic solution. Bromine decomposes it with evolution of hydrogen bromide, but the product is an uncrystallisable resin.

Dibromophenanthrene, $C^{14}H^8Br^2$.—This is the composition of the above-mentioned yellow powder insoluble in ether; it is formed in small quantity only. It dissolves sparingly in hot alcohol, and separates from solution in glacial acetic acid in the form of a yellowish-white indistinctly crystalline powder melting at 202° . Another dibromophenanthrene is formed on adding bromine to a solution of the monobromoderivative in carbon sulphide. The reaction goes on to the end, with evolution of hydrogen bromide, even at ordinary temperatures; and on distilling off the carbon sulphide after a few hours, and dissolving the residue in warm alcohol, dibromophenanthrene separates on cooling in nodular groups of white needles (still retaining a little of the monobromo-derivative), which melt at about 110° and gradually soften even below this temperature (Hayduck).

Two other dibromophenanthrenes are described by Zetter (*Ber.* xi. 164). One of these, formed by the action of bromine on phenanthrene in ethereal solution, crystallises from alcohol in long needles, melts at 148° , and sublimes in yellow needles. Most solvents dissolve it readily, and deposit it in crystals when evaporated. Another formed together with the last, crystallises in tables which melt at 158° , and do not sublime even when strongly heated. It dissolves easily in the ordinary solvents, and crystallises from the solution on evaporation. Neither of these dibromo-compounds is attacked by boiling alcoholic potash.

Tribromophenanthrene, $C^{14}H^7Br^3$, is formed when a solution of the dibromo-compound in carbon sulphide is heated with bromine for several hours in a reflux apparatus. The product which remains on evaporating off the carbon sulphide crystallises from hot glacial acetic acid in very slender white silky needles, melting at 126° . On heating it with bromine to 140° in sealed tubes, further bromination takes place, yielding products which are nearly insoluble in cold alcohol and glacial acetic acid, slightly soluble in benzene, more readily in hot xylene, from which they separate as a white long-fibred crystalline mass, which does not melt at 290° (Hayduck). Zetter obtained the same dibromophenanthrene by heating phenanthrene to 130° – 140° with the calculated quantity of bromine.

Tetrabromophenanthrene, $C^{14}H^6Br^4$, is produced when phenanthrene is heated to 200° – 210° with the requisite quantity of bromine. It forms small granular crystals, which melt at 183° – 185° , and dissolve in benzene and toluene, but scarcely in alcohol or ether (Zetter).

Hexbromophenanthrene, $C^{14}H^4Br^6$, is formed on heating phenanthrene to 280° with the calculated quantity of bromine and 1 mol. of iodine. It sublimes in snow-white

needles, which melt at 245° , and dissolve in glacial acetic acid, benzene, and toluene (Zetter).

Heptabromophenanthrene, $C^{14}H^9Br^7$, is produced by heating phenanthrene, with excess of bromine containing iodine, to 300° , or a higher temperature, in sealed tubes. It sublimes in small yellowish needles, which melt above 270° (Zetter).

Chlorophenanthrenes (Zetter, *loc. cit.*) A solution of phenanthrene in glacial acetic acid absorbs chlorine readily in the cold, and gives off hydrogen chloride. The product of the reaction consists mainly of dichlorophenanthrene tetrachloride, but contains also dichloro- and monochloro-phenanthrene.

Dichlorophenanthrene tetrachloride, $C^{14}H^9Cl^2Cl^4$, crystallises in small colourless needles, which dissolve very easily in alcohol, ether, benzene, and toluene, melt at 145° , and give off hydrogen chloride at a slightly higher temperature. When heated with alcoholic potash, it loses first one and then a second atom of chlorine, yielding tetrachlorophenanthrene.

Monochlorophenanthrene, $C^{14}H^9Cl$, is an oily liquid, easily soluble in the liquids named above, but not in water. It carbonises when slightly heated.

Dichlorophenanthrene, $C^{14}H^9Cl^2$, is an amorphous white substance, easily soluble in glacial acetic acid, ethyl acetate, alcohol, ether, benzene, and toluene. It melts to a transparent oily liquid at a low temperature.

Tetrachlorophenanthrene, $C^{14}H^9Cl^4$, is formed by the action of antimony pentachloride on phenanthrene in the cold, or by the action of iodine chloride at 100° – 110° . It crystallises in small yellowish needles, which dissolve easily in ether, benzene, and toluene, but very slightly in alcohol. The crystals melt at 171° – 172° , and sublime in thin yellowish needles. Neither this nor any of the higher chlorinated products is affected by boiling with alcoholic potash.

Hexachlorophenanthrene, $C^{14}H^9Cl^6$, is formed by the action of antimony pentachloride on phenanthrene in closed tubes at 120° – 140° , or in the oil-bath at 180° – 200° . It sublimes in white feathery crystals, which melt at 249° – 250° , and dissolves very sparingly in alcohol, ether, and acetic acid.

Octochlorophenanthrene, $C^{14}H^9Cl^8$, is produced on heating phenanthrene with excess of antimony pentachloride to 180° – 200° . It crystallises in indistinct granular forms, and sublimes in yellow needles, which melt at 270° – 280° . It is nearly insoluble in alcohol and ether, but dissolves easily in benzene and toluene.

Nitro- and Amidophenanthrenes (G. A. Schmidt, *Ber.* xii. 1153). Three mononitrophenanthrenes are obtained when nitric acid (sp. gr. 1.35) is allowed to act slowly on phenanthrene mixed with sand, and may be separated, though with great difficulty, by fractional crystallisation from alcohol, ether, toluene, and glacial acetic acid.

α -Mononitrophenanthrene, $C^{14}H^9(NO^2)$, is obtained in largest quantity, and is identical with the mononitrophenanthrene described by Graebe (vii. 85). It crystallises from alcohol or glacial acetic acid in straw-yellow needles melting at 74° (at 70° – 80° according to Graebe). The presence of small traces of impurities causes it to remain liquid even at very low temperatures. By reducing it with tin and hydrochloric acid, or with alcoholic ammonium sulphide, *α -amidophenanthrene hydrochloride*, $C^{14}H^9(NH^2).HCl$, is obtained as a white crystalline precipitate, which is sparingly soluble in water, and is rapidly decomposed on exposure to the air. The *sulphate*, $(C^{14}H^9.NH^2)^2H^2SO^4$, is much more stable, and consists of a white powder sparingly soluble in alcohol and in water.

α -Amidophenanthrene is insoluble in water, and crystallises from dilute alcohol in small yellow plates.

α -Mononitrophenanthraquinone is formed by the oxidation of the nitro-compound with chromic and acetic acids. It crystallises in brilliant orange-yellow plates (m. p. 215° – 220°), which are insoluble in water and sparingly soluble in alcohol, ether, and benzene, but more easily in glacial acetic acid.

β -Mononitrophenanthrene, $C^{14}H^9(NO^2)$, differs but little in appearance and solubility from the *α -compound*, although it is somewhat less soluble in ether than the latter. It is obtained in smaller quantity than either of the other isomerides, and melts at 127° . Unlike the *α -compound*, it is only acted on with difficulty by alcoholic ammonium sulphide, and is best reduced by tin and hydrochloric acid in alcoholic solution. *β -Amidophenanthrene hydrochloride* forms a moderately stable crystalline mass, which is sparingly soluble in water. *β -Amidophenanthrene* crystallises from alcohol in small brilliant plates. *β -Mononitrophenanthrene* is more difficult of oxidation than the *α -compound*, and gives a product which crystallises from glacial acetic acid in brilliant orange-yellow needles (m. p. 260° – 266°).

γ -*Mononitrophenanthrene*, $C^{14}H^9(NO^2)$, crystallises in small brilliant plates (m. p. 170°), which are of a darker yellow colour, and are more sparingly soluble in ether and alcohol than the α - or β -compound.

γ -*Amidophenanthrene hydrochloride*, $C^{14}H^9(NH^2).HCl$, obtained by reduction of the nitro-compound with alcoholic ammonium sulphide, forms yellowish brilliant crystals. The free base resembles the α - and β -compounds.

On oxidation with chromic and glacial acetic acids, γ -nitrophenanthrene gives a compound which crystallises in dark orange-yellow needles (m. p. 263°), which are only very sparingly soluble in alcohol, but easily in glacial acetic acid.

Dinitrophenanthrene, $C^{14}H^8(NO^2)_2$, is obtained by prolonged action of nitric acid on phenanthrene at 100° ,—also, together with the mononitro-derivative, when the temperature is not kept low enough in the preparation of the latter. It crystallises from glacial acetic acid and melts at 150° – 160° (Graebe).

Nitrobromophenanthrenes.—When monobromophenanthrene dissolved in glacial acetic acid is warmed with nitric acid, a mixture of at least two nitro-compounds is precipitated on the addition of water, in the form of yellow microscopic needles. From this mixture, carbon sulphide or ether extracts one of the bodies, and leaves the other as a reddish-yellow substance, which has not been further examined. The soluble portion after recrystallisation yields fine prisms or compact crystals of *mononitrobromophenanthrene*, $C^{14}H^8(NO^2)Br$, melting at 195° and subliming in long needles (Anschütz, *Ber.* xi. 1207).

Hydroxyphenanthrene, or Phenanthrol, $C^{14}H^{10}O = C^{14}H^9(OH)$. This compound is obtained by treating phenanthrene with the calculated quantity of fuming sulphuric acid, converting the resulting monosulphonic acid into an ammonium salt, and fusing the latter with potash. The product crystallises from a mixture of benzene and petroleum-spirit in thin laminae, which exhibit a bluish fluorescence, and melt at 112° .

Phenanthrol dissolves easily in alcohol and ether, less easily in benzene, and slightly in water. On exposure to air it acquires a red to brown colour. Alkalis dissolve it easily, forming crystalline compounds, which are readily soluble in water.

With acetic and benzoic anhydrides phenanthrol forms ethers which crystallise well. The *acetyl-compound*, $C^{14}H^9O(C^2H^3O)$, obtained by heating phenanthrol to 150° with acetic anhydride, crystallises from alcohol in shining laminae, which melt at 117° – 118° (G. Rehs, *Ber.* x. 1252).

Phenanthrene-carboxylic Acid, $C^{14}H^9.COOH$. Of this acid there are two modifications distinguished as α and β . The first, discovered by Japp a. Schultz (*Ber.* x. 1661), is obtained by converting crystallised calcium phenanthrenesulphonate into the corresponding sodium salt, distilling the latter with potassium ferrocyanide, saponifying the resulting nitril with alcoholic potash, and acidifying the solution with hydrochloric acid, which throws down the phenanthrene-carboxylic acid in bulky white flocks. It is nearly insoluble in water, but dissolves easily in alcohol, ether, and glacial acetic acid, melts at 260° , and sublimes with partial decomposition. Its alkali-salts are easily soluble in water. The barium salt, $(C^{14}H^9COO)^2Ba + H^2O$, dissolves easily in hot water, and crystallises therefrom in tufts of needles.

By distillation with soda-lime, the acid is converted into phenanthrene, and by oxidation with chromic acid in acetic acid solution it is converted into phenanthraquinone-carboxylic acid; this determines its formula as under:

β -*Phenanthrene-carboxylic acid*, discovered by Japp (*Chem. Soc. J.* 1880, xxxvii. 83), is obtained from the dark syrupy mother-liquor which remains after the crystallisable calcium phenanthrenesulphonate above-mentioned has separated out. This mother-liquor contains an isomeric calcium phenanthrenesulphonate; and on converting it into sodium salt, distilling this salt in the dry state with $1\frac{1}{2}$ times its weight of potassium ferrocyanide, and boiling the resulting nitril with alcoholic potash for more than 100 hours, with inverted condenser, then distilling off the alcohol, digesting the contents of the flask with water, diluting, filtering, and acidifying with hydrochloric acid, β -phenanthrene-carboxylic acid separates out as a dirty-white flocculent precipitate (above 80 grams from 2 kilos. of commercial phenanthrene). It is most readily purified by converting it into the sodium salt, recrystallising this salt till it is quite colourless, and acidulating its solution with hydrochloric acid, which throws down the β -acid as a white flocculent precipitate.

β -Phenanthrene-carboxylic acid is soluble in alcohol, ether, and glacial acetic acid

almost insoluble in water. From a hot saturated solution in acetic acid, it crystallises in stellate groups of colourless needles.

The following table exhibits a comparison of the physical characters of the two phenanthrene-carboxylic acids and of their sodium and barium salts. Most of the crystallographical characteristics can be perceived only with the aid of a microscope :

	α -Acid	β -Acid
Acid . .	Crystallises from hot glacial acetic acid in colourless, curved blades, with paralleled edges, and a rectangular termination. This curvature is very characteristic. Sublimes in fern-shaped leaves. M. p. 266°.	Crystallises from hot glacial acetic acid in stellate groups of colourless, straight, pointed needles. Sublimes in fern-shaped leaves. M. p. 250°-252°.
Sodium salt .	$C^{14}H^9.CO^2Na + 4H^2O$. Tufts of colourless, pointed blades. 100 parts of water at 20° dissolves 6·8 parts of the anhydrous salt. Almost indefinitely soluble in boiling water.	$C^{14}H^9.CO^2Na + 5H^2O$. Colourless, rhomboidal laminae, with a slightly satiny lustre. 100 parts of water at 20° dissolve 6·2 parts of the anhydrous salt. Almost indefinitely soluble in boiling water.
Barium salt .	$(C^{14}H^9.CO^2)^2Ba + 7H^2O$. Colourless, long needles of extraordinary fineness and flexibility, radiating from one point to form large balls or tufts. Under the microscope a tangled mass of these flexible needles has the appearance of vegetable fibre. 100 parts of water dissolve— At 20° . . 0·066 } part of anhy- „ 100° . . 560 } drous salt.	$(C^{14}H^9.CO^2)^2Ba + 6H^2O$. Colourless, long, brittle, rectangular laminae, united in a ramiform crystallisation. 100 parts of water dissolve— at 20° . . 27 } parts of anhy- „ 100° . . 3·70 } drous salt.

The β -acid is converted by oxidation with chromic acid into phenanthraquinone, with elimination of the carboxyl-group: consequently it must contain this group attached to one of the carbon-atoms which in the quinone are united to the quinonic oxygen, thus :

and the sulphonic acid from which it is derived must be represented by a similar formula with $SO^2.OH$ in place of $CO.OH$.

Phenanthraquinone, $C^{14}H^8O^2 = \begin{array}{c} C^6H^4-CO \\ | \\ C^6H^4-CO \end{array}$. The preparation, properties,

and principal reactions of this compound have already been described (vii. 92-95). When distilled with dry *soda-lime*, it is almost completely converted into diphenyl, but when the *soda-lime* contains a considerable amount of moisture, fluorene, fluorene alcohol, diphenylene ketone, and a red body are formed. The latter result is explained by the fact that the water and soda in the *soda-lime* convert the phenanthraquinone into diphenylene ketone and diphenylene-glycollic acid, which latter decomposes, yielding fluorene alcohol, $(C^6H^4)^2.CH.OH$ (p. 673). Heated with quicklime, phenanthraquinone forms fluorene and diphenylene ketone. In the same way when diphenic acid, $C^{14}H^{10}O^4$, is distilled with quicklime, it yields diphenylene ketone, a red body, and traces of diphenyl, but when heated with a mixture of slaked and quicklime, it gives diphenylene ketone, diphenyl, and a red body, whilst with slaked lime, *soda-lime*, or zinc-dust, it yields diphenyl and only a trace of the red body (Anschütz a. Schultz, *Ber.* ix. 1400).

Alcoholic potash converts phenanthraquinone into diphenic acid, $C^{14}H^{10}O^4$; with *alcoholic ammonia* it yields phenanthraquinonimide, $\begin{array}{c} C^6H^4-CNH \\ | \\ C^6H^4-CO \end{array}$, which

crystallises in brownish needles melting at 167°. Its formation is represented by the equation:

By strong hydrochloric or sulphuric acid the imide is reconverted into phenanthraquinone. When phenanthraquinone is heated with alcoholic ammonia for several days in sealed tubes, a mixture of several substances is obtained, one of which has the composition $\text{C}^{14}\text{H}^{10}\text{N}^2$, and forms dark-green or brown needle-shaped crystals, slightly soluble in amyl alcohol (Anschütz a. Schultz, *Liebig's Annalen*, cxvi. 49–53). E. Schmidt (*Ber.* vii. 1365), by treating phenanthraquinone with aqueous ammonia, obtained two compounds represented by the formulæ $\text{C}^{14}\text{H}^{11}\text{N}^2\text{O}^2$ and $\text{C}^{28}\text{H}^{16}\text{N}^2$.

Oxidation by Permanganate.—Phenanthraquinone, treated with very weak soda-ley and potassium permanganate at 100°, yields diphenylene ketone. When boiled with weak soda-ley alone it yields diphenylene-glycollic acid, and when heated with dilute solution of permanganate alone it yields diphenic acid. Diphenylene ketone and diphenic acid, when further oxidised with alkaline permanganate, yield phthalic acid, but apparently no isophthalic or terephthalic acid. The same product was obtained also by the oxidation of sodium phenanthrene-sulphonate with potassium permanganate (Anschütz a. Japp, *Ber.* xi. 211).

Action of Zinc-ethyl.—When finely powdered phenanthraquinone is gradually added to zinc-ethyl diluted with ether to such an extent that it is no longer spontaneously inflammable, a reaction takes place accompanied by evolution of gas and precipitation of a whitish powder. The addition of the quinone must be continued so as nearly to exhaust the zinc-ethyl, but leave it in slight excess. On decomposing the product with excess of alcohol, boiling, and filtering hot, a substance is obtained having the composition $\text{C}^{16}\text{H}^{14}\text{O}^2 \cdot \text{C}^2\text{H}^2\text{O}$, in transparent nearly colourless rectangular plates, often nearly an inch long, sometimes grouped in rosettes. It begins to soften at 73° and melts at 77°; dissolves readily in all the ordinary solvents except water, which takes up only traces of it. Exposed to the air for some days in the finely divided state, it gradually changes to a deep orange-coloured gummy mass; in a vacuum, however, it remains unaltered.

The compound $\text{C}^{16}\text{H}^{14}\text{O}^2$ has not been obtained in the pure state, inasmuch as the last traces of alcohol cannot be expelled without decomposing it; but its *acetyl-derivative*, $\text{C}^{16}\text{H}^{13}\text{O}^2(\text{C}^2\text{H}^3\text{O})$, obtained by boiling it for some hours with acetic anhydride and adding alcohol to decompose the excess of acetic anhydride, crystallises from the solution on standing in large well-formed colourless prisms, which after being purified by recrystallisation from alcohol and from petroleum-ether, melt at 103° (Japp, *Chem. Soc. J.* 1879, xxxv. 526).

Reaction with Toluene.—On mixing 5 c.c. of a solution of phenanthraquinone in glacial acetic acid (1 : 200) with 1 c.c. of toluene, adding 4 c.c. of concentrated sulphuric acid, drop by drop, and keeping the liquid cold, a bluish-green colour is produced. When this liquid after a few minutes is poured into water, a turbid purple solution is obtained, from which ether dissolves the colouring matter with a deep reddish-violet colour. This reaction is so sensitive, that even 0.0005 gram of the quinone may be detected by it. On evaporating the ether, a black mass is left behind which in thin layers appears indigo-blue. *Xylene* yields a similar body, dissolving in ether with a cherry-red colour (Laubenheimer, *Ber.* viii. 224).

Dibromophenanthraquinone, $\text{C}^{14}\text{H}^8\text{Br}^2\text{O}^2$, is produced by heating the quinone to 180° for six hours with the calculated quantity of bromine and a little water, and crystallises from glacial acetic acid in yellow nodules, slightly soluble in alcohol, glacial acetic acid, and benzene, more readily in xylene, melting at 230°. When treated with alkalis, it does not yield an isomeride of alizarin (Hayduck, *Liebig's Annalen*, clxvii. 185). According to Ostermayer (*Ber.* vii. 1090), it melts at 233°, and is converted by oxidation with chromic acid mixture into dibromodiphenic acid, which, as well as the dibromoquinone itself, is but sparingly soluble in all solvents. Its formation is always attended with that of a comparatively small quantity of *tribromophenanthraquinone*, from which it is best separated by means of chloroform.

by oxidation of phenanthrene-carboxylic acid with chromic acid, is a body having the colour of phenanthraquinone, but distinguished therefrom by its solubility in cold aqueous sodium carbonate, and from phenanthrene-carboxylic acid by its solubility in acid sodium sulphate. It melts at 315° (Japp a. Schultz, *Ber.* x. 1661).

Constitution of Phenanthrene.

The formation of this hydrocarbon from stilbene or symmetrical diphenyl-ethylene (p. 675), by abstraction of hydrogen (vii. 84), shows that it has the constitution of symmetrical diphenylene-ethylene:

Further, G. Schultz (*Ber.* xi. 215) has converted Griess's diamidodiphenic acid, $\text{C}^{14}\text{H}_9(\text{NH}_2)_2\text{O}^4$ (p. 658), on the one hand, into benzidine or diamidodiphenyl, $\text{C}^{12}\text{H}_8(\text{NH}_2)_2$, by heating its barium salt with caustic baryta, and, on the other hand, into diphenic acid, $\text{COOH.C}^6\text{H}_4-\text{C}^6\text{H}_4.\text{COOH}$, by treating it with dilute nitric acid, converting the resulting nitrate by the action of nitrous acid into the corresponding nitrate of tetrazodiphenic acid, which, when treated with hydriodic acid, yields di-iododiphenic acid, $\text{C}^{12}\text{H}_8\text{I}_2(\text{CO}_2\text{H})_2$, and reducing this latter with sodium-amalgam. Now benzidine is diparadiamidodiphenyl, H^2N  NH_2 , and Griess's diamidodiphenic acid is prepared from meta-amidobenzoic acid, and

must therefore be represented by the formula H^2N  NH_2 , and diphenic acid and phenanthrene by the following formulæ:

They are therefore di-ortho-compounds, and this conclusion is corroborated by the production of phthalic acid, without admixture of isophthalic or terephthalic acid, by the oxidation of phenanthraquinone by potassium permanganate (p. 1518).

Moreover, as recently pointed out by Japp (*Chem. Soc. J.* 1880, xxxvii. 88), many of the chemical reactions of phenanthrene seem to indicate that the dyad ethylene residue $-\text{CH}=\text{CH}-$ in the diphenylene-ethylene forms part of an aromatic nucleus. On oxidation the two atoms of hydrogen are replaced by *two* atoms of oxygen (not by one), a quinone being formed. This quinone on reduction yields a quinol (hydroquinone) containing the group $-\text{C}(\text{OH})=\text{C}(\text{OH})-$, and dissolving in caustic alkalis by virtue of these phenylic hydroxyl-groups. Monobromophenanthrene, in which the substitution of bromine takes place in the $-\text{CH}=\text{CH}-$ group—the compound yielding on oxidation phenanthraquinone with elimination of the bromine atom—may, as Anschütz has shown (*Ber.* xi. 1217), be heated with strong alcoholic potash to 170° without undergoing change, and taking into consideration the relative mobility of the bromine-atom in monobromomethylene and monobromostilbene, when these compounds are heated with alcoholic potash, this stability of monobromophenanthrene must be allowed to furnish very strong evidence that the group $-\text{CH}=\text{CH}-$ forms part of an aromatic nucleus.

Further evidence of a similar character may be found in the direct formation from phenanthrene and sulphuric acid of a sulphonic acid, in which the sulphonic group replaces one of the hydrogen atoms of the $-\text{CH}=\text{CH}-$ group (p. 1517). A direct sulphonation of a hydrocarbon has as yet been observed only in the aromatic nucleus. In the fatty series the presence of an electro-negative group (CN , CO.OH , &c.) is necessary, in order that direct sulphonation may take place. All these reactions are specifically aromatic in character, and, taken together, form a strong cumulative proof that the $-\text{CH}=\text{CH}-$ group belongs to a benzene nucleus.

The synthesis of phenanthrene from symmetrical diphenyl-ethylene amounts therefore to the construction of a benzene-nucleus, on the one hand from the ethylene residue $-\text{CH}=\text{CH}-$ (which, as long as it exists in diphenyl-ethylene, shows by its entire behaviour that it does not belong to a benzene-nucleus) and, on the other, from two pairs of carbon-atoms, each of which pairs contained in previously existing benzene-nuclei; thus:

Phenanthrene is therefore diortho-diphenylene-ethylene, and consists of three benzene-nuclei, one of which shares four adjacent carbon-atoms with the two others—one ortho-pair with each. This is the constitution originally attributed to anthracene (vi. 214). According to this view, phenanthrene may be derived from naphthalene by a repetition of the process by which naphthalene is derived from benzene, a suggestion thrown out by Graebe in the memoir above cited (*Liebig's Annalen*, clxvii. 133).

PHENANTHROL, $C^{14}H^9(OH)$. *Hydroxyphenanthrene* (p. 1516).

PHENETHEYLAMINE, or *Amido-ethyl-benzene*, $C^6H^4(C^2H^5).NH^2$. A base isomeric with ethyl-aniline, $C^6H^5.NH(C^2H^5)$, and produced therefrom by intramolecular atomic interchange. See **BENZENES** (**ETHYLAMIDO-**), (p. 205).

PHENOL, $C^6H^5O = C^6H^5.OH$. This compound is a constant product of the putrefaction of albumin (E. Baumann, *Ber.* x. 685), and is formed, together with indole, when fibrin which has putrefied in contact with the air is subjected for several weeks in closed vessels to the action of water under a layer of ether (Weyl, *Zeitschr. physiol. Chem.* i. 339).

Reactions.—1. Phenol-vapour passed through a red-hot tube is resolved into benzene, toluene, naphthalene, anthracene, phenanthrene, and a liquid boiling between 112° and 145° , which appears to consist for the most part of xylene (Kramers, *Liebig's Annalen*, clxxxix. 129).

2. Phenol, subjected to exhaustive chlorination (p. 1066), is converted into perchlorobenzene, together with perchloromethane, perchlorethane, and carbon dioxide (Ruoff, *Ber.* ix. 1483); by exhaustive bromination in like manner it yields perbromobenzene, together with carbon dioxide (Gessner, *ibid.* 1505).

3. By heating with *antimony pentachloride*, it is completely decomposed (Lössner, *J. pr. Chem.* [2], xiii. 418).

4. Heated in a sealed tube at a temperature below 100° with *chromyl chloride*, it yields quinol-ether or quinyloxyde, $(C^6H^4OH)^2O$ (Etard, p. 1444).

5. Phenol heated in an alcoholic solution containing excess of potash or soda with *carbon tetrachloride*, yields a mixture of *ortho*- and *para*-hydroxybenzoic acids (p. 285), and a similar reaction takes place with substituted phenols, according to the general equation:

In this manner chloro-, nitro-, &c. hydroxybenzoic acids may be formed, and similarly phenol-dicarboxylic acid from salicylic acid:

6. With *Alkaline Carbonates*.—Anhydrous phenol, strongly heated for some time in a sealed tube with solid *ammonium carbonate*, yields a colouring matter which dyes silk

and wool a very fine grey, capable of withstanding the action of soap, acids, and light (J. Roth, *Dingl. pol. J.* cccxvi. 560). Phenol fused with *sodium carbonate* yields chiefly catechol, resorcinol, and phloroglucinol, together with small quantities of other substances (Barth a. Schreder, *Ber.* xii. 417). A solution of *potassium carbonate* is decomposed by phenol at the boiling heat (Baumann, *ibid.* x. 686).

6. With *Glycerol*.—When a mixture of 2 pts. phenol, 2 pts. glycerol and 3 pts. sulphuric acid is heated for some time at 120°–130°, the mixture first turns yellow, then yellowish-red, and finally dark red; and on dissolving the thick mass in water, and adding hydrochloric acid, a colouring matter is precipitated which dissolves sparingly in ether, easily in alcohol and in water, but does not appear to be crystallisable. It is coloured a fine red by alkalis, and by salts which have an alkaline reaction, and forms lakes with baryta, alumina, lead oxide, and other metallic oxides. Heated with *aniline*, it forms a red dye-stuff coloured violet-red by ammonia. Similar bodies are obtained from pyrogallol and thymol (C. Reichl, *Ber.* ix. 1429).

7. With *Aniline* and *Sodium Hypochlorite*.—When aniline is added to an alcoholic liquid containing phenol, and then sodium hypochlorite, a brown colour is produced, gradually changing to greenish blue; and on diluting after a while with an equal volume of water, and adding a very small quantity of ammonium sulphide, the colour changes to a pure blue. This colour, which soon turns to brown, is restored by further addition of the hypochlorite (Jacquemin, *Ann. Chim. Phys.* [5], ix. 571). See *ERYTHROPHENIC ACID* (p. 738).

8. On the reactions of phenol with *Cinchona-bases*, see pp. 486, 492, 493.

Distinction between Phenol and Creosote.—The following distinguishing characters of phenol and creosote are given by A. M. Read (*Arch. Pharm.* [3], iv. 444):

	<i>Creosote</i>	<i>Phenol</i>
3–4 vols. saturated baryta-water	Turbid solution	Clear solution: after some time slight precipitate or none
Alcoholic solution of ferric chloride	Green	Brown
Aqueous solution of ferric chloride	No reaction	Blue
Glycerin	Soluble; reprecipitated by water	Soluble: not precipitated by water

See also Wätzel (p. 581).

Distinctive tests for Phenol, Cresol, and Creosote are given by H. Allen (*Analyst*, 1878, 319; *Chem. Soc. J.* xxxvi. 182).

Volumetric Estimation.—W. F. Koppeschaar estimates phenol volumetrically by a method, originally suggested by Landolt (*Ber.* iv. 770), founded on the insolubility of tribromophenol. The estimation may be effected by adding a known excess of bromine to phenol, whereby tribromophenol is precipitated, replacing the excess of bromine by iodine, and titrating the latter with sodium thiosulphate. The use of bromine-water is, however, inconvenient in many respects, and it is therefore better to make use of nascent bromine evolved from a mixture of bromide and bromate of sodium. This mixture of salts, 5NaBr + NaBrO₃, is obtained by treating a solution of sodium hydroxide with excess of bromine, evaporating to dryness, and pulverising the residue. Its chemical value must be determined by means of potassium iodide and sodium thiosulphate. To perform the analysis, 25 c.c. of the phenol-solution containing 0.1 g. of the sample are placed in a bottle of 250 c.c. capacity; 100 c.c. of the triturated solution of the mixed salts, and 5 c.c. of strong hydrochloric acid are added, and the bottle, after being closed and shaken, is left at rest for a quarter of an hour, after which it is opened, 10 c.c. of potassium iodide solution are poured in, the bottle is again shaken, and after a while the separated iodine is determined by titration (*Zeitschr. anal. Chem.*, 1876, 233; *Chem. Soc. J.* xxxvi. 182).

Phenol-ethers. *Methyl Phenate* or *Anisoil*, C⁶H⁵O = C⁶H⁵.OCH₃.—Some new derivatives of this compound have been obtained by W. H. Perkin (*Chem. Soc. J.* xxxiii. 211).

o-Vinyl-anisoil, C⁶H⁴ < $\begin{matrix} \text{OCH}_3 \\ \text{CH}=\text{CH}^2 \end{matrix}$, is prepared by leaving methyl-*o*-oxyphenylacrylic acid (p. 506) in contact with hydriodic acid (sp. gr. 1.94) for two or three days; agitating the mixture frequently, and adding the product by small quantities and with frequent agitation, to a cold aqueous solution of sodium carbonate; boiling the resulting milky liquid in a retort till no more oily product distils over; then warming the distillate to promote the separation of the oil in the form of a layer, and drying this oil

with potassium carbonate. This compound boils between 195° and 200°, but it polymerises so quickly when heated, that its boiling point cannot be determined within narrower limits. When heated for an hour at 150°, it changes into a transparent vitreous polymeride, which is insoluble in alcohol, but dissolves in benzene, and is reconverted into *o*-vinyl-anisöl by distillation. In like manner, *ortho*-allyl-anisöl, $C^6H^4(OC^6H^5)C^3H^5$, is obtained from methyl-*o*-oxyphenylcrotonic acid and *ortho*-butenyl-anisöl, $C^6H^4(OC^6H^5)C^4H^7$, from methyl-*o*-oxyphenylangelic acid.

The boiling points and specific gravities of these bodies, and of the corresponding compounds of the *para*-series, are given in the following table:

	Boiling point	Specific gravity		
		at 15°	at 30°	at 45°
Paravinyl-anisöl . . .	204°-205°	1·0029	0·9956	—
Orthovinyl-anisöl . . .	uncertain	1·0095	1·0000	—
Parallyl-anisöl . . .	232°	—	0·9852	0·9761
Orthoallyl-anisöl . . .	222°-223°	0·9972	0·9884	0·9793
Parabutenyl-anisöl . . .	242°-243°	—	0·9733	—
Orthobutenyl-anisöl . . .	232°-234°	0·9817	0·9740	—

The *para*-compounds crystallise readily; the *ortho*-compounds do not solidify even in a freezing mixture.

Ethyl Phenate or *Phenetoil*, $C^6H^5O = C^6H^5(OC^2H^5)$, is formed by heating a mixture of phenol and ethyl alcohol with zinc chloride, and by heating a solution of phosphoric anhydride in phenol with alcohol (Kastropp, *Ber.* x. 1685). By exhaustive chlorination, it yields perchlorobenzene, together with carbon dioxide and perchlorethane. Methyl phenate, or anisöl, similarly treated, yields perchlorobenzene, carbon dioxide, and perchloromethane (Ruoff, *Ber.* ix. 1483).

Nitrophenetöils are obtained by the action of sodium ethylate on the corresponding nitrochlorobenzenes, e.g.:

It is advisable to use double the quantity of sodium required by the equation, and to add it by small portions. The liquid becomes hot and acquires a red colour; hydrogen is rapidly evolved; and the nitrated phenetoil separates as a brown precipitate, which, after dilution and acidulation, may be collected on a filter, and crystallised several times from boiling alcohol, with addition of animal charcoal. *Trinitrophenetoil* thus obtained crystallises in amber-coloured needles; *dinitrophenetoil* in small yellow needles.

Amidophenols. When *ortho*-amidophenol is treated with bleaching powder, or better with potassium ferricyanide, an amorphous humus-like body is obtained which forms red crystals when heated, and appears to have the composition $C^{14}H^{10}N^2O^2$. It is slightly basic, and forms bright-coloured solutions with acids (G. Fischer, *J. pr. Chem.* [2], xix. 317).

Diamidophenols, $C^6H^5(NH^2)^2OH$. (1). *a-Diamidophenol*, $C^6OH.NH^2.H.NH^2.H^2$, or [1 : 2 : 4]. The hydrochloride of this base is obtained by acting upon *a*-dinitrophenol with tin and hydrochloric acid, and precipitating the resulting tin salt with strong hydrochloric acid. When heated in an oil-bath at 80°-210° with benzoyl chloride, it yields a di- and a tri-benzoyl derivative.

The *di*benzoyl-derivative, $C^6H^5(NH.CO.C^6H^5)^2OH$,* is contained in the portion of the crude product which is soluble in alcohol, and may be precipitated from the solution by water. By repeating these operations of solution and precipitation, and finally crystallising the product, best from benzene, it is obtained in crystals having a faint reddish colour and melting at 187°-188°. It dissolves readily in aniline, alcohols, chloroform, and glacial acetic acid, sparingly in benzene, very sparingly in ether, and not at all in water. Cold fuming nitric acid converts it into *nitrodi*benzoyl-*a*-*diamidophenol*, $C^6H^2(NO^2)(OH)(NH.CO.C^6H^5)^2$, which crystallises from glacial acetic acid in slender yellow needles, very slightly soluble in alcohol (K. Stuckenberg, *Ber.* x. 885).

Tribenzoyl-a-diamidophenol, $C^6H^5(OH) \begin{smallmatrix} N(CO.C^6H^5)^2 \\ NH.CO.C^6H^5 \end{smallmatrix}$, is the chief constituent of the residue left on digesting the product of the above-described reaction in alcohol, and may be extracted therefrom by glacial acetic acid and purified by recrystallisation.

Note by Dr. Armstrong.—Stuckenberg has given no proof that these benzoyl-derivatives have the constitution above indicated. It is more than probable that the H of the OH-group is displaced in the tri-, if not in the di-derivative.

tion. It forms colourless microscopic crystals melting at 231° – 233° , easily soluble in aniline, sparingly in glacial acetic acid, insoluble in alcohol, benzene, ether, chloroform, and water (Stuckenberg).

β -*Diamidophenol*, $\text{C}^6\text{H}_3(\text{NH}_2)^2\text{OH}$. The *hydrochloride*, $\text{C}^6\text{H}_3(\text{NH}_2)^2\text{OH} \cdot 2\text{HCl}$, prepared as above described from β -dinitrophenol, [1, 2, 6], is easily soluble in water, sparingly in alcohol, insoluble in ether, soluble in warm dilute hydrochloric acid, from which it crystallises in long rather thick needles. The *sulphate*, $\text{C}^6\text{H}_3(\text{NH}_2)^2\text{OH} \cdot \text{SO}_4\text{H}_2$, is formed by adding an excess of sulphuric acid to the concentrated solution of the hydrochloride, or by dissolving the latter in dilute sulphuric acid, and separates from the solution on addition of alcohol, in shining needles, light yellow by transmitted light; easily soluble in water, sparingly in alcohol, insoluble in ether. It has not been found possible to obtain any other salts of this base or the base itself.

Benzoyl-derivatives are obtained by treating the hydrochloride with benzoyl chloride at 60° – 195° ; and on digesting the somewhat fluid pulp thereby produced with a solution of sodium carbonate, and filtering, the filtrate deposits a dingy yellow body, and the residue on the filter, when several times dissolved in alcohol, precipitated by water, and finally crystallised from benzene, yields *dibenzoyl- β -diamidophenol*, $\text{C}^6\text{H}_3(\text{NH} \cdot \text{CO} \cdot \text{C}^6\text{H}_5)^2\text{OH}$,* in small prisms having a faint greenish colour, melting at 209° – 213° , easily soluble in alcohol and glacial acetic acid, sparingly in benzene.

The yellow body above mentioned, after being once crystallised from alcohol, may be resolved by chloroform into two compounds, one soluble in that liquid, the other insoluble. The latter consists of *tribenzoyl- β -diamidophenol*, $\text{C}^6\text{H}_3(\text{OH}) \cdot \text{N}(\text{CO} \cdot \text{C}^6\text{H}_5)^2 \cdot \text{NH} \cdot \text{CO} \cdot \text{C}^6\text{H}_5$, which when purified by crystallisation from alcohol, forms broad needles, melting at 183° – 184° , nearly colourless by reflected light, but exhibiting a rather strong dichroism when examined by the polarising microscope.

Tetrazobenzoyl- β -diamidophenol, $\text{C}^6\text{H}_3[\text{N}(\text{CO} \cdot \text{C}^6\text{H}_5)^2]\text{OH}$, is the portion of the yellow body which deliquesces in chloroform. When recrystallised from alcohol it forms thin plates, appearing colourless to brownish yellow by transmitted light, and likewise acting on polarised light, but exhibiting merely alternations of light and darkness. This compound melts at 182° , is insoluble in water, dissolves in alcohol as easily as the preceding, and is more soluble in benzene and in ether.

Triamidophenol, $\text{C}^6\text{H}_3(\text{NH}_2)^3\text{OH}$ (vi. 916). The action of bromine and water on this compound has lately been studied by Weidel a. Gruber (*Ber.* x. 1137). The chief product of this reaction is bromodichromazin, $\text{C}^{18}\text{H}^7\text{N}^3\text{Br}^{11}\text{O}^7$, which is produced by gradually adding bromine (90 c.c.) to a solution of triamidophenol hydrochloride (200 grams) in 50 pts. of water. The blue colour of the diimidoamidophenol first produced then passes into yellow, and on leaving the filtered solution at rest, impure *bromodichromazin* is deposited in glistening brownish-yellow needles; the mother-liquors yield a little more of the substance on agitation with ether. It is purified by washing it with boiling chloroform, and crystallising the residue from alcohol, with the aid of animal charcoal. The long yellow prismatic crystals formed on spontaneous evaporation of the alcoholic solution exhibit a feeble violet dichroism. The compound is very slightly soluble in ether, and insoluble in benzene, chloroform, and carbon bisulphide; boiling alcohol and acetic acid dissolve it with facility. When heated it is decomposed without previous fusion, giving off bromine vapour. It dissolves in concentrated sulphuric acid, but is precipitated by water unchanged, so that it is evidently not a hydrobromide of the compound $\text{C}^{18}\text{H}^7\text{N}^3\text{Br}^{10}\text{O}^7$.

Mercuric acetate, added to a solution of bromodichromazin in acetic acid or alcohol, produces a pale-yellow crystalline precipitate of the compound $(\text{C}^{18}\text{H}^7\text{N}^3\text{Br}^{11}\text{O}^7)_2\text{Hg} + 3\text{Hg}(\text{C}^2\text{H}_3\text{O}_2)^2$, which, when heated to 100° , becomes brown, evolves bromine, and at a somewhat higher temperature explodes. It is decomposed by sodium-amalgam, with formation of ammonia, and when fused with potassium hydrate yields only oxalic acid.

Bromodichromazin, boiled with a mixture of equal parts of sulphuric acid and water until it no longer separates on dilution, is converted into *bromodichroic acid*, $\text{C}^{18}\text{H}^7\text{Br}^{11}\text{O}^{11}$, which separates after some time in crystalline crusts, the reaction being $\text{C}^{18}\text{H}^7\text{Br}^{11}\text{N}^3\text{O}^7 + 4\text{H}_2\text{O} = \text{C}^{18}\text{H}^7\text{Br}^{11}\text{O}^{11} + 3\text{NH}_3$. A further quantity may be obtained by exhausting the acid liquors with ether. It may be purified by repeated crystallisation from a mixture of ether and benzene with the aid of animal charcoal, and then forms colourless tabular prismatic crystals of considerable size, easily soluble in water, alcohol, and ether. When heated it decomposes below 100° , turning brown, and at a higher temperature evolves bromine, and chars without previous fusion. Its solution has an acid bitter taste, and easily decomposes carbonates. Bromodichroic acid yields

* See note on p. 1522.

precipitates with lead and silver salts, but they quickly decompose, being transformed into the bromides; alkalis also decompose it very rapidly. The calcium and barium salts are obtained by acting on their respective carbonates with a solution of the acid. They crystallise in slender needles, which are very hygroscopic, and quickly change on contact with the air. Bromodichroic acid is reduced by sodium-amalgam, but the product has not been obtained in the pure state; when fused with potash, it yields acetic acid and resorcinol.

Bromodichromazin boiled for some time with dilute nitric acid, is changed into an oil having the composition of *hexbromacetone*, which crystallises on standing, whilst bromine and bromopierin are produced at the same time. Chromic acid or chromic mixture acts in a similar manner; but an alkaline solution of permanganate completely decomposes the compound. Bromine acts strongly on bromodichromazin suspended in water, causing an evolution of carbonic anhydride, and although the action goes on slowly at the ordinary temperature, it may be completed in a few minutes by heating the mixture at 100°. On cooling, the hexbromacetone above mentioned separates in lustrous scales, which may be purified by crystallisation from chloroform. Its formation by this last reaction is represented by the equation

Hexbromacetone crystallises in monoclinic prisms. It is insoluble in water even at the boiling heat, but dissolves easily in chloroform, carbon sulphide, benzene, and ether, and with partial decomposition in alcohol. It melts in the dry state at 107°–108°, under water at 100°, and decomposes at 200°. By boiling with alkalis, or by heating with water at 180°, it is converted into bromoform. Heated in a sealed tube at 150° with red fuming nitric acid, it is converted into bromopierin; with ammonia it yields bromoform and tribromacetamide. Dissolved in aqueous methyl alcohol and treated with sodium-amalgam, it is converted into pseudopropyl alcohol.

Diazophenol compounds (Weselsky, *Ber.* viii. 895). When nitrous gas is passed into an ethereal solution of phenol cooled with ice, it is quickly absorbed, with formation of diazophenol nitrate together with mono- and dinitrophenol, the reaction taking place according to the following equations:

When the operation is carefully conducted on a rather large scale (200 g. phenol and a litre of ether), the yield of diazophenol nitrate is nearly equal to the theoretical amount. As soon as the nitrous gas ceases to be absorbed, the liquid is left to cool, and after a while needle-shaped crystals are deposited, the formation of which indeed goes on during the absorption of the gas. The liquid separated from them yields on further treatment fresh quantities of the *diazophenol nitrate*, contaminated with resinous products, from which it may be freed by solution in alcohol and precipitation with ether, but even then it retains a faint brownish colour. Diazophenol nitrate is very explosive, but burns without detonation, leaving a large quantity of charcoal. It is decomposed by alkaline liquids, also by boiling with alcohol or with water. The *sulphate*, $\text{C}^6\text{H}^4\text{N}^2\text{O} \cdot \text{HSO}^4$, prepared by treating the nitrate with 1 vol. sulphuric acid, 2 vols. water, and a small quantity of alcohol, filtering, and mixing the solution with ether till it becomes turbid, crystallises well, is not explosive, and may be dried at 100°. By decomposition with barium chloride, it yields the explosive *hydrochloride*, and from this, or from a mixture of the sulphate with hydrochloric acid, the well-crystallised *platinochloride*, $(\text{C}^6\text{H}^4\text{N}^2\text{OCl})_2\text{PtCl}_4$, may be obtained.

Bromophenols. *Orthobromophenol* has been prepared by Fittig a. Mager (*Ber.* viii. 362) by converting orthobromaniline into diazobromobenzene sulphate and decomposing the latter with water; distilling the product with steam; agitating the distillate with ether; distilling off the greater part of the ether; drying the concentrated ethereal solution with calcium chloride, and distilling it twice. As thus prepared, it is a colourless liquid having a very disagreeable and persistent odour; it boils at 194°–195°, does not solidify on cooling, and is slightly soluble in water. When decomposed by strong potash-ley at the lowest possible temperature, it yields resorcinol as chief product, together with a small quantity of catechol.

Metabromophenol, prepared in like manner from metabromaniline, is a laminar, perfectly colourless mass, which does not alter even in sunshine. Its odour is phenolic, but not nearly so disagreeable as that of the ortho-compound. It melts at 32°–33°, boils at 236°–236.5°, and when pure solidifies in a short time after distillation. The oily compound obtained from metabromaniline by Körner and by Wurster a. Nölting (vii. 905) was impure. Metabromophenol, decomposed with strong potash-ley, yields chiefly resorcinol, together with a small quantity of catechol.

Parabromophenol melts at 64°, not at 66.4° as stated by Körner.

The fact that the three bromophenols, when fused with potash, all yield resorcinol, shows that this compound is the most stable of the three dihydroxybenzenes, and that fusion with potash is by no means a trustworthy method of determining the constitution of an isomeric aromatic compound (Fittig a. Mager).

Tribromophenol, $C^6OH.Br.H.Br.H.Br$, is converted by the action of potassium sulphite, chiefly into a body which is perhaps a bromo-derivative of $C^{12}H^8O^2$ (Armstrong a. Harrow, *Chem. Soc. J.* xxix. 476). By direct nitration it is converted into orthobrom- α -dinitrophenol (m. p. 117°), but by treating 1 mol. tribromophenol dissolved in glacial acetic acid with 1 mol. nitric acid, diorthobromoparanitrophenol, $C^6OH.Br.H.NO^2.H.Br$, is produced (Armstrong a. Harrow, *ibid.* 477). **Tribromophenol bromide**, $C^6H^2Br^3.OBr$, is formed by the action of bromine-water in excess on tribromophenol, and is reconverted into the latter by boiling with alcohol or by reduction with tin and hydrochloric acid (Benedikt, *Ber.* xii. 681).

Chlorophenols. **Trichlorophenol**, $C^6OH.Cl.H.Cl.H.Cl$, heated at 170° with potassium sulphite, yields the potassium salts of dichlorophenolsulphonic and chlorophenoldisulphonic acids. The former treated with strong nitric acid yields **dichlororthonitrophenol** melting at 121° ; the latter, **diorthonitroparachlorophenol** melting at 80.5° (Armstrong a. Harrow, *loc. cit.*)

Perchlorophenol Chloride, $C^6H^5HO = C^6Cl^5.OH.Cl$, is formed by passing an excess of chlorine into an acetic acid solution of metachloracetanilide. The product is precipitated by water, and the precipitate extracted with dilute acetic acid; the insoluble residue is then treated with carbon bisulphide to dissolve the chloride, which crystallises out on evaporation of the bisulphide. By washing with alcohol and recrystallisation from light petroleum, it is obtained in large colourless prisms melting at 78.5° – 80° . It is easily soluble in benzene, carbon bisulphide, and alcohol, but only slightly soluble in acetic acid. Alkalis decompose it completely; when heated at 230° with alcohol it yields pentachlorophenol, C^6Cl^5OH , melting at 183° (Beilstein, *Ber.* xi. 2182).

Iodophenols. **Ortho-iodophenol** forms fine crystals melting at 43° . **Para-iodophenol** fused with potash at 165° yields quinol (Körner), but at higher temperatures it yields resorcinol (Nölting a. Wrzesinski, *Ber.* viii. 820).

Cyanophenol, $C^6H^4(CN)OH$, is formed by boiling diazocyanobenzene nitrate, $C^6H^4(CN)N^2.NO^3$ (vii. 426), with water, filtering the solution after cooling, neutralising the filtrate with ammonia, and evaporating. It is then obtained as a dark-coloured oil which quickly solidifies and may be purified by washing with water, drying, and distillation. It dissolves readily in alcohol and ether, and crystallises therefrom in small white rhombic prisms; from hot water it separates on cooling, also in rhombic prisms. It melts at 82° , has an intensely sweet and at the same time biting taste, and an odour like that of phenol, but fainter. Heated for some hours with strong hydrochloric acid in a sealed tube placed in the water-bath, it is converted into meta-hydroxybenzoic acid (Griess, *Ber.* viii. 859).

Nitrophenols. Determinations of the crystalline form, specific gravity, and solubility of the potassium, barium, and silver salts of the three isomeric mononitrophenols have been made by Post a. Mertens (*Ber.* viii. 1549; *Jakresb. f. Chem.* 1875, 423.)

The action of nitric acid on phenol and the nitrophenols has been studied by Goldstein (*Ber.* xi. 1943) with the following results:

(1). The ratio of the quantity of the more to that of the less volatile of the isomeric nitrophenols, obtained by the action of nitric acid on phenol, bears, within certain limits, a direct proportion to the temperature employed.

(2). By the action of strong nitric acid on orthonitrophenol, a crystalline body is formed, which melts at 105° , and dissolves in hot water to an intensely yellow solution having a bitter taste.

(3). A quick method of preparing dibromonitrophenol from orthonitrophenol consists in adding aqueous bromine to its alkaline solution until no further separation of the product is observed. On filtering, the dibromonitrophenol (m. p. 117°) is obtained nearly pure.

Metanitrophenol, formed from metanitriline by the diazo-reaction, is easily soluble in alcohol and ether, crystallises from carbon sulphide in feathery plates, melts at 96° , and distils unchanged at 194° under a pressure of 70 mm. It decomposes carbonates, forming beautiful salts. The potassium salt crystallises with 2 mol. H^2O , in orange-coloured flat needles.

Metanitranisöl is obtained by heating this potassium salt in alcoholic solution with excess of methyl iodide. It crystallises from alcohol in colourless needles, melts at 38° , boils undecomposed at 254° , and is easily volatilised by steam. **Metanitrophenetöl**, prepared in like manner, melts at 34° , boils with slight decomposition at 264° under ordinary pressure, and at 169° under a pressure of 70 mm.

Resorcinol is easily obtained from metanitrophenol through the amido-compound and diazo-reaction. *Trinitroresorcinol* or *Styphnic acid* is formed in theoretical quantity by the long-continued action of boiling concentrated nitric acid on metanitrophenol (A. Bantlin, *Ber.* xi. 2099).

Paranitrophenol.—O. Lehmann (*Zeitschr. f. Kryst.* i. 45) finds that this compound is dimorphous; he distinguishes the ordinary modification by the prefix *b*; the other, which is unstable and produced by the fusion of the first, by the prefix *a*. The *a*-modification is monoclinic. Axes $a : b : c = 0.6796 : 1 : 0.3445$. $\beta = 79.6^\circ$. Combinations $\infty R2$, $+P$, and frequently also $\infty R\infty$. Observed angles: $\infty R2 : \infty R2$ forwards = $106^\circ 19'$; $+P : +P$ in the vertical edge = $36^\circ 22'$; $+P : +P$ backwards = 65° . Cleavage distinct parallel to $+P\infty$. The first median line forms with the vertical axis an angle of 22° , in the acute angle of the axes *a* and *c*. Through a cleavage-plate parallel to $+P\infty$, both axes may be seen at the edge of the field of view, and situated in the plane of symmetry. The angle of the optic axes is very large. The *b*-modification is also monoclinic, and was formerly regarded by Kokscharow (iv. 396) as identical with the *a*-modification. The first median line for yellow light forms with the principal axis an angle of $47\frac{1}{2}^\circ$ in the obtuse angle of the crystallographic axes. The true angle of the optic axes is 70° , and their plane is parallel to the plane of symmetry.

Dinitrophenols, $C^6H^3(NO^2)_2OH$. Two of these compounds, having the constitutional formulæ $1 : 2 : 4$ and $1 : 2 : 6$ (OH in 1), and designated respectively as the α and β modifications, are described in vii. 909. 910. The following ethers of the α -compound have been examined by Willgerodt (*Ber.* xii. 762), who prepares them by dissolving α -dinitrochlorobenzene, $[Cl : NO^2 : NO^2 = 1 : 2 : 4]$, in the corresponding alcohols, and adding a solution of potash in the same alcohols. The reaction may be represented by the general equation:

Thus by acting on α -dinitrochlorobenzene dissolved in methyl alcohol with a methyl alcohol solution of potash, α -dinitroanisole, $C^6H^3(NO^2)_2.OCH^3$, is obtained. The same compound is formed by the action of a methyl-alcohol solution of potash on an ethereal solution of the dinitro-compound; the reaction may also take place in presence of water. The ether crystallises in long yellow needles melting at 86° – 87° .

α -Dinitrophenetole, $C^6H^3(NO^2)_2.OC^2H^5$, prepared in a similar manner, substituting ethyl for methyl alcohol, crystallises in long white needles melting at 86° . The corresponding propyl and amyl ethers are yellowish oily liquids.

α -Dinitrophenyl allyl-ether, obtained by acting on α -dinitrochlorobenzene dissolved in allyl alcohol with an alcoholic solution of potash diluted with water, crystallises in long needles or asbestos-like masses, melting at 46° – 47° .

The *glycerol ether*, $C^6H^3(NO^2)_2.OC^3H^7(OH)_2$, is obtained by dissolving dinitrochlorobenzene in glycerol with the aid of heat, and adding to it a solution of potash in glycerol. The product may be crystallised from water, alcohol, or ether; from the latter it separates out as a crystalline mass, melting at 83° .

α -Dinitrophenyl phenyl-ether, $C^6H^3(NO^2)_2.OC^6H^5$, is obtained by acting on a solution of α -dinitrochlorobenzene in carbon bisulphide with potassium phenylate. Crystallised from alcohol it forms long prisms or needles resembling urea-crystals. It melts at 71° . Maikopar (*Ber.* vi. 564) obtained an ether melting at 65° by the action of potash on an alcoholic solution of phenol and dinitrochlorobenzene. This Willgerodt concludes to have been impure, since he has obtained an ether melting at 71° by acting on an alcoholic solution of dinitrochlorobenzene with the calculated quantity of potassium phenylate.

Three other dinitrophenols (γ , δ , ϵ) have been obtained by Bantlin (*loc. cit.*) by the action of nitric acid on metanitrophenol. They are separated by taking advantage of the difference of solubilities of their barium salts in water (δ from γ and ϵ), and in alcohol (γ from ϵ).

γ -Dinitrophenol is soluble in ether and in hot alcohol; is easily volatilised by steam, separating on condensation in yellow needles (m. p. 104°). The potassium salt crystallises with 2 mol. H^2O in thick, bright red needles; the barium salt, with 3 mol. H^2O , in bright red needles.

δ -Dinitrophenol crystallises from water in long colourless silky needles, which melt under water at 50° – 60° , in the dry state at 134° . The potassium salt crystallises from water in red needles; the barium salt with 3 mol. H^2O in red-brown prisms.

ϵ -Dinitrophenol crystallises from water in small yellow needles (m. p. 144°). The

potassium salt crystallises with 2 mol. H_2O in yellow needles; the barium salt crystallises anhydrous in large brown needles.

Dinitroanisols are obtained by heating the potassium salts of the corresponding dinitrophenols with alcohol and methyl iodide at 100° ; also by the action of concentrated nitric acid on metanitroanisole.

γ -*Dinitroanisole* crystallises from alcohol in bright yellow needles melting at 96° ; it boils undecomposed above 360° , and is easily volatilised by steam.

δ -*Dinitroanisole* crystallises in slender golden-yellow needles melting at 70° ; it is less easily volatilised by steam than the γ -compound.

ϵ -*Dinitroanisole* crystallises from alcohol in colourless thick plates melting at 118° .

The three dinitrophenols, γ , δ , and ϵ , are converted by the action of boiling concentrated nitric acid into trinitroresorcinol or styphnic acid, $C_6H(NO_2)_3(OH)_2$ (p. 526).

Constitution of the Dinitrophenols.— α - and β -dinitrophenol are, as already observed, the 1 : 2 : 4 and 1 : 2 : 6 modifications (vii. 908). The constitutional formula of the γ , δ , and ϵ modifications are determined, at least approximately, by the following considerations:

γ -Dinitranisole, $C_6H^3(NO_2)_2.OCH^3$, heated in a sealed tube with ammonia at 170° , is converted, like the α - and β -modifications, into a dinitraniline, $C_6H^3(NO_2)_2.NH^2$, which when treated with ethyl nitrite yields [1 : 3] dinitrobenzene. The δ - and ϵ -modifications, treated in like manner, behave differently, being converted into nitroanisidines or nitro-amido-anisols, $C_6H^3(NO_2)(NH^2).OCH^3$. The base thus obtained from δ -dinitranisole, crystallises in brown needles melting at 129° , and subliming without decomposition in light yellow laminae; when treated with ethyl nitrite it is converted into *para*-nitroanisole which volatilises easily with aqueous vapour and melts at 52° .* ϵ -Dinitroanisole, treated in like manner, yields a nitroanisidine which crystallises in long yellow needles melting at 76° , and is converted by ethyl nitrite into metanitroanisole.

The relations between these several compounds, and their derivation from metanitrophenol, $C_6.OH.H.NO^2.H^3$, may be represented by the following scheme:

γ -Compounds.						
	1	2	3	4	5	6
Dinitrophenol . . .	OH	—	NO^2	—	NO^2	—
Dinitro-anisole . . .	OCH^3	—	NO^2	—	NO^2	—
Dinitro-aniline . . .	NH^2	—	NO^2	—	NO^2	—
<i>m</i> -Dinitrobenzene . . .	—	—	NO^2	—	NO^2	—
δ -Compounds.						
Dinitrophenol . . .	OH	—	NO^2	NO^2	—	—
Dinitroanisole . . .	OCH^3	—	NO^2	NO^2	—	—
Nitro-anisidine . . .	OCH^3	—	NH^2	NO^2	—	—
Para-nitroanisole . . .	OCH^3	—	—	NO^2	—	—
ϵ -Compounds.						
Dinitrophenol . . .	OH	NO^2	NO^2	—	—	—
Dinitro-anisole . . .	OCH^3	NO^2	NO^2	—	—	—
Nitro-anisidine . . .	OCH^3	NH^2	NO^2	—	—	—
Meta-nitro-anisole . . .	OCH^3	—	NO^2	—	—	—

The formation of trinitroresorcinol or styphnic acid from metanitrophenol must be preceded by that of a tetranitrophenol, since styphnic acid may be produced from either of the dinitrophenols above mentioned. This tetranitrophenol has probably, according to Bantlin, the constitution $C_6.OH.NO^2.NO^2.NO^2.H^3$; and as the styphnic acid formed from it must, as a derivative of resorcinol, have its two OH-groups in the meta-position with regard to each other, it may be represented by either of the formulae $C_6.OH.NO^2.NO^2.NO^2.OH.H^3$ or $C_6.OH.NO^2.OH.NO^2.NO^2.H^3$. The former is regarded by Bantlin as the more probable of the two.

* The melting point of this compound is usually given too low. Bantlin finds that when prepared from potassium paranitrophenate and methyl iodide it melts at 52° and boils without decomposition at 274° .

Trinitrophenol or **Picric Acid**, $C^6H^2(NO^2)_3OH$, [1 : 2 : 4 : 6, OH in 1]. On the thermal relations of this compound and its salts, see *HEAT* (pp. 954, 973, 981).

On the explosive force of *Potassium Picrate*, see p. 767.

On the preparation of *Lead Picrate*, and its use for filling percussion-caps, see *Prat (Monit. scient.* [3], iv. 665; *Jahresb. f. Chem.* 1874, 1124). This salt is intermediate in explosive power between gunpowder and nitroglycerol.

Ethyl Picrate, $C^6H^2(NO^2)_3OC^2H^5$, which Müller a. Stenhouse obtained by digesting dry silver picrate with ethyl iodide (vi. 911), is also produced by the action of alcoholic potash on an alcoholic solution of picryl chloride, $C^6H^2(NO^2)_3Cl$. The *phenyl-ether* prepared in like manner with an alcoholic solution of potassium phenate, crystallises in white needles (Willgerodt, *Ber.* xii. 1277).

Acetyl Picrate, $C^6H^2(NO^2)_3(OC^2H^3O)$.—When 1 pt. of picric acid and 4 pts. of acetic anhydride are heated in a reflux apparatus for two hours, a yellowish liquid is obtained, consisting of a solution of acetyl picrate in acetic anhydride. On adding water, the picrate is precipitated as a yellowish-white crystalline powder, which is to be washed with water and dried, first by pressure and then in a vacuum. Acetyl picrate melts at 75° – 76° , becoming pale yellow and oily; at 120° it gives off acetic acid; it darkens at 180° , and decomposes completely at 260° . It is soluble in ether, alcohol, and ethyl acetate, also in sulphuric, nitric, and hydrochloric acids. A few hours' exposure to air, and even less when in contact with water, causes it to become yellow, owing to partial decomposition. With an alkali it splits up into picrate and acetate of the alkali-metal. The ethereal solution, when evaporated, deposits beautiful crystals of a deep yellow colour (Tommasi a. David, *Compt. rend.* lxxvii. 207).

Diazobenzene Picrate is formed by the action of diazobenzene nitrate on sodium picrate; also by that of picric acid on diazobenzene-piperidine, $C^6H^2.N^2.NO^2.H^{10}$, dissolved in ether. It forms gold-yellow crystals, which decompose at 95° – 100° ; large quantities detonate when heated. It is insoluble in water, alcohol, ether, and benzene (Baeyer a. Jäger, *Ber.* viii. 893).

Isopicric acid, $C^6H^2(NO^2)_3OH$, [1 : 3 : 4 : 5, OH in 1].—This acid is formed by the action of fuming nitric acid on metanitrophenol and on γ and δ dinitrophenols, whence its constitution is established. It crystallises from water, or better from nitric acid, in light yellow, shining, transparent prisms, which melt at 174° , dissolve readily in hot water, with moderate facility in cold water, and colour the skin deep yellow (Bantlin, *Ber.* viii. 21).

Amidonitrophenols, $C^6H^3(NH^2)(NO^2).OH$ (Stuckenberg, *Ber.* x. 382, 385). *α -Amidonitrophenol*, [$OH : NH^2 : NO^2 = 1 : 2 : 4$], is formed by the action of ammonium sulphide on α -dinitrophenol, and best in the following manner. The solution of α -dinitrophenol in a small quantity of alcohol is mixed with a saturated solution of ammonium hydrosulphide till a thin pulp is formed, and into this pulp hydrogen sulphide is passed till the whole has assumed a dark-red colour. The crystalline mass, after filtration, pressing, and drying on bricks, is exhausted with ether, and the filtrate mixed with acetic acid is again filtered, evaporated, and neutralised with strong ammonia. The crystals which separate on cooling are exhausted in the dry state with ether, and the resulting ethereal extract, which contains the α -amidonitrophenol, is mixed with the preceding and left to evaporate. The product may be purified by recrystallisation from boiling water, into which it is introduced in the state of powder, and is thus obtained in orange-coloured hydrated prisms, which melt between 80° and 90° ; the anhydrous compound melts at 142° – 143° .

Benzoyl- α -amidonitrophenol, $C^6H^3(NO^2).NH(COC^6H^5).OH$, formed by the action of benzoyl chloride on the compound just described, may be purified by means of sodium carbonate and recrystallised from aniline. It is insoluble in water, dissolves slowly and with decomposition in alcohol and in glacial acetic acid, easily in aniline, and crystallises in colourless, microscopic, rhombic prisms which melt with decomposition above 200° . *Nitrobenzoyl- α -amidonitrophenol*, $C^6H^2(NO^2)_2.NH(COC^6H^5).OH$, is produced on adding the benzoyl-compound to fuming nitric acid diluted with an equal volume of ordinary strong nitric acid, or better glacial acetic acid, the mixture being kept cool. It crystallises from glacial acetic acid in pale-green prisms melting at 218° – 219° , dissolves sparingly in that liquid, in still smaller quantity in alcohol, and not at all in water. Together with this compound there is formed a secondary product which deliquesces in glacial acetic acid.

Amidodinitrophenol, $C^6H^3(NH^2)(NO^2)_2OH$, is formed, together with benzoic acid, on heating the benzoyl-derivative just described with hydrochloric acid in a sealed tube at 130° , and may be obtained pure by filtering the product, the benzoic acid then remaining behind; evaporating the filtrate; dissolving the residue in alcohol; precipitating with water; repeating the solution and precipitation several times; and finally crystallising from alcohol. The compound is thus obtained in broad, thick, dark-red

crystals, melting at 169°–170°, sparingly soluble in ether and in chloroform, easily in warm benzene, glacial acetic acid, water, and strong hydrochloric acid; deliquescent in aniline. From solution in chloroform it separates in monoclinic prisms. From its properties and its reaction with nitrous acid, it appears to be identical with the picramic or nitrophenamic acid which Laurent a. Gerhardt obtained by the action of ammonium sulphide on dinitrophenol (iv. 406).

***β*-Amidonitrophenol**, $[\text{OH} : \text{NH}^2 : \text{NO}^2 = 1 : 2 : 6]$, is prepared, like the *α*-compound, from *β*-dinitrophenol, and purified by dissolving the crude product in alcohol, adding twice the volume of water, and repeating this treatment on the resulting precipitate, till the water which runs away remains clear. It forms red needles, melting at 110°–111°, dissolving very easily in glacial acetic acid, benzene, ether, and chloroform, easily in alcohol, with moderate facility in boiling water, and with great difficulty in cold water. The *sulphate*, $(\text{C}^6\text{H}^3.\text{NH}^2.\text{NO}^2.\text{OH})^2\text{H}^2\text{SO}^4$, obtained by heating the base with dilute sulphuric acid and precipitating with alcohol, forms colourless laminæ, gradually decomposed by water and by alcohol (Stuckenberg).

Bromonitrophenols. The crystalline form of parabromonitrophenol, $[1 : 2 : 4]$ (vi. 915), has been determined by Arzruni (*Zeitschr. f. Kryst.* i. 436). It forms sulphur-yellow monoclinic prisms having the axial ratio $a : b : c = 2.941 : 1 : 1.6249$; $\beta = 64^\circ 2'$. Combination $\infty P \infty . \infty P . 0P . -P \infty . +P \infty$, with $-\frac{1}{2}P$ and $+\frac{1}{2}P$ mostly small. The crystals are tabular in the direction of the orthopinacoid. Observed angles, $\infty P : \infty P \infty = 69^\circ 17'$; $\infty P \infty : 0P = 64^\circ 2'$; $\infty P \infty : -P \infty = 42^\circ 14'$. Cleavage imperfect, parallel to $+P \infty$. The plane of the optic axes coincides with the plane of symmetry; the first median line is inclined at about 106° to the axis c in the obtuse angle β . Both axes are indistinctly visible in oil in a natural plate having its faces parallel to $\infty P \infty$.

Dibromonitrophenol, $[\text{OH} : \text{NO}^2 : \text{Br} : \text{Br} = 1 : 2 : 4 : 6]$, (p. 915). This compound crystallises in sulphur-yellow monoclinic prisms melting at 117.5° , $a : b : c = 0.5151 : 1 : 0.5912$; $\beta = 65^\circ 23'$. Faces $\infty R2$, rarely with ∞P , $0P$, $R \infty$, and in a few crystals also $+P$ and $+2P2$. Observed angles, $\infty R2 : \infty R2 = 86^\circ 15'$; $\infty R2 : 0P = 72^\circ 18'$; $0P : P \infty = 28^\circ 15' 30''$. Cleavage uneven, parallel to $\infty R \infty$ and $0P$. The plane of the optic axes is perpendicular to the plane of symmetry, and nearly perpendicular to the principal axis. The first median line lies in the plane of symmetry, and is very nearly normal to $\infty R \infty$. Apparent angle of axes 70° to 73° for different colours. Dispersion of axes $\rho < \nu$ (Arzruni, *loc. cit.*)

Bromodinitrophenol, $\text{C}^6\text{H}^2\text{Br}(\text{NO}^2)_2\text{OH}$, $[\text{OH} : \text{NO}^2 : \text{Br} : \text{NO}^2 = 1 : 2 : 4 : 6]$, forms yellow monoclinic crystals melting at 85.6° . $a : b : c = 2.7947 : 1 : 1.7783$; $\beta = 67^\circ 53'$. Observed forms $P \infty$, $\infty P \infty - P \infty$, $+P \infty$. Measured angles, $P \infty : P \infty = 62^\circ 31'$; $P \infty : \infty P \infty = 78^\circ 44'$; $-P \infty : \infty P \infty = 42^\circ 27'$. The plane of the optic axes coincides with the plane of symmetry; both axes are visible through $-P \infty$. The first median line is inclined at about $57\frac{1}{2}^\circ$ to the axis c in the obtuse angle β . $2E = 100^\circ$ nearly (Arzruni).

Bromiodonitrophenol, $[\text{OH} : \text{NO}^2 : \text{Br} : \text{I} = 1 : 2 : 4 : 6]$, forms monoclinic crystals having the axes $a : b : c = 0.5198 : 1 : 0.5871$; $\beta = 65^\circ 32'$. The crystals are dark brown-yellow, melt at 102° , are thickly tabular in the direction of the base, and exhibit, together with the base, which is mostly much rounded, the faces $\infty P \infty$, $P \infty$, ∞P , and $\infty P2$. Observed angles, $\infty P \infty : \infty P2 = 46^\circ 35'$; $\infty R \infty : P \infty = 61^\circ 53'$; $P \infty : \infty P = 57^\circ 42'$. Cleavage imperfect, parallel to $0P$. The plane of the optic axes is perpendicular to the plane of symmetry; the axis b is the first median line (P. Groth, *Zeitschr. f. Kryst.* i. 437).

Nitrosophenol, $\text{C}^6\text{H}^4(\text{NO})\text{OH}$ $[1 : 4]$. This compound, discovered by Baeyer a. Caro (vii. 911), has been further examined by E. ter Meer (*Ber.* viii. 622) and by C. Jaeger (*ibid.* 894). The former prepares it by adding nitrosodimethylaniline to boiling dilute soda-ley, cooling the solution quickly, neutralising it with dilute sulphuric acid, and exhausting with ether. The ether is then agitated with dilute ammonia not in excess; the brown ammoniacal solution is saturated with carbonic acid, and shaken with animal charcoal till a filtered sample is precipitated white by an acid; the red-brown filtrate is poured into ice-cold dilute sulphuric acid; and the white or slightly yellowish-green precipitate is drained and dissolved in ether. From the deeply coloured solution thus obtained, the nitrosophenol crystallises, as the ether evaporates, in concentric groups of large laminæ, having a faint brownish-green tinge, the yield being equal to 35 to 40 per cent. of the theoretical quantity.

Pure nitrosophenol separates from the hot saturated light green aqueous solution on rapid cooling in small nearly colourless needles; on slow cooling in dendritic groups of laminæ having a brownish-green colour. The solution when boiled turns brown, and yields the brown crystals described by Baeyer a. Caro. Nitrosophenol

when pure may be kept without alteration, but when impure it decomposes quickly, turning brown and afterwards black. Ether, acetone, and alcohol dissolve it readily with light green colour. It dissolves less easily in glacial acetic acid, and still less in hydrocarbons. Aqueous alkalis and alkaline earths dissolve it readily with light-brown colour. Acids precipitate it from its solutions as a white amorphous substance.

Sodium-nitrosophenol, $C^6H^4(NO)ONa + 2H^2O$, is obtained by adding 1 pt. of sodium dissolved in alcohol to a cold ethereal solution of 7 pts. nitrosophenol, washing the minium-coloured amorphous precipitate with ether, and drying it in a vacuum. From alcohol and acetone it crystallises in short red needles. Water dissolves it very easily with red colour; the alcoholic solution is red-brown in thick layers, yellow-green in thin layers; the solution in acetone is blue-green. It does not dissolve in ether or in hydrocarbons. When exposed to the air in contact with ether, it becomes dark-red and crystalline on the surface. It is permanent in the dry state at ordinary temperatures, but detonates when heated. Its solutions are not decomposed by boiling, but on adding an acid (not carbonic acid), nitrosophenol separates out. *Potassium-nitrosophenol* is obtained by precipitation as an amorphous substance, becoming red and crystalline when moist. From alcohol or acetone it crystallises in thin blue-green tablets, sometimes also in red crystals. *Ammonium-nitrosophenol* is a green unstable salt. *Barium-nitrosophenol*, $[C^6H^4(NO)O]^2Ba$, is prepared by adding a concentrated solution of 10 pts. barium hydrate to an alcoholic solution of 8 pts. nitrosophenol, precipitating with ether, mixing the saline solution which separates with alcohol, and again precipitating with ether. By a repetition of this treatment, a red crystalline precipitate is obtained, which, when dried at 100° , has the composition above given. It is easily soluble in water, and crystallises therefrom in large red needles. *Silver-nitrosophenol*, $C^6H^4(NO)OAg.H^2O$, is formed on adding an aqueous solution of 1 pt. silver nitrate to a solution of 1 pt. of the sodium salt in 600 pts. of hot water, and separates after a short time in blackish-violet crystals having a green reflex and appearing red by transmitted light under the microscope. The other metallic salts of nitrosophenol may be obtained in like manner as amorphous or crystalline dark-coloured precipitates. Ethers have not been obtained; but the action of methyl iodide on the alkali-salts gives rise to well-crystallised products (ter Meer). R. Lex (*Ber.* iii, 457) observed that when an aqueous solution of nitrosophenol is mixed with a nitrite and then supersaturated with soda, a dark-brown solution is formed, which by certain reducing agents (warming with sugar, aluminium, or zinc) is rendered lighter, and, if then exposed to the air or left in contact with a hypochlorite, assumes a deep blue colour. According to ter Meer, however, this reaction does not take place with nitrosophenol alone, but requires also an excess of phenol; with pure nitrosophenol only a brown colour is obtained.

The following reactions of nitrosophenol have been observed by C. Jaeger (*Ber.* viii, 894). When nitrous gas is passed into an ethereal solution of nitrosophenol, the latter is converted into Weselsky's diazophenol nitrate (p. 1524), which when heated with phthalic anhydride yields quinizarin, while small quantities of the three nitrophenols remain in the mother-liquor.

When nitrosophenol is treated with strong hydrochloric acid, an energetic reaction takes place, and amorphous products are formed, but when a stream of gaseous hydrogen chloride is passed into a cooled ethereal solution of nitrosophenol, brownish needles separate, consisting of a *dichloramidophenol*, soluble in acids and in alkalis, slightly soluble in water, non-volatile with water-vapour, melting at 175° , not distilling without decomposition. Chlorophenol is obtained at the same time by a secondary reaction.

When finely pounded nitrosophenol, cooled with ice, is treated with a solution of hydrochloric acid in methyl alcohol, a brownish solution is obtained, which deposits fine needles, consisting principally of the hydrochloride of a solid base, which passes over, together with a small proportion of a basic oil and chlorophenol, when the crystals are distilled with water. This base is *methyl-dichloramidophenol*; it melts at 71.5° , separates from dilute alcohol in long needles, and differs from the non-methylated base by being volatile with water-vapour, and insoluble in alkalis.

When the methyl-alcohol used in the above experiment is replaced by ethyl-alcohol, an *ethylated dichloramidophenol* or *dichloramidophenetol* is obtained, which separates from dilute alcohol in splendid long colourless needles, melting at 46° , distilling at 275° , and volatilising readily at 100° , or with water-vapour. Its *hydrochloride* and *platinum salt* form needles, and most of its salts are partially decomposed by water.

When nitrosophenol is dissolved in excess of strong potash-ley, the solution evaporated and heated for some time at 180° , the melt dissolved in water, and the brown aqueous solution treated with hydrochloric acid, a precipitate is obtained consisting of a *zophenol*, which may be purified by repeated crystallisation from dilute alcohol. It melts at 214° , dissolves readily in alcohol and alkalis, sparingly in ether

and in hot water, scarcely at all in benzene. Though stable for the most part, it cannot be sublimed without decomposition (Jaeger).

On the formation of Oxyazobenzene, $C^{12}H^{10}N^2O$ (vii. 151), and Azophenin, $C^8H^8N^2O$, by the action of nitrosophenol on aniline acetate, see AZOPHENIN (p. 138).

Phenol-carboxylic or Hydroxybenzene-carboxylic Acids. The phenol-monocarboxylic acids, $C^6H^4(OH).COOH$, are identical with the three hydroxybenzoic acids (pp. 278-287 and 1459-1463).

Hydroxybenzene-ortho-dicarboxylic, Hydroxy-ortho-phthalic, or simply **Hydroxyphthalic Acid**, $[OH : CO^2H : CO^2H = 1 : 3 : 4]$. This acid is produced by the following series of reactions: 1. Metacresol, $C^6H^4(OH)(CH^3)$, heated in strongly alkaline solution with carbon tetrachloride, is converted into a salt of *meta-methyl para-hydroxybenzoic* or $[1 : 3 : 4]$ hydroxytoluic acid:

2. This sodium salt treated with methyl iodide yields the methylic ether of the corresponding methoxytoluic acid, $C^6H^3(OCH^3)(CH^3)(CO^2CH^3)$. 3. This acid oxidised with

potassium permanganate yields methoxy-orthophthalic acid $C^6H^3(OCH^3)(CO^2H)(CO^2H)$, which crystallises in stellate groups of needles melting at $138^\circ-144^\circ$; and 4. The methoxy-acid is converted by heating with hydrochloric acid under pressure, or by fusion with potash, into hydroxyorthophthalic acid, $C^6OH.H.CO^2H.CO^2H.H^2$ (C. Schall, *Ber.* xii. 816).

The same acid is formed as an ethyl-salt, by the action of nitrous acid on ethyl amidophthalate. The amido-ether is dissolved in 10 pts. of dilute sulphuric acid (1 : 5); the solution is clarified with animal charcoal; a quantity of solution of sodium nitrite, not quite sufficient for complete decomposition, is added by small portions; and the mixture is heated to 100° . The ethyl hydroxyphthalate then separates as a yellowish, mobile, uncrystallisable oil which cannot be volatilised without decomposition. It may be saponified by boiling with strong potash-ley, and the resulting solution yields, with normal or basic acetate of lead, a precipitate of lead hydroxyphthalate, from which the hydroxyphthalic acid may be separated by hydrogen sulphide, and obtained by extraction with ether and evaporation, as a crystalline mass of microscopic plates. For purification, it is converted into the anhydride (*infra*), the solution of which in hot water deposits the acid on cooling in rosettes of short specular crystals (Baeyer, *Ber.* x. 124, 1079).

Hydroxyphthalic acid dissolves very easily in hot water and in 32.4 pts. of water at 10° . It is very soluble in alcohol and acetone, less so in ether; dissolves easily in glacial acetic acid on heating; hydrocarbons dissolve only traces of it. At about 180° it melts and is partially resolved into water and the anhydride. The hydroxyphthalates of the alkalis and the alkaline earths are very soluble. The ammonium salt crystallises well, and its solution forms with lead acetate a white amorphous precipitate; with silver nitrate a white precipitate of the silver salt, $C^6H^4Ag^2O^5$, consisting of tufts of needles slightly soluble in water. The aqueous solution of the acid gives a red colour with ferric chloride.

Fuming nitric acid converts hydroxyphthalic acid into a nitro-product; nitrous acid turns it yellow on heating. Dilute sulphuric acid (1 : 2 and 1 : 4) does not alter it even after six hours' heating at $160^\circ-180^\circ$; the strong acid dissolves it without colour at ordinary temperatures, with brown coloration and evolution of gas at 180° . When hydroxyphthalic acid is heated with 10 pts. of strong sulphuric acid for four hours at 200° , and the resulting solution is mixed with water, a dingy greenish-yellow precipitate is formed, from which ether extracts at least three substances, viz.: 1. A yellow sublimable body resembling anthraflavone. 2. A substance resembling phenolphthalidein, and forming, with strong sulphuric acid, a solution which has a splendid red colour and exhibits three absorption-bands. 3. A colourless substance which melts at 120° , sublimes without alteration, dissolves in strong sulphuric acid without colour, and in melting potash with yellowish colour. Hydroxyphthalic acid in aqueous solution is easily reduced by sodium-amalgam.

Hydroxyphthalic anhydride, $C^6H^4O^4 = C^6H^2OH(CO)^2O$, is best prepared in large quantity by heating the acid at 210° in a retort through which a slow stream of dry air is passing. It melts at $165^\circ-166^\circ$, sublimes at $200^\circ-210^\circ$ in feathery groups of long needles, and may be distilled in small quantities without decomposition. It dissolves slowly in cold water, quickly in hot water, reproducing the acid; easily in methyl alcohol, ethyl alcohol, acetone, and ether, but is nearly insoluble in benzene, chloroform, and carbon sulphide. With aniline at $160^\circ-180^\circ$, it forms a crystalline anilide.

With *phenols*, hydroxyphthalic anhydride forms hydroxyphthaleins, compounds which exactly resemble the corresponding phthaleins, with the exception of slight differences of colour, their coloured salts generally exhibiting a more decided red colour than those of the phthaleins. This reaction affords a means of distinguishing hydroxyphthalic acid from hydroxyiso- and hydroxyterephthalic acids. See *PHTHALEINS*.

2. **Hydroxybenzene-*m*-dicarboxylic** or **Hydroxyisophthalic** Acids. Two of these acids, distinguished as α and β , are known, their constitution being represented by the following formulæ:

They are obtained: (a). By fusing the three aldehyde-hydroxybenzoic acids $C^6H^3(OH)(COH)(COOH)$, already described (pp. 288, 1463), with potassium hydroxide the β -acid being thus produced from orthoaldehydosalicylic acid, $[OH : COH : COOH = 1 : 2 : 6]$, and the α -acid either from para-aldehydosalicylic acid, $[OH : COOH : COH = 1 : 2 : 4]$, or from orthoaldehyde-parahydroxybenzoic acid, $[OH : COH : COOH = 1 : 2 : 4]$ (Tiemann a. Reimer, *Ber.* x. 1562). (b). By the action of carbon tetrachloride and a caustic alkali (Reimer a. Tiemann's reaction) on salicylate of potassium or sodium:

The solution of the salicylate in an aqueous alkali is mixed with a quantity of alcohol sufficient to dissolve nearly the whole of the carbon tetrachloride, and the mixture is somewhat strongly heated in a sealed tube till an abundant separation of potassium or sodium chloride takes place. Both the α - and β -acids are obtained by this process, the α -acid being, however, by far the more abundant. The two acids are separated by converting them into their barium salts, that of the α -acid being the more soluble of the two (G. Hasse, *Ber.* x. 2185). (c). The α -acid is produced—together with phenol-tricarboxylic acid and phenol—by heating the disodic salt of salicylic or parahydroxybenzoic acid in a stream of carbon dioxide:

The same result may also be obtained by heating sodium phenate, or better a mixture of the phenates of potassium and sodium, in a stream of carbon dioxide, a salt of salicylic acid being first produced, and afterwards converted into the hydroxyisophthalate. The best result is obtained by using 3 mol. sodium phenate to 1 mol. potassium phenate, and passing the gas over the mixture first at 120° – 130° , then for some time (two hours with 50 grams of phenol) at 300° – 320° . 50 grams of phenol yield by this process 10 to 20 grams of pure hydroxy-isophthalic acid (Ost, *J. pr. Chem.* [2], xiv. 93; xv. 301).

(d) α -Hydroxyisophthalic acid is also produced from

by a series of transformations exactly analogous to those just described for the formation of hydroxy-orthophthalic acid from metamethyl-parahydroxybenzoic acid.

α -Hydroxyisophthalic acid, when pure, crystallises in needles, dissolves easily in alcohol and ether, and in 5000 pts. of water at 10° . According to Tiemann a. Reimer (*Ber.* x. 1562), it dissolves in 145 pts. water at 100° , and in 300 pts. of water at 24° . It resembles salicylic acid in general appearance; produces a deep reddish-violet coloration with ferric chloride; melts at 270° – 280° (Tiemann a. Reimer); above 300° (Schall), and sublimes with partial decomposition. The acid is a bi-basic hydroxyacid, and is, therefore, capable of forming three series of salts, normal, acid, and so-called basic salts, that is, salts in which the phenolic as well as the carboxylic hydrogen is replaced by metals. The normal salts are formed by neutralising the acid with carbonates.

* On the preparation of these and the other acids of the formula $C^6H^2(OH)(CH^3)(CO^2H)$, see page 1540; also *TOLUIC ACIDS, HYDROXY-*.

The *sodium salt*, $\text{C}^6\text{H}^3(\text{OH})(\text{COONa})^2 + \text{aq.}$, crystallises in long needles, which retain 2 mols. of water when dried in the air, and dissolve easily in water. The *potassium, ammonium, barium, calcium, zinc, manganese, cobalt, nickel, and cadmium salts* are all soluble in water. The sodium salt, when heated to $220^\circ\text{--}250^\circ$, decomposes in the same manner as normal sodium salicylate, yielding the basic salt, phenol, and carbon dioxide :

The *normal silver salt*, $\text{C}^6\text{H}^3(\text{OH})(\text{COOAg})^2$, obtained by precipitating the ammonium salt with silver nitrate, is amorphous and nearly insoluble in water. The *acid silver salt*, $\text{C}^6\text{H}^3(\text{OH})\text{COOH}.\text{COOAg}$, is formed by adding to the free acid an excess of silver nitrate. It crystallises in needles, which dissolve in water. The *basic calcium salt*, $\text{C}^6\text{H}^3\text{O} \cdot \text{Ca} \left(\begin{smallmatrix} \text{COO} \\ \text{COO} \end{smallmatrix} \text{Ca} \right)^2 + 5\text{H}_2\text{O}$, obtained by adding lime-water to a solution of the normal salt, is sparingly soluble in water.

The *ethylic ether*, $\text{C}^6\text{H}^3(\text{OH})(\text{COOC}^2\text{H}^5)^2$, obtained by passing hydrogen chloride into an alcoholic solution of the acid, distils with steam in snow-white crystals which melt at 52° (Ost).

β . Hydroxyisophthalic acid is also produced from orthomethylsalicylic acid, $\text{C}^6\text{H}^3.\text{OH}.\text{CH}_3.\text{CO}^2\text{H}$, by a series of transformations analogous to those described for the preceding modification (Schall, *loc. cit.*) It crystallises from water in capillary needles, or sometimes in well-defined prisms, having the composition $\text{C}^6\text{H}^3\text{O}^3 + \text{H}_2\text{O}$; dissolves in 35 to 40 pts. water at 100° , and in 700 pts. at 24° , easily in alcohol and ether, less easily in chloroform. In the air-dried state it melts at 239° ; after drying over the water-bath, at $243^\circ\text{--}244^\circ$. It can only be partially sublimed without decomposition. The aqueous and alcoholic solutions exhibit a blue-violet fluorescence which disappears on addition of excess of alkali. The aqueous solution gives a cherry-red colour with ferric chloride. The acid reddens litmus, the solution turning blue again on addition of a quantity of alkali sufficient to form a normal or bi-metallic salt. The *potassium, sodium, and ammonium salts* are very soluble. The characters of the other salts are exhibited in the table on p. 1536, which gives a comparative view of the reactions of α - and β -hydroxyisophthalic or hydroxybenzene-metadicarboxylic acid, also of those of phenol-tricarboxylic or hydroxytrimesic acid (Tiemann a. Reimer, *Ber.* x. 1562).

Aldehydro-hydroxyisophthalic acids, or *Formyl-hydroxyisophthalic acids*,

(Reimer, *Ber.* xi. 793). Two of these acids, α and β , are known, and are represented by the following formulæ :

They are formed by the action of chloroform in alkaline solution on α - and β -hydroxyisophthalic acids respectively, the mode of action being similar to that by which the aldehydro-hydroxybenzoic acids are formed from salicylic and parahydroxybenzoic acids (p. 288). α -Hydroxyisophthalic acid thus treated yields a mixture of *aldehydro-a-hydroxyisophthalic* and *para-aldehydro-salicylic acids*, which may be separated by treating the ethereal extract of the crude product with solution of acid sodium sulphate, boiling the compound thus formed with sulphuric acid to set free the two aldehydro-acids; then dissolving them in ammonia; adding sal-ammoniac and magnesium sulphate; and leaving the mixture at rest for a day or two. The magnesium salt of the aldehydro-a-hydroxyisophthalic acid is then deposited in crystalline form, and the aldehydro-acid separated from it, crystallises from water in felted needles which melt with decomposition at 260° . It is very soluble in boiling water, less soluble in cold water, easily soluble in alcohol and ether. Its solution is coloured blood-red by ferric chloride. Like the other ortho-aldehydrohydroxybenzoic acids, it forms colourless neutral solutions and yellow alkaline solutions, both exhibiting a green fluorescence. In the neutral solutions, calcium and magnesium salts form no precipitates; barium chloride, a crystalline precipitate after some time from cold solutions, more quickly on warming; ferric chloride, a dark-red coloration, and a flocculent precipitate on warming; silver nitrate, a gelatinous precipitate which when dried

over sulphuric acid has the composition $C^6H^4Ag^2O^6 + H^2O$, and gives off its water at 100° . The solution of the free acid gives with silver nitrate a crystalline acid silver salt easily soluble in hot water. The basic or trimetallic salts, except those of the alkali-metals, are for the most part sparingly soluble. The basic cupric salt, like that of ortho-aldehydo-salicylic acid, dissolves, when recently precipitated, in excess of ammonia, but is reprecipitated on heating, and is then nearly insoluble in ammonia.

Aldehydo- β -hydroxyisophthalic acid, $C^6H^1.COOH.H.CO^2.H.CO^4.OH$, is the only product of the action of chloroform and alkalis on β -hydroxyisophthalic acid. It crystallises in tufts of long slender needles which melt, with decomposition, at 237° – 238° . When dried at 100° it contains $\frac{1}{2}H^2O$. In crystalline form, melting point, solubility, reaction with ferric chloride, and fluorescence, it closely resembles β -hydroxyisophthalic acid. From solution in sulphuric acid, it is precipitated by water in the form of a crystalline pulp (β -hydroxyisophthalic acid is not thus precipitated). Its alkaline solutions are colourless. Amongst its normal (bi-metallic) salts, those of calcium and magnesium are easily soluble, that of barium is sparingly soluble in water. The normal silver salt is moderately soluble in hot water, and crystallises on cooling; its ammoniacal solution does not blacken when heated. The neutralised solution of the acid is coloured dark-red by ferric chloride. The solution of the free acid is not precipitated by silver nitrate. Its ammoniacal solution gives a precipitate with barium chloride, none with calcium chloride or magnesium sulphate. Cupric sulphate added to the slightly ammoniacal solution, forms a green precipitate, which dissolves easily in ammonia.

The aldehydo-hydroxyisophthalic acids cannot be oxidised by fusion with potash, as they are decomposed thereby, with separation of carbon dioxide. When oxidised by potassium permanganate in cold alkaline solution, they both yield a small quantity of phenol-tricarboxylic or hydroxytrimesic acid, identical with that which Ost obtained, together with the two phenol-dicarboxylic acids, by heating disodic salicylate in a stream of carbon dioxide (p. 1532).

3. Hydroxybenzene-*p*-dicarboxylic or Hydroxyterephthalic Acid, is obtained: (a) By dissolving crystallised amidoterephthalic acid in soda-ley, acidifying the solution with sulphuric acid, adding the requisite quantity of potassium nitrite in aqueous solution, and boiling. It forms a white powder easily soluble in methyl and ethyl alcohols, sparingly in water; melts above 300° , and sublimes with partial decomposition at a higher temperature. Mixed with sand and subjected to dry distillation, it is resolved into carbon dioxide and phenol, and by prolonged heating with hydrochloric acid at 120° into carbon dioxide and methahydroxybenzoic acid. Its aqueous solution gives with ferric chloride a deep violet-red coloration, resembling that produced by salicylic acid. (b) From meta-methylsalicylic acid, $C^6H^3(OH)(CO^2H)(CH^5)$, or from ortho-methyl-meta-hydroxybenzoic acid, $C^6H^3(OH)(OH)(CO^2H)$, by a series of processes analogous to those employed in the preceding cases (Schall).

The *silver salt*, $C^6H^3(OH).(COOAg)^2$, is white and insoluble in water. The *barium salt*, $C^6H^3.OH.(COO)^2Ba + Aq.$, crystallises from water in white laminae.

Dimethyl hydroxyterephthalate, $C^6H^3(OH)(COOCH^3)^2$, obtained by passing hydrogen chloride into a solution of the acid in methyl alcohol, crystallises from methyl alcohol in beautiful silky needles, which melt at 94° . It dissolves in hot water, and easily in aqueous alkalis, alcohol, and ether. The solution in ammonia gives precipitates with salts of the heavy metals.

Dimethyl acetoxyterephthalate, $C^6H^3\{OC^2H^3O\}(CO^2CH^3)^2$, obtained by heating the dimethyl-ether to 100° with excess of acetyl chloride in sealed tubes, crystallises from alcohol in white, cauliflower-like masses, melting at 76° . It is insoluble in soda-ley (G. A. Burkhardt, *Ber.* x. 144).

Dinitro-hydroxyterephthalic acid, $C^6H(NO^2)^2(OH)(COOH)^2$, is obtained by treating hydroxyterephthalic acid with a mixture of fuming nitric and Nordhausen sulphuric acids, and crystallises from cold water in fine golden-yellow transparent crystals, dissolving easily in cold water, and melting at 178° . No isomeric acid is formed. The dinitro-acid and its salts are explosive.

The *acid silver salt*, $C^6H(NO^2)^2OH(COOH)COOAg$, formed on mixing concentrated solutions of the acid and of silver nitrate, is a yellow crystalline powder, moderately soluble in water. The *normal silver salt*, $C^6H(NO^2)^2OH(COOAg)^2$, is obtained by triturating a concentrated solution of the acid with moist silver oxide, and evaporating the filtrate over sulphuric acid. It forms blood-red prismatic crystals, very easily

soluble in water; crystallises from aqueous solution with 2 mols. of water. The *acid lead salt*, $C^6H(NO_2)^2OH(COOH)COOpb$ ($pb = 103.5$), formed on adding neutral lead acetate to a solution of the acid, is a yellow crystalline powder, sparingly soluble in water. The *neutral calcium salt*, $C^6H(NO_2)^2OH(COO)^2Ca$, formed by boiling a solution of the acid with calcium carbonate, is yellow and crystalline, and dissolves sparingly in water (Burkhardt, *Ber.* x. 1273).

Phenol-tricarboxylic Acid, $C^6H^6O^7 = C^6H^2(OH)(COOH)^3$ (Ost, *J. pr. Chem.* [2], xiv. 93; xv. 301). This acid is formed, together with α -hydroxybenzene-*m*-dicarboxylic or α -hydroxyisophthalic acid, by heating disodic salicylate in a stream of carbon dioxide at a temperature above 300° . It is not however necessary to make use of ready-prepared sodium salicylate; a better mode of proceeding is to start from sodium phenate, the process being first conducted in the manner already described for the preparation of salicylic acid (vii. 1065), and the temperature being afterwards raised to 370° – 380° . The reaction takes place by two stages, as represented by the following equations:

The yield amounts to nearly the theoretical quantity, viz. three-fourths of the phenol employed.

Phenoltricarboxylic acid crystallises from alcohol in needles, and from water in prisms containing 1 mol. or needles containing 2 mols. of water. It dissolves freely in alcohol, sparingly in ether, and in 200 pts. of water at 10° . It produces a deep red coloration with ferric chloride. When heated it undergoes complete decomposition, yielding chiefly phenoldicarboxylic acid and carbon dioxide, with a little salicylic acid and phenol. Being a tribasic acid, and containing the hydroxyl-group of phenol, it is capable of forming four series of salts. The normal salts of the alkalis are crystallisable and easily soluble in water. All the other salts are either insoluble or but sparingly soluble.

The *normal barium salt*, $[C^6H^2(OH)(COO)^2]^2Ba^3 + 8H^2O$, and the corresponding *calcium salt*, obtained by double decomposition, are very sparingly soluble in water.

The *normal silver salt*, $C^6H^2(OH)(COOAg)^3 + 3H^2O$, is a crystalline precipitate.

The *di-acid calcium salt*, $[C^6H^2(OH)(COOH)^2COO]^2Ca + 6H^2O$, and the corresponding barium salt, are formed by mixing solutions of the free acid with calcium or barium chloride; they are crystalline and soluble in water. The other acid phenoltricarboxylates are likewise soluble in hot water, and crystallise on cooling, the potassium and ammonium salts in slender needles.

Ethyl phenoltricarboxylate, $C^6H^2(OH)(COOC^2H^5)^3$, is readily formed by passing hydrogen chloride into an alcoholic solution of the acid. It crystallises from a hot alcoholic solution in long colourless prisms, which melt at 84° , and sublime with partial decomposition at a higher temperature. When boiled with aqueous soda it is slowly decomposed, yielding phenoltricarboxylic acid, but when it is digested with soda in the cold, the hydrogen of the hydroxyl-group is replaced by sodium, whereby the following compound is formed.

Ethyl-sodium phenoltricarboxylate, $C^6H^2(ONa)(COOC^2H^5)^3$.—This body is best obtained by dissolving the foregoing ether in absolute alcohol and adding alcoholic soda, whereupon it crystallises in large oblique prisms. It is insoluble in water, cold alcohol, and ether. When boiled with water for some time, it gradually dissolves, forming a solution which on cooling deposits needles of *sodium diethylphenoltricarboxylate*, $C^6H^2(OH)(COOC^2H^5)^2COONa$, which crystallises from alcohol with 1 mol. of water. Its aqueous solution, which is neutral, gives precipitates with salts of barium, silver, and other metals.

Diethylphenoltricarboxylic acid, $C^6H^2(OH)(COOC^2H^5)^2COOH$, is precipitated on saturating an aqueous solution of the foregoing salt with hydrogen chloride. It crystallises from alcohol in long needles containing 1 mol. of water. The anhydrous substance melts at 118° .

Phenoltricarboxylic acid heated in a reflux apparatus for several hours with 4 mols. phosphorus pentachloride, is converted into chlorotrimelic acid, $C^6H^2Cl(COOH)^3$, which when reduced with zinc and a dilute acid, or better with sodium-amalgam, is converted into trimelic acid, $C^6H^3(COOH)^3$, [1 : 3 : 5]: hence

Reactions of Phenol-carboxylic Acids.

Reagents	α -Phenol-dicarboxylic or α -Hydroxy-isophthalic acid		β -Phenol-dicarboxylic or β -Hydroxy-isophthalic acid		Phenol-tricarboxylic or Hydroxy-trimesic acid	
	Neutral solution	Ammoniacal solution	Neutral solution	Ammoniacal solution	Neutral solution	Ammoniacal solution
Calcium Chloride .	—	A basic calcium salt separates after long standing, more quickly when heated.	A calcium salt crystallising in stellate groups of needles separates after some time. Crystalline barium salt separates on heating.	A white bulky basic calcium salt is quickly precipitated.	White calcium salt becoming crystalline when heated.	White bulky precipitate.
Barium Chloride .	—	—	—	Precipitation of basic barium salt at ordinary temperatures. No precipitation in presence of sal-ammoniac.	Immediate precipitation of white barium salt.	The same.
Magnesium Sulphate .	—	No precipitation in presence of sal-ammoniac.	—	—	After long standing, more quickly on heating, or on rubbing with a glass rod, a magnesium salt separates in fine needles.	The same.
Silver Nitrate .	White crystalline silver salt nearly insoluble in boiling water. A solution strongly acidulated with acetic acid deposits an acid silver salt soluble in hot water.	The normal silver salt dissolves easily in excess of ammonia.	Behave like α -Phenol-dicarboxylic acid.			
Lead acetate .	White crystalline lead-salt easily soluble in acetic acid. In a solution strongly acidulated with acetic acid, no precipitation takes place.	Bulky white basic lead salt.	White crystalline lead salt only slightly soluble in acetic acid. From a solution acidulated with acetic acid, an acid lead salt is precipitated, which may be recrystallised from boiling water.	Bulky white basic lead salt.	White crystalline lead salt, not completely soluble in acetic acid. From a solution acidulated with acetic acid, lead salts are precipitated, which dissolve but sparingly even in boiling water.	Bulky white basic lead salt.

it follows that phenoltricarboxylic acid has the constitution of hydroxy-trimesic acid, $C^6H^3O^3H.OH.CO^2H.H.CO^2H.H$.

The table on page 1536 exhibits a comparative view of the reactions of the two phenol-meta-dicarboxylic acids and of phenoltricarboxylic acid with various saline solutions.

Phenol-diazobenzene, $C^{12}H^{10}N^2O = C^6H^5O.C^6H^4N^2$, and **Phenol-didiazobenzene**, $C^{18}H^{14}N^4O = C^6H^5O.2C^6H^4N^2$. These compounds, discovered by Griess, were originally produced by the action of barium carbonate on a cold aqueous solution of diazobenzene nitrate (see iv. 433, where they are designated as phenates of azophenylamine and diazophenylamine respectively).

Phenol-diazobenzene, $C^{12}H^{10}N^2O$, is also produced by fusing azobenzene-sulphonic acid, $C^{12}H^8N^2.SO^3H$, with potash (Griess, *Lieb. Ann.* cliv. 208), and by the action of diazobenzene nitrate on an aqueous solution of potassium phenate, whereupon it separates as a resin which soon becomes crystalline (Kekulé a. Hidegh, *Ber.* iii. 233). Treated with alcoholic ammonium sulphide, it is converted into a base, probably $C^{12}H^{12}N^2O$ (Griess). On heating it at 100° with phosphorus pentachloride, hydrochloric acid is evolved, and a crystalline body is formed, probably *hydroxy-*

azoxybenzene, $O \begin{matrix} \swarrow N.C^6H^5 \\ \searrow N.C^6H^4OH \end{matrix}$, which separates from alcohol in long orange-yellow needles (Kekulé a. Hidegh).

Phenol-didiazobenzene, $C^{18}H^{14}N^4O = C^6H^5(OH) \begin{matrix} \swarrow N.C^6H^5 \\ \searrow N.C^6H^5 \end{matrix}$, is formed on mixing a solution of phenol-diazobenzene in potash with an aqueous solution of diazobenzene nitrate, and separates as a brown-red precipitate easily purified by crystallisation from alcohol. Its formation is represented by the equation $C^{12}H^{10}N^2O + C^6H^4N^2 = C^{18}H^{14}N^4O$ (Griess, *Ber.* ix. 637).

An isomeric compound, perhaps $\begin{matrix} N=N.C^6H^4.C^6H^4.OH \\ | \\ N=N.C^6H^5 \end{matrix}$, is formed by the action of potassium phenate on diazo-diamidobenzene. When treated with nascent hydrogen it yields aniline, paradiamidobenzene, and paramidophenol (Caro a. Schraube, *Chem. Centr.* 1878, 558).

Phenol-diazobenzo-diazotoluene, $C^{18}H^{16}N^4O$, is formed in like manner when an alkaline solution of phenoldiazobenzene is mixed in molecular proportion with diazotoluene nitrate (from paratoluidine). By recrystallisation from hot alcohol, with addition of animal charcoal, it is obtained in small brownish-yellow nodules melting at 110° . It agrees closely in its properties with phenol-didiazobenzene (Griess, *Ber. loc. cit.*)

Phenol-glucoside, $C^{12}H^{16}O^6 = C^6H^5(OC^6H^5)(OH)^4.CHO$ (A. Michael, *Compt. rend.* lxxxix. 355). This compound is formed, together with ethyl acetate, on mixing the alcoholic solutions of potassium phenate and acetochlorhydrate (p. 12), whereupon potassium chloride separates out, and on leaving the filtrate to evaporate, phenol-glucoside is deposited in long silky needles:

Phenol-glucoside melts at 171° – 172° , dissolves in water forming a dextrogyrate solution, and when boiled with aqueous potash or with dilute sulphuric or hydrochloric acid, is resolved into glucose and phenol: $C^{12}H^{16}O^6 + H^2O = C^6H^{12}O^6 + C^6H^5O$.

Orthoformyl-phenol-glucoside, $C^{18}H^{16}O^7 = C^6H^5(OC^6H^4.CHO)(OH)^4.CHO$, produced in like manner by the action of acetochlorhydrate on potassium salicylate, forms white needle-shaped crystals, which melt at 175° and decompose at a higher temperature.

The action of acetochlorhydrate on sodium-saligenin appears to give rise to the glucoside of saliretin.

Phenolglycollic or Phenoxyacetic Acid, $C^8H^6O^3 = CH^2(OC^6H^5).COOH$. Heintz obtained acid this (ii. 918) by heating monochloroacetic acid with sodium-phenol at 150° :

A more advantageous mode of preparation is to melt together equivalent quantities of
Vol. VIII. 5 G

phenol and chloroacetic acid on the water-bath, and add soda-ley (sp. gr. 1.3), slowly and with continual stirring, in quantity equal to about four times that of the phenol :

The reaction is soon completed, and the liquid on cooling solidifies to a crystalline mass of sodium phenol-glycolate which, when decomposed with hydrochloric acid, yields the free acid (Giacosa, *J. pr. Chem.* [2], xix. 396).

In like manner pyrogallol (1 mol.) reacts with sodium chloracetate (3 mol.) to form the sodium salt, $\text{C}^6\text{H}^3(\text{OCH}^2\text{COO}^-\text{Na})^3$, which, when decomposed by dilute hydrochloric acid, yields pyrogallol-glycollic acid :

Pyrogallol-glycollic acid crystallises from aqueous solution in long colourless needles melting at 198° . The normal potassium salt is precipitated by alcohol from its aqueous solution in white needles, and on adding acetic acid to this solution a slightly soluble monopotassic salt, $\text{C}^{12}\text{H}^{11}\text{O}^6\text{K} + \text{H}^2\text{O}$, is precipitated (Giacosa).

Phenol-lactic or Phenoxypropionic Acid, $\text{C}^6\text{H}^{10}\text{O}^3 = \text{CH}^3.\text{CH}(\text{OC}^6\text{H}^5).\text{COOH}$, formed by the action of sodium-phenate on α -chloropropionic acid, crystallises from hot water in shining needles, which melt at 112° – 113° . On adding bromine-water to its hot aqueous solution, *bromophenol-lactic acid*, probably $\text{CH}^3.\text{CH}(\text{OC}^6\text{H}^4\text{Br}).\text{COOH}$, is produced (Saarbach, *J. pr. Chem.* [2], xix. 175).

Phenol-phthalein. See PHTHALEINS.

Phenolphosphenylic Acid, $\text{C}^6\text{H}^5\text{PO}(\text{OH})\text{O.C}^6\text{H}^5$, is formed by the action of boiling water on the chloride, $\text{C}^6\text{H}^5(\text{PO})\text{ClO}$, produced, together with phenyl phosphenylate, by the action of phosphorus oxychloride on phenol. This acid forms long capillary needles melting at 57° , slightly soluble in water, easily in alcohol, ether, benzene, and alkalis. Its *ammonium salt* forms colourless needles; the *silver salt*, needles having a silky lustre (Michaelis a. Kammerer, *Ber.* viii. 48).

Phenol-sulphonic Acids, $\text{C}^6\text{H}^4\text{OH.SO}^3\text{H}$. The *meta*-acid, $[\text{OH} : \text{SO}^3\text{H} = 1 : 3]$, hitherto but little known, has lately been studied by Barth a. Senhofer (*Ber.* ix. 969), who prepare it as follows: Benzene-metadisulphonic acid dissolved in the smallest possible quantity of water, is heated at 170° – 180° with two or three times its weight of potassium hydrate in a silver basin. The solution gradually becomes more and more concentrated until it acquires a thick pulpy consistence, at which stage the heating must be stopped. The product is then dissolved in water, neutralised with sulphuric acid, and evaporated, and the residue is exhausted with absolute alcohol, which takes up potassium phenolmetasulphonate, leaving potassium sulphate undissolved. The alcoholic solution, when evaporated, deposits crystals of the potassium salt, from which the free acid is obtained by adding to it the necessary quantity of sulphuric acid and a little water, evaporating to a syrup, agitating this with a mixture of alcohol and ether, filtering from potassium sulphate, and distilling with water. The acid thus obtained in aqueous solution is purified by converting it into lead-salt, decomposing the latter with hydrogen sulphide, and evaporating the liquid to a syrup, which gradually deposits the acid in delicate needles. The crystals dried in a vacuum contain 2 mols. of water: at 100° – 112° they retain $\frac{1}{2}$ mol., which is expelled at 140° . The acid gives a violet coloration with ferric chloride.

The *potassium salt*, $\text{C}^6\text{H}^4(\text{HO})\text{SO}^3\text{K.H}^2\text{O}$, crystallises in a mass of small needles, which melt at 200° – 210° , and effloresce in the air. A *basic potassium salt*, obtained by dissolving the normal salt and the necessary quantity of potash in alcohol, crystallises in silky needles. The *barium salt*, $(\text{C}^6\text{H}^4.\text{HO.SO}^3)^2\text{Ba}$, forms laminae very easily soluble in water. The *copper salt*, $(\text{C}^6\text{H}^4.\text{HO.SO}^3)^2\text{Cu} + 6\text{H}^2\text{O}$, crystallises in large bright-green rhombic tables, very freely soluble in water. The dried salt is extremely hygroscopic, taking up water from calcium chloride. The *lead salt*, $(\text{C}^6\text{H}^4.\text{HO.SO}^3)^2\text{Pb} + 3\text{H}^2\text{O}$, forms colourless quadratic tables. The *silver salt* crystallises in delicate needles, which dissolve easily in water. The *ammonium salt* crystallises from strong solutions in slender needles, and from dilute solutions in tables: it is freely soluble in water. The *sodium salt* crystallises with 1 mol. of water in large rhombic tables.

Potassium phenolmetasulphonate, heated to 250° with potash, exchanges the group SO^3H for HO , yielding resorcinol free from quinol or catechol. This behaviour of the meta-acid distinguishes it from the isomeric acids, neither of which yields resorcinol when similarly treated.

The following table exhibits the differences characteristic of some of the salts of the three phenolsulphonic acids :

Salt	Ortho-acid	Meta-acid	Para-acid
K	Melts at 240°. Crystallises in long flat needles, with 2 mols. water.	Melts at 200°. Crystallises in masses of confused microscopic needles with 1 mol. water.	Does not melt at 260°. Crystallises in anhydrous hexagonal tables.
Ba	Indistinctly crystalline masses with 2 mols. water. Very soluble in water.	Small laminæ, composed of microscopic needles, containing $\frac{1}{2}$ mol. water.	Long silky matted needles, containing 3 mols. water.
Pb	Indistinct tables, with 1 mol. water. Dissolves with great difficulty in water.	Crystallises in large rhombic tables, containing 3 mols. water.	Long needles grouped in nodules. Contains 2 mols. water.
Cu	Pale-blue prisms.	Large thin bright green rhombic tables, containing 6 mols. water.	Thick blue plates, resembling cupric sulphate. Contains 10 mols. water.
Na	Indistinctly crystalline masses, containing $1\frac{1}{2}$ mol. water.	Flat needles, or large rhombic tables, with 1 mol. water.	Prismatic crystals, containing 2 mols. water.

Phenolparasulphonic acid oxidised with manganese dioxide and sulphuric acid yields a large quantity of quinone; the meta-acid yields none (Schrader, *Ber.* viii. 759).

Conversion of Phenol-orthosulphonic acid into the Para-modification.—The ortho-acid, in presence of water, is resolved at comparatively low temperatures into phenol and sulphuric acid:

the sulphuric acid then acting further on the phenol, and producing a mixture of the ortho- and para-acids, provided the temperature of decomposition of the ortho-acid has not been exceeded.

The ortho-acid is not the sole product of the action of sulphuric acid on phenol at low temperatures, considerable quantities of the para-acid being always formed, even at 0°.

When the potassium salt of phenol-orthosulphonic acid is heated with excess of sulphuric acid in sealed tubes, there separates after a time a reddish-brown oily layer of phenol, which, when the tube is more strongly heated, disappears either partially or entirely, according to the strength of the solution, and forms a dark-red liquid, doubtless containing free sulphuric and phenolparasulphonic acids. When a concentrated aqueous solution of the same salt is heated with a quantity of sulphuric acid insufficient for complete decomposition, the separation of phenol takes place much more slowly. It seems probable that the conversion of ortho- into para-acid would not take place in the absence of sulphuric acid (Post, *Ber.* viii. 1547).

The crystalline form of potassium parasulphonate has been examined by C. Bode-wig. The crystals are orthorhombic, having the axial ratio $a : b : c = 0.8790 : 1 : 1.0017$. Observed faces P, ∞ P, ∞ \bar{P} ∞ . The crystals are tabular according to ∞ \bar{P} ∞ , and have no distinct cleavage. Angle, ∞ P : ∞ P = $82^\circ \pm 2'$; P : ∞ P = $33^\circ 8'$. The plane of the optic axes is 0P; the axis b is the first median line. Double refraction positive.

Dihydroxybenzene-sulphonic acid, $\text{C}^6\text{H}_2(\text{OH})_2(\text{SO}^3\text{H})_2$.^{1 3 4}—The potassium salt of this acid is formed by the action of melting potash on that of the corresponding phenol-disulphonic acid, $\text{C}^6\text{H}_2(\text{SO}^3\text{H})_2$ (vi. 926); and on decomposing it with hydrochloric acid, and leaving the solution to evaporate, dihydroxybenzene-sulphonic acid is obtained in needle-shaped crystals. The aqueous solutions of this acid have a strong acid reaction, and give with ferric chloride an intense green coloration, which becomes successively blue, violet, and red on the addition of sodium carbonate. These colour-reactions are similar to those obtained with protocatechuic acid (p. 239), to which, in fact, the sulphonic is analogous in constitution, containing SO^3H in place of CO^2H . Lead acetate gives no precipitate with the aqueous solutions of the acid or its salts, but basic lead acetate gives a white precipitate.

The *potassium salt*, $\text{C}^6\text{H}_2(\text{OH})_2(\text{SO}^3\text{K})_2$, is easily soluble in water, and sparingly in

absolute alcohol. The *sodium salt*, $\text{C}^6\text{H}_3(\text{OH})^2\text{SO}^3\text{Na} + \text{H}^2\text{O}$, crystallises in colourless prisms. The *barium salt*, $[\text{C}^6\text{H}_3(\text{OH})^2\text{SO}^3]^2\text{Ba}$, is easily soluble in water, and crystallises from alcohol in needles united in concentric masses. The acid fused with potash yields catechol or orthodihydroxybenzene.

Sulphoxybenzene-phenols. This name was given by Griess (*Ber.* xi. 2191) to a series of compounds obtained by the action of alkaline solutions of phenols and their derivatives on the diazobenzenesulphonic acids and other diazo-compounds. See SULPHONIC ACIDS.

PHENOL: HOMOLOGUES OF. I. Cresols. 1. The isomeric cresols, $\text{C}^6\text{H}^4(\text{CH}_3)(\text{OH})$, and several of their derivatives have already been described in vol. vii. pp. 931-934, and this volume, pp. 581-584.

Conversion of Cresols into Hydroxytoluic Acids and Aldehydes.—The three isomeric cresols, treated in strongly alkaline solution with carbon tetrachloride, are converted into hydroxytoluic acids, $\text{C}^6\text{H}_3(\text{OH})(\text{CH}_3)\text{CO}^2\text{H}$, viz. homosalicylic and homoparahydroxybenzoic acids, according to the equation :

By this reaction *ortho*-cresol gives orthohomosalicylic and orthohomoparahydroxybenzoic acids, $[\text{OH} : \text{CH}_3 : \text{CO}^2\text{H} = 1 : 2 : 6 \text{ and } 1 : 2 : 4 \text{ respectively}]$; *meta*-cresol gives metahomosalicylic and metahomoparahydroxybenzoic acids, $[\text{OH} : \text{CH}_3 : \text{CO}^2\text{H} = 1 : 3 : 6 \text{ and } 1 : 3 : 4]$, together with another acid, probably parahomohydroxyisophthalic acid, and *para*-cresol gives only parahomosalicylic acid, $[\text{OH} : \text{CH}_3 : \text{CO}^2\text{H} = 1 : 4 : 6]$ (C. Schall, *Ber.* xii. 816). See TOLUIC ACIDS (HYDROXY-).

The corresponding hydroxytoluic aldehydes, $\text{C}^6\text{H}_3(\text{OH})(\text{CH}_3)\text{COH}$, are obtained in like manner by treating the three cresols in alkaline solution with chloroform :

(Tiemann a. Schotten, *Ber.* xi. 767). See TOLUIC ALDEHYDES.

Tetrabromoparacresol, $\text{C}^6\text{H}^4\text{Br}^4\text{O}$.—When bromine-water is added to an aqueous solution of pure paracresol until a permanent colour is obtained, a cloudiness is first produced, and in a short time crystalline plates of tetrabromoparacresol are deposited, which, after rapid filtering and drying over sulphuric acid, melt at 109° . This substance, on keeping, gradually undergoes decomposition. The yield of the bromophenol is always less than the calculated quantity.

If the precipitate be left over night in contact with the bromine-water, it is partly converted, with evolution of carbon dioxide, into tribromophenol (m. p. 91°), whereby the proportion of bromine in it is lowered by about 2 per cent.; this change taking place more rapidly and completely when the temperature is raised to 30° - 40° (Bauermann a. Brieger, *Ber.* xii. 804).

Nitrocresols.—See p. 583.

Cresolsulphonic acids.—vii. 932; viii. 583.

II. Xylenols, $\text{C}^6\text{H}^{10}\text{O} = \text{C}^6\text{H}_3(\text{OH})(\text{CH}_3)^2$ (O. Jacobsen, *Ber.* xi. 23). Four of these compounds are known, and are distinguished by the prefixes, *ortho*-, *meta*-, and *para*-, according to the xylenes from which they are derived, viz. :

				CH ³	CH ³	OH
Ortho-xyenol	.	.	.	1	2	4
<i>α</i> -Meta-xyenol	.	.	.	1	3	4
<i>β</i> -Meta-xyenol	.	.	.	1	3	2
Para-xyenol	.	.	.	1	4	2

They are prepared by fusing the potassium salts of the corresponding xylenesulphonic acids, $\text{C}^6\text{H}_3(\text{CH}_3)^2\text{SO}^3\text{K}$, with four times their weight of potassium hydroxide; acidulating the melt with hydrochloric acid; shaking it up with ether; treating the ethereal solution with sodium carbonate, to remove hydroxytoluic acids, which are always formed at the same time in small quantity; drying the product with calcium chloride; removing the ether by evaporation; and distilling the xylenol which remains behind. The yield is very satisfactory, sometimes amounting to more than three-fourths of the calculated quantity.

(1). **Orthoxylenol** crystallises from water in very long needles, from alcohol of 8 to 10 per cent. in large rhombic octohedrons, melts at 61° , and boils at 225° (bar.

757 mm.) Its *sodium salt*, C^8H^7ONa , is but slightly soluble in cold strong soda-ley, and crystallises from the hot solution in very large flattened needles having a silky lustre. Tribrom-*o*-xylenol, $C^8H^4Br^3OH$, crystallises from hot alcohol in woolly masses of thin snow-white needles melting at 169° .

Orthoxylenol forms only one sulphonic acid, the *sodium salt* of which, $C^8H^6(OH)SO^3Na$, crystallises in very fine long flat anhydrous prisms, or on quicker separation, in small laminæ, mostly united in large hemispherical groups. The *barium salt*, $(C^8H^6OHSO^3)^2Ba$, is somewhat sparingly soluble in cold water, and separates on cooling from the hot solution, or on slow evaporation, in hard nodular crusts, or separate hemispherical nodules consisting of microscopic rhombic laminæ. The *copper salt* and the very soluble *zinc salt* crystallise well. The salts give a violet reaction with *ferric chloride*.

(2). ***α*-Metaxylenol**, [1 : 3 : 4]. This modification, which forms the principal part of the xylenol described by Wurtz, Wroblevsky (vi. 1129), and Lako (*Liebig's Annalen*, clixiii. 30) differs from all the other xylenols in being liquid at ordinary temperatures. It is colourless, strongly refractive, has a phenolic odour, does not solidify at -20° , but merely becomes viscid; boils constantly at 211.5° (bar. 766 mm.; mercury-column wholly in the vapour). Sp. gr. 1.0632 at 0° . It mixes in all proportions with alcohol and ether, but dissolves very sparingly in water. The aqueous solution is coloured blue by ferric chloride; the alcoholic solution green. The *sodium salt*, C^8H^7ONa , differs from its isomerides in being easily soluble in strong soda-ley.

Bromo-α-metaxylenol, $C^8H^6Br(OH)$, obtained by the action of bromine on the solution of the xylenol in acetic acid, is a colourless oily liquid, decomposing when distilled. The *dibromo-derivative*, $C^8H^4Br^2.OH$, separates on dropping water into its alcoholic solution in long slender colourless needles melting at 73° . The *tribromo-derivative*, $C^8H^2Br^3.OH$, crystallises from hot alcohol in long perfectly colourless needles, melting at 179° .

Sulphonic acids.—On agitating *α*-metaxylenol with an equal volume of ordinary sulphuric acid, two sulphonic acids are formed, and crystallise after a while in stellate groups of needles. On adding a small quantity of water, one of these acids separates in greatest abundance, forming white rhombic laminæ. The two acids may, however, be more completely separated in the form of barium salts, $[C^8H^6(OH)SO^3]^2Ba$, that of the acid which separates in rhombic laminæ crystallising out first from the aqueous solution in anhydrous rectangular laminæ or thicker rectangular tablets, which often look like irregularly formed cubes. This salt dissolves somewhat sparingly in cold, much more readily in hot water. The *potassium salt* of the same acid, which is not very soluble in cold water, crystallises in dendritic groups of colourless anhydrous laminæ. The *sodium salt* forms large anhydrous tablets. The *barium salt* of the second sulphonic acid is obtained in microscopic needles by evaporating the mother-liquor of the first; the *sodium salt*, $C^8H^6OH.SO^3Na + 4H^2O$, forms large laminæ.

Acetyl-α-metaxylenol, $C^8H^7O(C^2H^3O)$, is a colourless liquid having a faint odour like that of bergamot-oil, not miscible with water, boiling at 226° (bar. 760 mm.)

Methyl-α-metaxylenol, $C^8H^9O(CH^3)$, is also a colourless liquid, which does not solidify at low temperatures, boils at 192° , and has a very faint odour resembling that of the pure hydrocarbons of the benzene series. Treated at low temperatures with excess of bromine, it yields a tribromo-derivative, $C^8H^6Br^3.OCH^3$, which dissolves rather sparingly in cold, more freely in hot alcohol, and crystallises in large flat colourless needles melting at 120° .

(3). ***β*-Metaxylenol**, $[CH^3 : OH : CH^3 = 1 : 2 : 3]$, crystallises from water in silky laminæ or long flat needles, melts at 74.5° , and boils at 211° – 212° . With bromine it forms a *tribromo-derivative*, which crystallises from alcohol in long light yellow needles melting at 175° . With sulphuric acid it forms two *sulphonic acids*, only one of which yields a distinctly crystallised barium salt.

(4). ***Paraxylenol***, $[CH^3 : OH : CH^3 = 1 : 2 : 4]$, crystallises from dilute alcohol in large flat needles, melting at 74.5° , and sublimes a little above its melting point in small woolly needles. It boils at 211.5° (bar. 762 mm.), and, like its isomerides, volatilises readily with vapour of water. Its aqueous solution is not coloured by ferric chloride. The *sodium-derivative*, C^8H^7ONa , is very slightly soluble in cold concentrated soda-ley, and separates on cooling from the hot solution in large crystalline laminæ.

Monobromo-p-xylenol, $C^8H^6Br.OH$, obtained by bromination in acetic acid solution, precipitation with water, and crystallisation from dilute alcohol, forms a loose colourless mass of long flexible needles melting at 87° . *Tribromo-p-xylenol*, $C^8H^2Br^3.OH$,

formed by adding excess of bromine to cooled paraxyleneol, crystallises from hot alcohol in long needles of deep golden-yellow colour, and melts at 175°.

Paraxyleneol, dissolved in moderately warm sulphuric acid, yields only one sulphonic acid, which separates on addition of water in hydrated laminae. Its *barium salt*, $(C^6H^4OH.SO_3)^2Ba$, crystallises in stellate or larger nodular groups of microscopically anhydrous needles which begin to decompose at 115°. The *sodium salt*, $C^6H^4OH.SO_3Na + 5H^2O$, crystallises in large very fine rhombic tablets, having an acute angle of 86.5°, and efflorescing in dry air at ordinary temperatures.

Acetyl-p-xyleneol, $C^6H^3O.C^2H^3O$, is a colourless liquid, not solidifying at -20°, having a faint odour somewhat like that of bergamot-oil, a sp. gr. of 1.0264 at 15°, and boiling at 237° (bar. 768 mm.).

Methyl-p-xyleneol, $C^6H^3O.CH^3$, is a colourless non-solidifying liquid smelling like the pure benzene-hydrocarbons, and boiling at 194° (bar. 772 mm.).

The salts of the above-described xyleneolsulphonic acids give a deep violet coloration with ferric chloride.

The xyleneols are converted by prolonged fusion with potassium hydroxide into hydroxytoluic acid, $C^6H^3(CH^3)(OH).CO^2H$, and hydroxyphthalic acid, $C^6H^3(OH)(CO^2H)^2$.

III. Nine-carbon-phenols, $C^9H^{12}O = C^6H^4OH(C^3H^7)$. 1. **Normal Propylphenols**, $C^6H^4(OH).CH^2.CH^2.CH^3$ (P. Spica, *Gazz. chim. ital.* 1878, 406). Two of these compounds, $[OH : C^3H^7 = 1 : 2 \text{ and } 1 : 4]$, are obtained by the action of melting potash on the corresponding propylbenzenesulphonic acids, $C^6H^4(C^3H^7)SO^3H$, which are produced by treating normal propylbenzene with sulphuric acid, and separated by means of their barium salts. The *para*-compound, also called *a-propylphenol*, is a colourless liquid boiling at 230.6°-232.6° (corr.), and having a density of 1.0091 at 0° and 0.9324 at 99.8°. The *acetyl-derivative*, $C^6H^4(C^3H^7)OC^2H^3O$, is a colourless liquid having a density of 1.02904 at 0° and 0.94229 at 100°, and boiling between 242.7° and 244° (corr.) The *methyl ether*, $C^6H^4(C^3H^7)OCH^3$, is a colourless liquid having a pleasant odour of anise, boiling between 214° and 215.5°, and having a density of 0.96364 at 0° and 0.91251 at 99.6°. By oxidation with potassium dichromate and sulphuric acid, it is converted into anisic acid. *Para-propylphenol*, treated with carbon dioxide and sodium, is converted into the sodium salt of a *p*-propylphenolcarboxylic acid represented by the formula $C^6.C^3H^7.H.CO^2OH.OH.H^2$. This acid melts at 98°, and its aqueous solution produces a violet colour with ferric chloride. Its *barium salt* crystallises with 3 mol., the *lead salt* with 2 mol. H^2O . The *silver salt* has the composition $C^{10}H^{11}O^3Ag$.

Ortho-, or *β*-*Propylphenol*, is a colourless liquid which distils at 224.6°-226.6° (corr.), and has a density of 1.0150 at 0°, and 0.93702 at 99.8°; its aqueous solution is coloured violet by ferric chloride. The *methyl ether* boils between 207° and 209° (corr.), and has a density of 0.96944 at 0°, and 0.916772 at 99.88°. *o*-Propylphenolcarboxylic acid, probably $C^6.C^3H^7.OH.CO^2OH.H^2$, forms barium and lead salts which crystallise with $2\frac{1}{2}H^2O$. The *silver salt*, $C^{10}H^{11}O^3Ag$, is a white precipitate.

2. Isopropyl-phenol, Cumophenol, or Cumenol, $C^6H^4\begin{smallmatrix} CH(CH^3)^2 \\ OH \end{smallmatrix}$, produced

by fusing potassium cumenesulphonate with potassium hydroxide, melts at 61° and boils at 228.2°-229.2° (corr.) Its *methyl ether*, $C^6H^4(C^3H^7)(OCH^3)$, is a colourless liquid smelling like oil of anise, having a density of 0.962 at 0°, and boiling at 212°-213° (bar. 758.04 mm.). When oxidised with potassium dichromate and sulphuric acid, it yields a small quantity of anisic acid. The *ethyl ether* has a density of 1.026, and boils at 244°-245° (bar. 756.27 mm.) (Paternò a. Spica, *Gazz. chim. ital.* 1876, 535; *Ber.* ix. 455).

3. **Trimethyl-phenols**, $C^6H^2(OH)(CH^3)^3$. Two of these compounds are known, viz.:

Mesitol, which Biedermann a. Ledoux obtained by the decomposition of diazomesitylene nitrate, and by the action of melting potash on potassium mesitylenesulphonate (p. 1282), has been further studied by Jacobsen (*Liebigs Annalen*, cxv. 265), who prepares it by the last-mentioned reaction. It melts at 68°, boils at 219.5° (bar. 763 mm.), and dissolves in a strong sulphuric acid, yielding a sulphonic acid, which forms an easily soluble barium salt crystallisable in small needles. The sodium salt is also easily soluble in water and crystallises in flat prisms. Ferric chloride colours the aqueous solutions of these salts deep blue.

Monobromomesitol prepared by acting on mesitol dissolved in glacial acetic acid, with bromine in the cold, crystallises from hot dilute alcohol in white, long, flexible, silky needles (m. p. 80°), and is identical with the compound described by Biedermann and Ledoux.

Dibromomesitol is formed by acting on the monobromo-derivative with bromine, or by dissolving mesitol in an excess of well-cooled bromine. It is soluble in hot water, more easily in a hot aqueous solution of an alkaline carbonate, from which it separates on cooling, and is obtained by crystallisation from alcohol, in large, brittle, colourless prisms, melting at 150° . It cannot be volatilised without decomposition. If the bromine used in the preparation of this body contains moisture, a second compound is formed, which is the only product of the action when bromine acts on mesitol and water. This compound is more soluble in alcohol than dibromomesitol, crystallises in large acute golden-yellow rhombic plates, melting at 174° (corr. 176°), and subliming in shining golden-yellow leaflets. It is insoluble in water and in alkaline carbonates. It is decomposed by potash, forming a dark brown solution, from which, after acidifying with hydrochloric acid, ether extracts a new compound, in the form of a semi-liquid mass, which becomes crystalline after some time; it is soluble in alcohol, yielding a dark brown solution, which is decolorised by sodium-amalgam, but becomes brown again on exposure to air. This compound is identical with Fittig's *a*. Hoogewerff's dibromoxyleneol (vi. 1129); its properties are, however, those of a quinone, and analysis shows it to have the composition of *dibromoxylenequinone*, $C^8H^2Br^2O^2$. Mesitol fused with potash is converted into hydroxymesitylenic acid, $C^8H^{10}O^3$ (see ADDENDA).

Pseudocumenol, $C^8H^2OH(CH^3)^3$ (A. Reuter, *Ber.* xi. 29).—This compound is formed by fusing pseudocumenesulphonic acid (p. 1285) with potassium hydroxide. It is nearly insoluble in cold water, very easily soluble in alcohol and ether, volatilises very easily with vapour of water, and solidifies for the most part in the condensing tube to a white crystalline mass having a phenolic odour. When distilled by itself, it yields a loosely coherent crystalline mass composed of thin flexible needles. Its solutions are not coloured by ferric chloride.

Bromopseudocumenol, $C^8H^{10}BrOH$, formed by careful bromination of pseudocumenol dissolved in acetic acid, crystallises from dilute alcohol in long colourless needles, melts at 32° , and boils with partial decomposition at about 250° . *Dibromopseudocumenol*, $C^8H^8Br^2OH$, formed by the action of excess of bromine on cooled pseudocumenol, crystallises from hot alcohol in large hard colourless needles melting at 149° – 150° .

Pseudocumenolsulphonic acid, $C^8H^{10}(OH)(SO^3H)$, separates after some time from a solution of pseudocumenol in strong sulphuric acid, in small shining crystals having the form of cupric sulphate. On carefully mixing it with water, especially in the form of lumps of ice, a crystalline pulp is formed consisting of the hydrated acid. The sulphonic acid, when free from sulphuric acid, is very unstable, and decomposes in moist air, even at ordinary temperatures, into sulphuric acid and pseudocumenol. Its salts decompose at 100° . The *potassium salt* and the *zinc salt* crystallise in rather large elongated laminae; the *copper salt* in indistinctly crystalline nodules; the comparatively sparingly soluble *barium salt* in nodular groups of shining laminae.

Constitution of Pseudocumenol and its Derivatives.—Pseudocumenol, subjected to prolonged fusion with potassium hydroxide, is converted into hydroxy-xylic acid, $C^8H^2(CH^3)^3OH.COOH$, which may be extracted with caustic soda from the solution obtained by agitating the acidulated melt with ether, and purified by distillation with steam. It is but slightly soluble in boiling water, nearly insoluble in cold water, and crystallises from the hot aqueous solution in feathery groups of needles, or by slower cooling in small compact prisms, apparently orthorhombic. It is readily soluble in alcohol and ether, melts at 195° , but sublimes readily between 160° and 170° in feathery groups of microscopic prisms. With ferric chloride it produces a deep violet colour. The *barium salt* forms small compact hydrated crystals; the *calcium salt* dries up in a vacuum to an amorphous mass. Since now this calcium salt, when distilled with excess of lime yields the liquid 1 : 3 : 4 *m*-xyleneol (p. 1541) and moreover potassium pseudocumenesulphonate when fused with sodium formate yields the same cumylic or durylic acid (vi. 828) that is produced by oxidation of durenene (tetramethylbenzene), it follows that the compounds under consideration must be represented by the following constitutional formulæ

	1	2	3	4	5	6
Pseudocumene	—	CH ³	—	CH ³	CH ³	—
Liquid <i>m</i> -xyleneol . . .	OH	CH ³	—	CH ³	—	—
Hydroxy-xylic acid . . .	OH	CH ³	—	CH ³	CO ² H	—
Pseudocumenol	OH	CH ³	—	CH ³	CH ³	—
Pseudocumene-sulphonic acid	SO ³ H	CH ³	—	CH ³	CH ³	—
Cumylic or Durylic acid . .	CO ² H	CH ³	—	CH ³	CH ³	—
Durene	CH ³	CH ³	—	CH ³	CH ³	—

IV. **Cymophenols** or **Cymenols**, $C^{10}H^{14}O = C^6H^3(CH^3)(C^3H^7)OH$. Two of these phenols are known, viz:

	OH	CH ³	C ³ H ⁷
Thymol	1	3	6
Carvacrol	1	2	5

Thymol, obtained from the volatile oils of thyme, horse-mint, *Ptychotis Ajoowan*, and *Monarda punctata*, melts at 44° and boils at 230°; *carvacrol*, obtained by fusing cymene-sulphonic acid with potash, by heating camphor with iodine, and from the isomeric compound carvol, contained in oil of caraway, by heating with phosphoric acid, is an oil not solidifying at -25°, boiling at 233°-235° (i. 809; v. 793-4).

The following derivatives of these isomeric phenols have been examined by Paternò (*Gazz. chim. ital.* 1875, 13).

The *acetyl*- and *methyl*-derivatives are identical in boiling point and specific gravity, as may be seen from the following table:

		From thymol	From carvacrol
Acetate $C^{10}H^{12}.O.C^2H^3O$	(B. p. (corr.)	244.7°	245.8°
	Sp. gr. at 0° =	1.009	1.010
	" " 100° =	0.924	—
Methylate $C^{10}H^{13}.O.CH^3$	(B. p. (corr.)	216.7°	216.8°
	Sp. gr. at 0° =	0.954	0.954
	" " 100° =	0.869	0.870

The *ethylene*-derivatives, $\left. \begin{matrix} C^{10}H^{13}O \\ C^{10}H^{13}O \end{matrix} \right\} C^2H^4$, however, are different. The product obtained by adding ethylene bromide to an alcoholic solution of thymol mixed with alcoholic potash, boiling the whole for some hours in an apparatus with reversed condenser, and dissolving out the resulting potassium bromide with water, is solid at ordinary temperatures, and crystallises from ether in beautiful laminae melting at 99°, whereas the corresponding derivative of cymene-thymol does not appear to be crystallisable.

Barth (*Ber.* xi. 567), by fusing thymol with potassium hydroxide, has obtained four acids, viz. (1) hydroxybenzoic acid; (2) hydroxyterephthalic acid; (3) thymol-hydroxycinnamic acid, $C^{10}H^{12}O^3$, which forms needle-shaped crystals melting at 143°; (4) a bibasic acid (which Barth proposes to call *thymolic acid*), easily soluble in water, the aqueous solution precipitating lead salts and producing a deep red coloration with ferric chloride.

Dinitrothymol, $C^{10}H^{11}(NO^2)_2OH$. — The ethylic ether of this compound, $C^{10}H^{11}(NO^2)_2OC^2H^5$, obtained by heating the sodium salt in sealed tubes at 140°-150° with ethyl iodide and alcohol, crystallises in colourless plates, melts at 52°-53°, dissolves easily in alcohol and ether, and decomposes when distilled. By reduction with tin and hydrochloric acid it yields a lead salt which is converted by distillation with aqueous ferric chloride into hydroxythymoquinone and dihydroxythymoquinone.

Dinitrothymol, heated with phosphorus pentachloride, is converted into chloro dinitrocymene, $C^{10}H^{11}Cl(NO^2)_2$, which melts at 100°-101°, is moderately soluble in alcohol and ether, less freely in carbon sulphide and chloroform. By reduction with tin and hydrochloric acid, chlorodinitrocymene is converted into an amido-compound which, when oxidised with chromic acid mixture, yields dihydroxythymoquinone, $C^{10}H^{10}(OH)_2O^2$ (vii. 1156), and chlorhydroxythymoquinone, $C^{10}H^{10}(OH)ClO^2$ (Ladenburg & Engelbrecht, *Ber.* x. 1218). See THYMOQUINONES.

Nitrosothymol, $C^{10}H^{12}(NO)O$, is prepared by mixing a solution of thymol in potash with a solution of potassium nitrite, diluting the mixture with a large quantity of water, and adding dilute sulphuric acid, whereupon the whole liquid is speedily converted into a magma of crystals, which are to be thrown upon a cloth filter and washed, then dried and crystallised from benzene. The product, after repeated crystallisation from chloroform, forms small needles melting at 155°-156°. It is nearly

insoluble in water, but dissolves easily in alcohol, ether, and chloroform. It dissolves in alkalis with red coloration, also in strong sulphuric acid, from which it is deposited on addition of water.

The alkali-salts, obtained by dissolving nitrosothymol in potash or soda, form long yellow needles. Their solutions are decomposed by carbonic acid. The salts of the heavy metals are coloured amorphous precipitates. The *benzoyl-ether*, $C^{10}H^{17}NO^3$, formed by heating the potassium-salt with benzoyl chloride, crystallises from absolute alcohol in fine yellow needles, melting at 110° .

Potassium ferricyanide in alkaline solution oxidises nitrosothymol to nitrothymol, which crystallises in concentric groups of needles melting at 137° . Strong nitric acid converts nitrosothymol into dinitrothymol. Tin and hydrochloric acid reduce it, forming amidothymol hydrochloride, $(C^{10}H^{13}O.NH^2.HCl)$, a white crystalline substance decomposing at 210° – 215° . Free amidothymol is very unstable. The action of nitrous acid upon nitrosothymol in ethereal solution results in the formation of a very easily decomposable diazo-derivative, the sulphate of which, $(C^{10}H^{13}N^2O.HSO^4)$, forms white crystals decomposing at 120° (R. Schiff, *Ber.* viii. 1500).

Nitrosocarvacrol, prepared in like manner, crystallises from benzene in lemon-yellow prisms melting at 153° , insoluble in water, soluble in alcohol, ether, benzene, and chloroform. By reduction with tin and hydrochloric acid, it is converted into amidocarvacrol, which crystallises in slender needles, having a silvery lustre and melting at 134° . By oxidation in alkaline solution with potassium ferricyanide, it is converted into nitrocarvacrol, which crystallises in pale yellow needles melting at 77° – 78° , slightly soluble in water, easily in alcohol and ether (Paternò a. Canzoneri, *Gazz. chim. ital.* 1878, 501).

Cymenol-sulphonic acids, $C^{10}H^{14}SO^3 = C^{10}H^{13}SO^3H$ (Paternò, *Gazz. chim. ital.* 1875, 13).—Engelhardt a. Latschinoff have shown that the chief product of the action of sulphuric acid on *thymol*, under ordinary circumstances, is a sulphonic acid (distinguished as α), which forms lead and barium salts containing $2H^2O$, and a potassium salt containing $2\frac{1}{2}H^2O$.

Carvacrol, heated for some hours in the water-bath with rather more than its own weight of ordinary sulphuric acid, dissolves almost completely, and on adding water and neutralising with barium carbonate, a mixture of two salts is obtained, one of which crystallises in anhydrous laminae yielding 28.44 per cent. baryta, while the other crystallises in needles containing $5H^2O$, or 15.12 per cent., and 23.02 per cent. BaO. The *lead-salt*, $(C^{10}H^{12}OH.SO^3)^2Pb + 5H^2O$, crystallises in small shining needles very soluble in water. The *potassium salt* crystallises in shining needles containing a considerable quantity of water of crystallisation. On heating a solution of this potassium salt with dilute nitric acid, a heavy oil separates, which on cooling solidifies to orange-yellow crystals, soluble in ether and benzene, and slightly soluble in water. This substance melts at about 119° , and appears to be a nitrocymophenol.

Methyl-cymenolsulphonic acids, $C^{10}H^{12}(OCH^3)(SO^3H)$.—1. From Thymol. From the experiments of Engelhardt a. Latschinoff (*loc. cit.*), it appears probable that the action of sulphuric acid on the methylic ether of thymol gives rise to the formation of two isomeric sulphonic acids, one of which yields a crystallisable barium salt containing 3 mol. water, while the other yields an amorphous barium salt. Paternò's experiments confirm these results, and show that the products are the same whether the action takes place slowly at ordinary temperatures or quickly at the boiling heat. When 1 pt. of methyl-thymol is heated for several hours with $1\frac{1}{2}$ pt. sulphuric acid of $63^\circ B.$, and water is then added, an oily substance separates which crystallises on cooling; and the aqueous solution neutralised with barium carbonate deposits a well-crystallised barium salt, an additional quantity of which may be obtained from the mother-liquor, while the uncrystallisable salt mentioned by Engelhardt a. Latschinoff still remains dissolved.

The crystalline *barium salt*, $(C^{10}H^{12}.OCH^3.SO^3)^2Ba + 3H^2O$, forms large hexagonal plates having a vitreous lustre but becoming opaque after some time; it is nearly insoluble in cold, somewhat more soluble in hot water; gives off the whole of its crystallisation-water at 110° , and decomposes at a somewhat higher temperature. The *lead salt*, $(C^{10}H^{12}.OCH^3.SO^3)^2Pb + 2H^2O$, forms very light, slender, shining needles, which do not give off all their water at 100° , and decompose at higher temperatures. The *potassium salt*, $C^{10}H^{12}.OCH^3.SO^3K$, crystallises from aqueous solution in large splendid anhydrous plates.

The oily substance already mentioned as produced by the action of sulphuric acid on methyl-thymol, and afterwards crystallising, may be purified by pressure between bibulous paper, and recrystallisation from ether or from benzene. It then forms small needles, melting at 150° – 151° , very soluble in benzene, slightly soluble in ether.

It is in all probability a compound analogous to sulphobenzide, and represented by the formula :

It gave by analysis 8.05 per cent. of sulphur, the formula requiring 8.87.

2. From Carvacrol.—A mixture of carvacrol with twice its weight of ordinary sulphuric acid, left to itself for a few hours, solidifies to a crystalline mass, soluble for the most part in water; and on neutralising the solution with barium carbonate, a barium salt is formed, which crystallises only from very strong solutions, forming a white mass, separable by washing on a filter with cold water into two salts, one of which (α) remains on the filter, and may be purified by recrystallisation from hot water, while the other (β) may be obtained by evaporating the wash-water. The α -salt, $(\text{C}^{10}\text{H}^{12}.\text{OCH}^3.\text{SO}^2)^2\text{Ba} + 3\frac{1}{2}\text{H}^2\text{O}$, crystallises on cooling from its hot aqueous solution in small hard heavy prisms, having a vitreous lustre. The β -salt, $(\text{C}^{10}\text{H}^{12}.\text{OCH}^3.\text{SO}^2)^2\text{Ba} + 5\text{H}^2\text{O}$, is very soluble in water, and crystallises in very light and very white needles.

PHENOXYLIC ACID, $\text{C}^6\text{H}^6\text{O}^2 = \text{C}^6\text{H}^5.\text{CO}.\text{CO}.\text{OH}$. See PHENYL-GLYOXALIC ACID.

PHENYL (DI-) and its derivatives. See DIPHENYL (pp. 658-686).

PHENYL CARBAMATE, or **PHENYL-URETHANE**, $\text{NH}^2.\text{CO}.\text{OC}^6\text{H}^5$, See CARBAMATES (p. 384).

PHENYL CYANATE and **CYANURATE** are formed, together with benzoic acid and benzanilide, by the distillation of dibenzhydroxamic acid; the cyanate, also, together with anisanilide, from benzanishydroxamic acid (pp. 1080, 1081); methoxyl-phenyl cyanate, in like manner, together with benzoyl-anisidine and carbon dioxide, from anisbenzhydroxamic acid (Pieschel, *Liebigs Annalen*, clxxv. 305).

PHENYL CYANIDE, or **BENZONITRIL**, $\text{C}^6\text{H}^5-\text{C}\equiv\text{N}$, and **PHENYL ISOCYANIDE** or **PHENYL CARBAMINE**, $\text{C}^6\text{H}^5-\text{N}\equiv\text{C}$. Phenyl-carbamine is produced by desulphuration of phenyl-thiocarbimide, $\text{CSN}(\text{C}^6\text{H}^5)$, with finely divided copper (precipitated from a strong solution of the sulphate with excess of zinc; Gladstone's copper-zinc couple), and subsequently changes into normal phenyl cyanide or benzonitril. This transformation also takes place when phenyl-carbamine, freed as far as possible from aniline by distillation, is heated for two or three hours at 200° – 220° in sealed tubes, or when phenyl-carbamide containing aniline is heated in an open vessel with reflux condenser. The nearly colourless oil which passes over on heating the product of this reaction with steam may be freed from aniline by dilute sulphuric acid, and, when again distilled, yields pure benzonitril boiling at 191° (Weith, *Ber.* vi. 210).

Phenyl-carbamine may be converted into phenyl-thiocarbimide and subsequently into diphenyl-thiocarbimide or thiocarbaniide, by acting upon it while in the nascent state with sulphur, that is to say by gently heating a mixture of aniline, chloroform, and alcoholic potash with sulphur for two or three hours. On pouring the product into water, scarcely any odour of phenyl-carbamine becomes perceptible, and a heavy oily liquid separates, which, when freed from aniline by dilute hydrochloric acid and from chloroform by heating, solidifies to a mass yielding on crystallisation from hot alcohol, laminae of thiocarbaniide resulting from the combination of the phenyl-thiocarbimide formed in the first instance with aniline:

Phenyl-carbamine free from aniline is also converted into phenylthiocarbimide by direct addition of sulphur, the thiocarbimide being obtained in oily drops on distilling the product with steam. Benzonitril and sulphur do not react on one another in any way whatever (Weith, *loc. cit.*)

PHENYL HYDROSULPHIDE, or *Phenyl-mercaptan*, $\text{C}^6\text{H}^5.\text{SH}$. According to Friedel & Crafts (*Compt. rend.* lxxxvi. 884) this compound is formed, together with phenyl sulphide, $(\text{C}^6\text{H}^5)^2\text{S}$, and diphenylene disulphide, $(\text{C}^6\text{H}^4)^2\text{S}_2$, by heating benzene with sulphur at 75° – 80° , in presence of aluminium chloride, and treating the

product with water. Its formation is explained on the supposition that the aluminium first reacts with the benzene and sulphur in such a manner as to form the compound $Al^2Cl^3.S.C^6H^5$, which is then decomposed by water, as shown by the equation:

The phenyl hydrosulphide thus obtained boiled at 170° – 178° , formed a crystalline compound with mercuric chloride, and was converted by iodine into phenyl bisulphide.

PHENYL SULPHIDE, $(C^6H^5)_2S$, also called *Thiobenzene* (iv. 417; vii. 941). Krafft (*Ber.* vii. 384, 1164) prepares this compound by converting thioaniline, $C^{12}H^{12}N^2S$ (vii. 1154), into a diazo-compound, and decomposing the latter with alcohol. As thus prepared, it boils at 288° – 289° (uncorr.), and is identical with the compound formed by the decomposition of sodium benzenesulphonate (Stenhouse, iv. 417), and with that which is produced by the dry distillation of the lead-salt of phenyl-mercaptan: $(C^6H^5S)_2Pb = PbS + (C^6H^5)_2S$ (Kekulé a. Szuch, *Compt. rend.* lxiv. 752). The decomposition of sodium benzenesulphonate is best effected by Spring's method, which consists in treating the salt with phosphorus pentasulphide. The yellow-red oil thereby produced is decolorised by recently reduced copper-powder, and after two rectifications consists of nearly pure phenyl sulphide.

By adding phenyl sulphide to strong nitric acid, and reducing the resulting nitro-compound, thioaniline, $(C^6H^5.NH^2)_2S$, is obtained, melting at 106° , and crystallising from hot water in thin shining needles.

Bromophenyl Sulphide, $(C^6H^4Br)_2S$, produced by the action of bromine on phenyl sulphide, crystallises in nacreous laminae melting at 109° – 110° . It may also be formed by cautiously heating the perbromide of diazothiobenzene. *Chlorophenyl Sulphide*, $(C^6H^4Cl)_2S$, produced by treating phenyl-sulphide with chlorine, or by the action of heat on the platinochloride of diazothiobenzene, resembles the bromine-compound and melts at 88° – 89° . *Iodophenyl Sulphide*, $(C^6H^4I)_2S$, may be prepared by Kekulé's method (vi. 267), which consists in heating phenyl sulphide with iodine and iodic acid in sealed tubes; also by adding dilute hydriodic acid to an aqueous solution of diazothiobenzene sulphate. It resembles the bromo- and chloro-derivatives, and melts at 138° – 139° .

Hydroxyphenyl Sulphide, $(C^6H^4.OH)_2S$, is obtained by the action of water on diazobenzene sulphate, and is precipitated from the alkaline solution by acids in shining laminae which melt at 143° – 144° .

Thiobenzenesulphonic acid, $(C^6H^4.SO^2H)_2S$, is easily obtained by dissolving phenyl sulphide in fuming sulphuric acid: its salts crystallise well (Krafft).

Phenyl Disulphide or *Diphenyl Disulphide*, $(C^6H^5)_2S^2$ (iv. 417), is decomposed by distillation, and, when boiled for about an hour and then distilled, yields the monosulphide, $(C^6H^5)_2S$, nearly pure, while a greasy substance remains behind. It is only by distillation from a retort in which the vapour cannot rise high, that the greater part of the disulphide can be made to pass over without decomposition. A thermometer with only its bulb immersed in the vapour then shows a temperature of 110° (Graebe, *Liebig's Annalen*, clxxiv. 189).

PHENYL-ACEDIAMINE, -ACETAMIDINE, or -ACETAMIMIDE, $C^6H^5.CH^2\begin{smallmatrix} NH \\ \diagup \diagdown \\ NH^2 \end{smallmatrix}$. See AMIDINES (p. 71).

PHENYL-ACETAZIDE, or *Acetyl-phenyl-hydrazide*, $C^6H^5.N^2H^2.C^2H^2O$. See HYDRAZINES (p. 1053).

PHENYL-ACETIC ACID, $C^6H^5.CH^2.CO.OH$, *α-Toluic acid*. See TOLUIC ACIDS.

PHENYL-ACETOTHIAMIDE, $CH^2(C^6H^5).CS.NH$. See THIAMIDES.

PHENYL-ACETYL-CARBAMIDE, $CON^2H^2(C^2H^3O)(C^6H^5)$. See ACETYL-CARBAMIDES (p. 393).

PHENYL-ACETYL-THIOCARBAMIDE, $CSN^2H^2(C^2H^3O)(C^6H^5)$ (p. 400).

PHENYL-ALDEHYDINES (Ladenburg a. Engelbrecht, *Ber.* xi. 1653).

1. *Phenyl-benzaldehydine*, $C^6H^4(NC^2H^5)_2$, is prepared by agitating a dilute aqueous solution of orthophenylenediamine hydrochloride with benzaldehyde, recrystallising the hydrochloride which separates after some time from very dilute hydrochloric acid, and decomposing it with potash. It forms colourless six-sided prisms, insoluble in water, nearly insoluble in alkaline hydrates, easily soluble in alcohol and benzene; melts at 133° – 134° . Like other aldehydines, it is a mono-acid base. The *hydrochloride*, $C^{20}H^{14}N^2.HCl$, prepared as above mentioned, forms colourless anhydrous

prisms, difficultly soluble in water, and decomposed on boiling, with separation of hydrochloric acid. The *platinochloride*, $(C^6H^5N^2.HCl)^2PtCl_4$, crystallises from dilute alcohol, with addition of hydrochloric acid, in golden-yellow needles. The *nitrate*, $C^6H^5N^2.HNO_3$, prepared by treating the hydrochloride with dilute nitric acid, forms colourless prisms, soluble in cold water. The *sulphate*, $C^6H^5N^2.H_2SO_4$, prepared by dissolving phenyl-benzaldehyde in hot dilute sulphuric acid, crystallises in small colourless shining plates. The *ethiodide*, $C^6H^5N^2.C^2H^5I$, obtained by heating the base with ethyl iodide in sealed tubes for some hours at 100° – 120° , separates from aqueous solution in well-formed crystals melting at 211° – 213° . The *methiodide*, $C^6H^5N^2.CH_3I$, prepared in like manner, crystallises in shining prisms.

Phenyl-furfuraldehyde, $C^6H^4(NC^2H^3O)^2$, is prepared like phenyl-benzaldehyde, substituting furfuraldehyde for benzaldehyde:

The resulting hydrochloride separates after a while in somewhat dark-coloured crystals, which may be purified by repeated crystallisation and treatment with animal charcoal. The base, separated from the solution by potash, may be purified by crystallisation from high-boiling ligroin, in which it is sparingly soluble, and separates from the solution in nearly colourless compact crystals melting at 95° – 96° .

Phenyl-furfuraldehyde is mono-acid. It dissolves very easily in alcohol, less easily in benzene and toluene, sparingly in ligroin, and is insoluble in water. It dissolves easily in dilute hydrochloric acid, forming a crystalline *hydrochloride* which appears to be decomposed by washing. The *platinochloride*, $(C^6H^5N^2O^2.HCl)^2PtCl_4$, crystallises in yellow laminae. The *nitrate*, $C^6H^5N^2O^2.HNO_3$, obtained by decomposing a very dilute solution of the hydrochloride with dilute nitric acid, crystallises in needles. The *acid sulphate*, $C^6H^5N^2O^2.H_2SO_4$, is obtained by dissolving the base in dilute sulphuric acid. The *methiodide*, $C^6H^5N^2O^2.CH_3I$, obtained by heating the base to 100° with methyl iodide, crystallises from hot water in yellowish prisms melting at 192° – 193° . The *ethiodide* was obtained only as a viscid mass showing but little tendency to crystallise.

Phenylanisaldehyde, $C^{12}H^{10}N^2O^2 = C^6H^4(NC^2H^3O)^2$, is prepared from anisaldehyde and a dilute aqueous solution of orthophenylenediamine hydrochloride with addition of a little alcohol. When separated from the hydrochloride by ammonia and repeatedly crystallised from alcohol, it forms stellate needles very soluble in hot alcohol, melting at 128.5° – 129° . The *hydrochloride* forms needles almost insoluble in water (Ladenburg a. Rugheimer, *Ber.* xi. 1660).

PHENYL-AMIDACETIC ACID, $C^6H^5.CH(NH^2).COOH$. This acid, prepared by the action of aqueous ammonia on phenylbromacetic acid, crystallises in pearly scales, which are insoluble in the usual neutral solvents, but dissolve in acids, and in solutions of the alkalis and alkaline carbonates. It sublimes with partial decomposition without melting. It unites with hydrochloric, nitric, sulphuric, oxalic, and phosphoric acids, forming crystalline compounds which are decomposed by water. With phosphorus pentachloride it yields benzaldehyde and a resinous product (Stöckenius, *Ber.* xi. 2002).

PHENYL-AMIDODICHLORACETATE, ETHYLIC, $C^6H^5.NH.CCl_2.COOC^2H^5$, is formed by the action of phosphorus pentachloride at temperatures below 70° on ethylic phenyloxamate. See PHENYLOXAMIC ETHERS.

PHENYLAMINES. *Monophenylamine* or *Aniline*, and a large number of its derivatives, have already been considered in this volume (pp. 191–206 and 1305–1310).

Dichloranilines, $C^6H^3Cl^2.NH^2$ (p. 197).—Beilstein a. Kurbatow (*Ber.* xi. 1860) have completed the series of these bodies by the discovery of the 1 : 2 : 6 modification, $C^6H^3.NH^2.Cl.H.H.H.Cl$, which is obtained by the reduction of the corresponding nitro-dichlorobenzene (m. p. 71°). It crystallises in needles melting at 39° . Its acetyl-derivative melts at 175° . The following table exhibits the melting and boiling points of the six dichloranilines:—

	NH ²	Cl	Cl	Melting point	Acetyl-derivative.	
					Boiling point	Melting point
Consecutive	{ 1	2	3	23.5°	252°	156.5
	{ 1	2	6	39°	—	175°
Unsymmetrical	{ 1	2	5	50°	251°	132°
	{ 1	2	4	63°	245°	143°
	{ 1	3	4	71.5°	272°	120.5°
Symmetrical	1	3	5	50.5°	260°	186.5°

Trichloranilines, $C^6H^2Cl^3.NH^2$. In addition to the two modifications described

at p. 147, Beilstein a. Kurbatow have obtained the consecutive modification 1 : 2 : 3 : 4 by chlorinating [1 : 2 : 4] dichloraniline in acetic acid solution. By exchange of NH^2 for Cl it is converted into consecutive tetrachlorobenzene. The physical characters of the three known modifications are shown in the following table:

	NH^2	Cl	Cl	Cl	Melting point	Boiling point	Acetyl-derivative. Melting point
Consecutive	1	2	3	4	67.5°	292°	121°
Symmetrical	1	2	4	5	96.5°	270°	
Unsymmetrical	1	2	4	6	77.5°	260°	

Tetrachloranilines, $\text{C}_6\text{HCl}_4\text{NH}_2$. The modification $\text{NH}^2 : \text{Cl} : \text{Cl} : \text{Cl} : \text{Cl} = 1 : 2 : 3 : 4 : 6$, is obtained by chlorination of metachloraniline. It crystallises in needles melting at 88°. By the action of ethyl nitrite, it is converted into unsymmetrical tetrachlorobenzene (m. p. 50–51°). The acetyl-derivative melts at 173°–174°, and is not decomposed by heating with strong sulphuric acid.

The modification 1 : 2 : 3 : 4 : 5 [NH^2 in 1], obtained by reduction of the corresponding nitrotetrachlorobenzene, forms crystals melting at 118°.

The modification 1 : 2 : 3 : 5 : 6, prepared in like manner, melts at 90°.

Diphenylamine, $\text{C}^{12}\text{H}^{11}\text{N} = \text{NH}(\text{C}^6\text{H}_5)^2$ (p. 207). This base is formed, together with cyanic acid (carbimide), by the dry distillation of unsymmetrical diphenyl-carbamide:

and in like manner, together with phenyl-carbimide, by distillation of triphenyl-carbamide (Michler, *Ber.* ix. 715):

Diphenylamine hydrochloride is obtained, together with the hydrochlorides of cresylamine and phenyl-cresylamine, by heating liquid toluidine to 280° for ten hours with aniline hydrochloride (Gerard a. Wilm, *Bull. Soc. Chim.* [2], xxv. 218).

Action of Chlorine on Diphenylamine.—A solution of diphenylamine in glacial acetic acid absorbs dry chlorine, forming tetrachlorodiphenylamine, $\text{NH}(\text{C}^6\text{H}_2\text{Cl}_4)^2$ (p. 209). Diphenylamine subjected to exhaustive treatment with chlorine and iodine (p. 1066), yields perchlorobenzene, C^0Cl^6 , probably together with free nitrogen (Ruoff, *Ber.* ix. 1483).

Action of Bromine.—Tetra- and hex-bromodiphenylamine, $\text{NH}(\text{C}^6\text{H}_3\text{Br}_2)^2$, and $\text{NH}(\text{C}^6\text{H}_2\text{Br}_3)^2$, are produced by the action of bromine on diphenylamine dissolved in glacial acetic acid (p. 205). By exhaustive treatment with bromine containing iodine, diphenylamine is converted into octo- and deca-bromodiphenylamine. The former, $\text{NH}(\text{C}^6\text{HBr}_4)^2$, which is produced at 250°, crystallises in prisms, melts at 302°–305°, and dissolves with moderate facility in benzene, toluene, and chloroform. The latter, $\text{NH}(\text{C}^6\text{Br}_5)^2$, formed at 310°, crystallises in white slender needles, remains unmelted at 310°, dissolves sparingly in benzene, toluene, and chloroform, and is nearly insoluble in alcohol and ether (Gessner, *Ber.* ix. 1505).

Nitro-diphenylamines.—A dinitro-diphenylamine, crystallising in red needles, and melting at 153°, is formed by the action of aniline on the trinitrobenzene obtained from paradinitrobenzene (p. 175), (Hepp, *Bull. Soc. Chim.* [2], xxx. 4).

Tetranitro-diphenylamine, $\text{C}^{12}\text{H}^7(\text{NO}_2)^4\text{N}$, isomeric with Austen's parapiacryl-nitrilines (p. 199), is prepared by heating 1 pt. of diphenylamine dissolved in 40 pts. glacial acetic acid in a capacious flask with 3 to 5 pts. nitric acid, whereupon red fumes are evolved and the solution turns green. When the reaction is complete, excess of water is added, which throws down a yellowish flocculent precipitate, drying up to a dirty greenish-yellow powder, which becomes glutinous when heated, and solidifies to a brown resinous body when cold. It may be purified by boiling with dilute aqueous sodium carbonate, from which it separates on cooling in brownish-yellow flocculent masses melting at 150°–170°. Methyl-diphenylamine similarly treated yields the same body, and not a methyl-nitrodiphenylamine. The largest and purest yield is obtained by acting with 3 to 5 pts. nitric acid on 1 pt. of diphenyl-nitrosamine (p. 209) dissolved in 10 pts. of hot glacial acetic acid.

Tetranitrodiphenylamine, when pure, crystallises from glacial acetic acid in fine yellow needles or prisms melting at 192°; when more strongly heated in the air, it burns readily, but does not explode. It is soluble in alcohol, ether, and benzene, and, like its isomerides above mentioned, is easily dissolved by hot soda- or potash-ley, forming a solution of a fine scarlet colour, which on cooling deposits it in minute red-brown needles. It does not appear to yield an acetyl-derivative, even when heated in sealed tubes with acetyl chloride (Gnehm a. Wyss, *Ber.* x. 1318).

Dinitrotribromodiphenylamine, $C^{12}H^7Br^3N^2O^4 = C^{12}H^6Br^3(NO^2)^2N$, is formed, together with other compounds, by heating a solution of 1 pt. tetrabromodiphenylamine in 1 to 2 pts. nitric acid, whereupon large quantities of nitrogen tetroxide and bromine are evolved, and the solution on cooling deposits a crystalline mass, from which, by treatment with alcohol, glacial acetic acid, and caustic soda, different bodies may be separated, the portion soluble in alcohol yielding after repeated crystallisation thin glittering yellow plates of dinitrotribromodiphenylamine. This compound dissolves in ether with reddish-yellow, in benzene and chloroform with yellow colour, melts at 209° – 210° , and burns readily when strongly heated in the air (Gnehm a. Wyss).

Tetramidodiphenylamine, $C^{12}H^7(NH^2)^4N$.—Tetranitrodiphenylamine, reduced with zinc and dilute hydrochloric acid, yields an easily soluble colourless salt, from whose aqueous solution sodium hydrate precipitates a colourless, flocculent, basic substance, which in all probability consists of tetramidodiphenylamine, but has not been obtained in a state fit for analysis. Its solution in hydrochloric acid turns red-violet in the air; gives a violet colour with platinum chloride, gradually resolving itself into a dark precipitate; a dark violet with ferric chloride; a dark brown-red with zinc chloride; and with sodium nitrite a blue colour quickly turning red, and then resolving itself into a brown precipitate. By the addition of ammonia a colourless precipitate is formed, but on exposure to air this precipitate redissolves, and a splendid deep blue solution is formed, of very unstable character. Tetramidodiphenylamine is readily oxidised by exposure to the air, probably with formation of tetra-imidodiphenylamine, $NH[C^6H(NH^2)^2]$, the reaction being similar to that by which diamidonaphthol, $C^{10}H^{10}N^2O$, is converted into diimidonaphthol, $C^{10}H^8N^2O$ (vi. 857).

Methyl-diphenylamine, $N(CH^3)(C^6H^5)^2$.—This base, heated to 150° with fuming hydrochloric acid in a sealed tube, is resolved into methyl chloride and diphenylamine. Heated with nitric acid, as long as red vapours are given off, it yields a compound closely resembling Austen's diparapicrylamine, $NH[C^6H^2(NO^2)^2]$ (p. 199), and perhaps identical therewith. The product, after washing with water, may be crystallised from alcohol or glacial acetic acid, and separates from the latter in yellow prisms melting at 233° – 234° . Its barium derivative, $BaN^2[C^6H^2(NO^2)^2]$, crystallises in rhombohedrons of a fine red colour; the ammonium derivative in red laminæ. The same compound is formed by the action of nitric acid on diphenylamine itself, whence it appears that in the treatment of methyl-diphenylamine with nitric acid, the act of nitration is accompanied by a separation of the methyl-group (Gnehm, *Ber.* vii. 1399).

Methylene-diphenyldiamine, $C^{12}H^{14}N^2 = (C^6H^5)^2(CH^2)^2H^2N^2$, is formed by the action of methylene iodide on aniline. A gentle heat is required to start the action, which then takes place so violently that the entire mass becomes raised to the boiling point. In operating on considerable quantities, therefore, it is best to add the methylene iodide by drops to the aniline warmed in a water-bath. The thick crystalline pulp thus obtained is first distilled in a current of steam, then mixed with alkali and again distilled, whereupon there remains in the flask an oily substance, which must be separated from the alkaline solution by a tap-funnel and well washed with water. The oil which then remains is a strong base, which dissolves readily in acids. It does not, however, form crystallised salts, only the sulphate, $C^{12}H^{14}N^2 \cdot H^2SO^4$, being thrown down by alcohol from its aqueous solution as an indistinctly crystalline precipitate. The base prepared as above is analogous in all its chemical relations to the isomeric bases which Hugo Schiff obtained by the action of acetaldehyde and of ethylidene chloride on aniline (vi. 79, 922). *Dimethylene-diphenyldiamine* appears to be formed by treating aniline with excess of methylene iodide (Julie Lermontoff, *Ber.* vii. 1255).

Ethenyl-diphenyldiamine, $(C^2H^3)(C^6H^5)^2HN^2 = C^2H^3 \begin{smallmatrix} N.C^6H^5 \\ \backslash \\ NH.C^6H^5 \end{smallmatrix}$.—This base, which Hofmann obtained by the action of phosphorus trichloride on aniline mixed with acetanilide or acetyl chloride (vi. 585), is also formed by the action of phosphorus pentachloride on acetanilide:

$$2(C^6H^5)(C^2H^3O)NH + PCl^5 = (C^6H^5)^2(C^2H^3)HN^2 + C^2H^3OCl + POCl^3 + HCl.$$

Acetanilide (2 mols.) and PCl^5 (1 mol.) are mixed in a flask, whereupon the mass becomes hot, liquefies, and gives off hydrochloric acid, the evolution of which increases on heating the mixture with an inverted condenser attached to the flask. The solid residue is then to be shaken with water and precipitated with ammonia or potash, but it is only by repeated solution and precipitation that the base can be obtained crystalline and free from resin. When purified by recrystallisation from alcohol, it exhibits all the properties of the base described by Hofmann (E. Lippmann, *Ber.* vii. 241).

Ethenyldiphenyldiamine treated with reducing agents (tin or zinc and hydrochloric

acid), or sodium-amalgam in acetic acid solution, takes up $2\text{H}^2\text{O}$, and is resolved into acetic acid and aniline:

With *bromine* it forms ethenyl-dibromo-diphenyldiamine, which crystallises with some difficulty in broad laminae. With fuming nitric acid it forms ethenyldinitrodiphenyldiamine nitrate, $\text{C}^1\text{H}^{12}(\text{NO}^2)^2\text{N}^2\cdot\text{HNO}^3$, which does not dissolve in water, alcohol, ether, alkalis, or acids. By prolonged boiling with water or acids, or prolonged heating with water in a sealed tube, this nitro-compound is converted, first into nitraacetanilide and ultimately into paranitraniline (m. p. 141°). By reduction it is converted into paraphenylenediamine (R. Biedermann, *Ber.* vii. 539).

Ethylene-diphenyl-diamine, $\text{C}^2\text{H}^4(\text{C}^6\text{H}^5)^2\text{H}^2\text{N}^2$.—According to A. Gretillat (*Monit. Scient.* [3], iii. 383) this base, when prepared by treating ethylene bromide with a large excess of aniline (Hofmann's method, iv. 455), is always contaminated with diethylene-diphenyldiamine, $(\text{C}^2\text{H}^4)^2(\text{C}^6\text{H}^5)^2\text{N}^2$, which however may be separated by dissolving the whole in boiling concentrated acetic acid, and adding alcohol, whereupon the diethylene base separates in crystals.

The two free hydrogen-atoms in ethylenediphenyldiamine may be replaced by acid radicles, either fatty or aromatic. *Ethylenediacytyldiphenyldiamine* is a crystalline body easily soluble in alcohol and ligroin at the boiling heat, and still possessing basic properties; *ethylenedibenzoyldiphenyldiamine*, on the contrary, is destitute of basic properties (Gretillat).

Trichlorethylidene-diphenyldiamine, $\text{C}^1\text{H}^{13}\text{N}^2\text{Cl}^3 = \text{CCl}^3\cdot\text{CH}(\text{NH}\cdot\text{C}^6\text{H}^5)^2$, is formed by the action of aniline on anhydrous chloral. The action is violent, and the vessel must be cooled. The product is a thick liquid which soon becomes crystalline, and may be obtained by recrystallisation from alcohol in tabular crystals with well-developed faces. This compound dissolves readily in alcohol, ether, benzene, and chloroform, but is insoluble in water. It melts at 100° – 101° , and decomposes at 150° . By boiling with water, or by prolonged heating with alcohol, it is decomposed, with formation of phenyl isocyanide. The same product is formed by aqueous solutions of the alkalis, slowly in the cold, more rapidly when heated, and instantly with alcoholic potash. The first reaction is probably,

Chloroform cannot however be detected amongst the products of the reaction: it probably acts upon the aniline in such a manner as to produce another molecule of phenyl isocyanide.

Trichlorethylidene-diphenyldiamine does not appear to be a base: its alcoholic solution has a neutral reaction, and when treated with hydrochloric acid and platinum chloride yields the platinochloride of aniline (Wallach, *Liebig's Annalen*, clxxiii. 349).

Diphenylamine-blue.—Willm a. Girard (*Dingl. pol. J.* cxxxi. 192) have obtained a blue dye-stuff by the following process: Pure formodiphenylamine (p. 208) is first prepared by heating 100 kg. diphenylamine with 30 kg. formic acid to 120° – 160° for twelve hours, and expelling the excess of formic acid by distillation. 1 kg. of this compound is then heated to 110° – 120° for twenty to twenty-four hours with 2 kg. oxalic acid; the product is poured into benzene; and the residue insoluble therein, after being freed by boiling water from adhering oxalic acid, is dried and dissolved in strong alcohol. This solution, heated with weak potash-ley, filtered, and mixed with hydrochloric acid, deposits the blue dye-stuff; and this, when washed with water and treated at 40° – 50° with sulphuric acid, yields the corresponding sulphonic acid, which may be used directly as a dyeing liquid. The same colouring matter may be prepared from acetodiphenylamine. The corresponding dinaphthylamines, and the triamines formed from diphenylamine by introduction of methyl and benzyl instead of formyl and acetyl, are also said to yield the blue dye when treated as above; and similar blue colouring matters are said to be obtained by heating diphenylamine itself with dry oxalic acid, tartaric acid, &c.

Triphenylamine, $\text{N}(\text{C}^6\text{H}^5)^3$. On the formation of this base by the action of bromobenzene on potassium-aniline, see p. 209. It forms monoclinic crystals with the axial ratio $a : b : c = 0.9913 : 1 : 1.4119$. Angle $ac = 88^\circ 38'$. Observed forms 0P , $- \text{P}$, $+ \text{P}$, $+ \text{P} \infty$, $\infty \text{R} \infty$. The crystals are mostly twins according to 0P ; they are elongated in the direction of 0P and $- \text{P}$, and do not appear to be cleavable in any direction. Angle $- \text{P} : \infty \text{R} \infty = 51^\circ 16'$; $- \text{P} : \infty \text{P} = 26^\circ 19'$; $+ \text{P} : \infty \text{R} \infty = 50^\circ 38'5'$; $\infty \text{P} : 0\text{P} = 89^\circ 2'$. The plane of the optic axes is the plane of symmetry.

Triphenylamine, treated with *chlorine* and *iodine* (p. 1066), yields perchlorotriphenylamine, $\text{N}(\text{C}^6\text{Cl}^3)^3$; which by further chlorination is converted into perchlorobenzene:

(Ruoff, *Ber.* ix. 1483).

PHENYL-ARSENIC COMPOUNDS (Michaelis, *Ber.* viii. 1316; ix. 1566; x. 622; La Coste a. Michaelis, *ibid.* xi. 1883).

1. *Arsenious Dichlorophenide* or *Phenyl-dichlorarside*, $\text{C}^6\text{H}^5\text{AsCl}_2$, is formed by the action of arsenious chloride on mercury-diphenyl:

When three or four times the theoretical quantity of arsenious chloride is used, the action begins at ordinary temperatures, heat being evolved, and arsenious dichlorophenide produced, together with arsenious chlorodiphenide, $(\text{C}^6\text{H}^5)_2\text{AsCl}$, and mercuric chloride. The action is completed by heating the mixture for an hour, and the resulting liquid, when decanted from the solid sublimate and submitted to fractional distillation, yields the two phenyl-arsenic compounds above mentioned.

Arsenious dichlorophenide is also formed by heating arsenious chloride with benzene, $\text{C}^6\text{H}^6 + \text{AsCl}_3 = \text{HCl} + \text{C}^6\text{H}^5\text{AsCl}_2$. As thus produced, however, it is mixed with diphenyl formed by a secondary action, and cannot easily be separated; but its presence may be demonstrated by fusing the mass under water, and passing in chlorine to saturation, whereby arsenic tetrachlorophenide, $\text{C}^6\text{H}^5\text{AsCl}_4$, is first formed and then converted by the water into monophenylarsinic acid, $\text{C}^6\text{H}^5\text{AsO}(\text{OH})^2$ (La Coste a. Michaelis).

Arsenious dichlorophenide is a colourless, strongly refractive, not very mobile liquid, having a faint unpleasant smell in the cold, sharp and penetrating when warm, and exerting a violent corrosive action on the skin. It fumes in the air, and boils at 252° – 255° . It is not altered by boiling water, but alkalis dissolve it, forming salts which may be separated from the chloride of alkali-metal produced at the same time, by their solubility in absolute alcohol. The potassium salt, $\text{C}^6\text{H}^5\text{As}(\text{OK})^2$, heated with strong hydrochloric acid, is reconverted into arsenious dichlorophenide (Michaelis). By *bromine* in excess it is converted into arsenious bromodichloride, hydrogen bromide, and paradibromobenzene:

Arsenious Chlorodiphenide, or *Phenyl-cacodyl chloride*, $(\text{C}^6\text{H}^5)_2\text{AsCl}$, is the residue of higher boiling point obtained, as above mentioned, in the fractional distillation of the product of the action of arsenious chloride on mercuric phenide. When purified, it is a thick, oily, yellowish, non-fuming, and nearly scentless liquid, having a sp. gr. of 1.422 at 16° , and distilling unchanged at 333° , in an atmosphere of carbon dioxide. It is heavier than water, and is not decomposed thereby (Michaelis, *loc. cit.*)

Arsenic Trichlorodiphenide, or *Phenyl-cacodyl Trichloride*, $(\text{C}^6\text{H}^5)_2\text{AsCl}_3$, formed by direct combination of the last compound with chlorine, is a yellow solid resembling phosphorus pentachloride, but more stable in presence of water or damp air. It melts at 174° , and solidifies in crystals. It is decomposed by warm water, forming a liquid, probably an oxychlorophenide, which suffers further decomposition on boiling, yielding monophenylarsinic acid.

The *Bromodichlorodiphenide*, $(\text{C}^6\text{H}^5)_2\text{AsCl}_2\text{Br}$, a comparatively unstable body, is formed by direct combination of the dichlorophenide with bromine.

Arsenic Tetrachlorophenide, or *Phenyl-tetrachlorarside*, $\text{C}^6\text{H}^5\text{AsCl}_4$, formed by direct combination of arsenious dichlorophenide with chlorine, solidifies gradually at ordinary temperatures, quickly at 0° , to broad needles. It melts at 45° , and remains fluid for a long time after cooling. In moist air it is converted into arsenic oxydichlorophenide, $\text{C}^6\text{H}^5\text{AsOCl}_2$, and phenylarsinic acid, $(\text{C}^6\text{H}^5)\text{AsO}(\text{OH})^2$. It converts organic acids into chlorine-derivatives, acetic acid, for example, into monochloroacetic acid, being itself at the same time reduced to arsenious dichlorophenide:

It is not acted on by sulphur dioxide. When heated, especially in a stream of carbon dioxide, it is resolved into arsenious dichlorophenide and free chlorine. Heated to 150° in a sealed tube, it is resolved into arsenious chloride and monochlorobenzene.

Monophenylarsinic acid, $(\text{C}^6\text{H}^5)\text{AsO}(\text{OH})^2$, is formed by the action of excess of water on arsenic tetrachlorophenide:

It is very soluble in water, and crystallises in long white needles, which soften at 158°, and are converted into the anhydride. Phenylarsinic acid forms normal salts only with the heavy metals, and these salts are mostly amorphous. Its solution neutralised with ammonia yields with silver nitrate a white precipitate of *silver phenylarsinate*, $C^6H^5AsO(OAg)^2$, sparingly soluble in water, easily soluble in ammonia and in nitric acid. With the alkalis and alkaline earths, the acid yields salts of the form $C^6H^5AsO(OH)OM$; the *barium salt* crystallises in short radiating needles; the *copper salt* in pearly plates.

Monophenylarsenic Anhydride, $C^6H^5AsO^2$, obtained by heating the acid at 158°, is an amorphous powder, similar in constitution to nitrobenzene. On treating it or the corresponding acid with zinc and hydrochloric acid, the smell of an arsine becomes perceptible (La Coste a. Michaelis).

Diphenylarsinic or Phenylcacodylic acid, $(C^6H^5)^2AsO(OH)$, separates on cooling the filtrate obtained when the last-described body is decomposed by boiling water. It crystallises in slender needles, melts at 174°, dissolves with difficulty in cold, easily in hot water. The solution neutralised with ammonia gives, on addition of silver nitrate, a precipitate of *silver diphenylarsinate*, $(C^6H^5)^2AsO(OAg)$, soluble in ammonia and in nitric acid.

Arsenious Oxyphenide, C^6H^5AsO , obtained by the action of sodium carbonate on the dichlorophenide, crystallises from alcohol in crusts, smells like aniseed when cold, but when heated becomes very pungent, and attacks the mucous membranes of the nose. It is insoluble in water, melts at 120°, and is reconverted by aqueous hydrochloric acid into the dichlorophenide. When heated above its melting point, it is resolved into arsenious oxide and a high-boiling liquid, which solidifies on cooling and consists probably of triphenylarsine. Bromine acts violently on it, producing arsenic oxybromophenide and bromo-benzene:

Arsenic Oxychlorophenide, $C^6H^5AsOCl^2$, is formed by the action of water on arsenic tetrachlorophenide, but is more conveniently obtained by the action of chlorine on the oxyphenide, with which it combines very readily. It is a white crystalline body fuming in the air, and melting at about 100°. Water converts it into phenylarsenic acid; on heating it to 120°, it is resolved into arsenic oxychloride and chlorobenzene.

Arsenious Dibromophenide, $C^6H^5AsBr^2$, is obtained by heating the oxyphenide with concentrated hydrobromic acid, or by the action of arsenious bromide on mercurydiphenyl. It is a pale yellow liquid, having a faint smell, and boiling, not without decomposition, at 285°. It is not decomposed by water: bromine converts it into bromobenzene and arsenious bromide.

Diethylphenylarsine, $C^6H^5(C^2H^5)^2As$, is formed by adding a mixture of arsenious dichlorophenide and benzene or ether to zinc-ethyl. It is a refractive liquid having a faint but unpleasant smell, and boiling at 240°. It absorbs chlorine readily, forming crystalline arsenic dichlorodiethylphenide, $C^6H^5(C^2H^5)^2AsCl^2$. It also combines with ethyl iodide at 100°, forming the corresponding iodine-compound, $C^6H^5(C^2H^5)^2AsI^2$, which crystallises from water in thick needles.

Triphenylarsine or Arsenious Triphenide, $(C^6H^5)^3As$, is formed, together with $(C^6H^5)HgCl$ and $HgCl^2$, in the preparation of arsenious chlorodiphenide by heating arsenious dichlorophenide with mercuric phenide (p. 1552), and separates from the high-boiling residues left after the other products have passed over, in large rhombic plates. It is more easily prepared, however, by heating arsenious oxyphenide at 180°–200°: $3(C^6H^5)AsO = As^2O^3 + (C^6H^5)^3As$. It melts at 58°–59°, distils unchanged in an atmosphere of carbon dioxide at a temperature above 360°, dissolves easily in ether and benzene, sparingly in cold alcohol. It does not react with ethyl iodide at 100°.

Triphenylarsine Dichloride or Arsenic Dichlorotriphenide, $(C^6H^5)^3AsCl^2$, is obtained, by the action of dry chlorine on triphenylarsine, as a white powder, and crystallises from solution in benzene in colourless plates melting at 171°. At 280° it is resolved into monochlorobenzene and arsenious chlorodiphenide: $(C^6H^5)^3AsCl^2 = C^6H^5Cl + (C^6H^5)^2AsCl$. On treating it with boiling water or dilute ammonia, the chlorine-atoms are replaced by OH-groups, and triphenylarsine hydroxide, $As(C^6H^5)^3(OH)^3$, is formed, which crystallises from its aqueous solution in plates, from concentrated solutions in needles melting at 108°. Heated at 105°–110° it loses 1 mol. of H^2O , and is converted into triphenylarsine oxide, $As(C^6H^5)^3O$.

Triphenylarsine forms with *mercuric chloride* the compound $\text{As}(\text{C}^6\text{H}^5)^3.\text{HgCl}_2$, a crystalline body, soluble in alcohol, but almost insoluble in water. It is not decomposed by aqueous potash in the cold, but on boiling the mercury is reduced to the metallic state, and $\text{As}(\text{C}^6\text{H}^5)^3(\text{OH})_2$ is formed. By the action of alcoholic potash in the cold it is resolved into mercuric oxide and triphenylarsine, which dissolves in the alcohol.

Diphenyl-ethylarsine, $(\text{C}^6\text{H}^5)_2\text{As}(\text{C}^2\text{H}_5)$, obtained by the action of zinc-ethyl on arsenious chlorodiphenide, is a colourless liquid, having a fruity smell, and boiling at 305° . It unites directly with chlorine, forming the solid dichloride, $(\text{C}^6\text{H}^5)_2\text{As}(\text{C}^2\text{H}_5)\text{Cl}_2$, which crystallises from benzene in long colourless needles. It combines with 1 mol. ethyl iodide at 100° , forming diphenyl-diethylarsonium iodide, $\text{As}(\text{C}^6\text{H}^5)_2(\text{C}^2\text{H}_5)_2\text{I}$. The corresponding chloride is uncrystallisable, but on mixing its solution with platonic chloride, the *platino-chloride*, $[\text{As}(\text{C}^6\text{H}^5)_2(\text{C}^2\text{H}_5)_2]^+\text{PtCl}_6^-$, is obtained as a yellow precipitate, slightly soluble in water, amorphous at first, but quickly becoming crystalline, and forming when dried, gold-yellow crystalline laminae (La Coste a. Michaelis).

Monophenyltriethylarsonium Iodide, $(\text{C}^6\text{H}^5)\text{As}(\text{C}^2\text{H}_5)_3\text{I}$, is prepared by dropping zinc-ethyl diluted with 3 vols. benzene into a benzene-solution of the mixture of arsenious chlorodiphenide and diphenyl produced by the action of arsenious chloride on mercuric phenide. The benzene is then to be distilled off, and potash added, which precipitates monophenyl-diethylarsine and dissolves the diphenyl; and the arsine separated by filtration from the alkaline liquid, is heated in a sealed tube with ethyl iodide, whereby it is converted into phenyltriethylarsonium iodide, which may be freed from adhering diphenyl by recrystallisation from water.

This iodide melts at 112° – 113° , and is resolved at a higher temperature in a stream of carbon dioxide into ethyl iodide and phenyl-diethylarsine. Heated for two or three hours at 110° in a sealed tube with silver oxide and water, it yields a strongly alkaline solution of the corresponding hydroxide, which remains on evaporation in the form of a syrup, and is easily converted into the chloride by neutralisation with hydrochloric acid. The chloride is uncrystallisable, but yields a platinochloride, $[\text{As}(\text{C}^6\text{H}^5)(\text{C}^2\text{H}_5)_2]^+\text{PtCl}_6^-$, in the form of a precipitate consisting of golden-yellow crystalline laminae, which may be recrystallised from water (La Coste a. Michaelis, *Ber.* xi. 1884).

PHENYLAZODIETHYLAMIDOBENZOIC ACID,

$\text{C}^6\text{H}^5.\text{N}=\text{N}.\text{C}^6\text{H}^3(\text{COOH})\text{N}(\text{C}^2\text{H}_5)_2$. Syn. with AZOBENZENE-DIETHYLAMIDOCARBOXYLAMINE. (p. 215). Similarly with regard to the corresponding methyl-compound.

PHENYLAZOPHENYLENE-AZOPHENYLENE HYDROXIDE,

$\text{C}^6\text{H}^5.\text{N}_2.\text{C}^6\text{H}^4.\text{N}_2.\text{C}^6\text{H}^4(\text{OH})$, formed from potassium-phenol and diazobenzene, is resolved by nascent hydrogen into aniline, paradiamidobenzene, and paramidophenol:

(Caro a. Schraube, *Ber.* x. 2230).

PHENYL-BENZENE SULPHAZIDE, $\text{C}^6\text{H}^5.\text{N}_2.\text{H}_2.\text{SO}_2.\text{C}^6\text{H}_5$,

formed by the action of phenyl sulphochloride on phenyl-hydrazine in ethereal solution, crystallises in slender white needles, melting at 140° , slightly soluble in ether, benzene, and chloroform, easily in hot alcohol. By oxidation with mercuric oxide, it is converted into the diazo-compound, $\text{C}^6\text{H}^5.\text{N}_2.\text{SO}_2.\text{C}^6\text{H}_5$, which Koenigs obtained (*Ber.* x. 1531) by the action of benzenesulphonic acid on diazobenzene (E. Fischer, *Liebigs Annalen*, cxc. 132).

PHENYL-BENZOYL-THIOCARBAMIDE, $\text{C}^6\text{H}^5.\text{NH}.\text{CS}.\text{NH}.\text{CO}.\text{C}^6\text{H}_5$.

See CARBAMIDES (p. 400).

PHENYL-BUTYLS or **BUTYL-BENZENES**, $\text{C}^{10}\text{H}^{14} = \text{C}^6\text{H}_5.\text{C}^4\text{H}_9$. *Normal Phenyl-butyl*, $\text{C}^6\text{H}_5.(\text{CH}_2)_3.\text{CH}_3$, is obtained by the action of sodium on a mixture of benzyl chloride or bromide and normal propyl bromide:

The reaction may be carried out on the sand-bath without the use of any diluent (Radziszewski. *Ber.* ix. 260). According to Balbiano (*ibid.* x. 296), normal phenyl-butyl is also formed by the action of sodium on a mixture of bromobenzene and normal butyl bromide.

Normal phenyl-butyl is a colourless, strongly-refractive, fragrant liquid, having a density of 0.8622 at 16° , and boiling at 180° (cymene boils at 175° – 176°). Heated with bromine it yields a substitution-product, which when distilled gives off hydrogen bromide and yields two hydrocarbons, one of which is readily polymerised, while the other (normal phenyl-butylene) distils without alteration (Radziszewski):

Phenyl-isobutyl, $C^6H^5.CH^2.CH(CH^3)_2$.—Of this hydrocarbon there are two modifications, distinguished as α and β . The α -modification is obtained in small quantity by the action of sodium on an ethereal solution of the bromides cooled by a mixture of ice and salt. It is a transparent colourless liquid, having a fragrant but very pungent odour, a specific gravity of 0.8577 at 0°, and boiling at 159°–161° (J. Riess, *Ber.* iii. 779); sp. gr. 0.89 at 15°, boiling point 167.5° (Radziszewski, *ibid.* ix. 260). By oxidation with chromic acid mixture, it is converted into benzoic acid. Its *bromo-* and *nitro-*derivatives are uncrystallisable; the *monamido-*derivative does not form crystallisable salts. The *sulphonic acid* crystallises in fine, transparent and colourless, rhombic needles; its *barium salt* in fine white laminae easily soluble in water and dilute alcohol, sparingly in absolute alcohol and in ether (Riess).

β -*Phenyl-isobutyl* is formed, with brisk reaction, on treating an ethereal solution of phenyl-bromethyl, $C^6H^5.CHBr.CH^2$, with zinc-ethyl. It is a colourless liquid, having a specific gravity of 0.8726 at 16°, and boiling at 170°–172° (Radziszewski, *loc. cit.*)

PHENYL-BUTYLENE, $C^{10}H^{12} = C^4H^7(C^6H^5)$. The hydrocarbon of this composition (b. p. 176°–178°), which Aronheim obtained in 1872 by mixing benzyl chloride with allyl iodide in ethereal solution (vii. 945), is now regarded by him as constituted according to the formula $C^6H^5.CH^2.CH=CH.CH^3$, and supposed to be formed (on the hypothesis of molecular transposition) according to the equation :

Its *bromide*, $C^{10}H^{12}Br^2$, is converted by oxidation with nitric acid into the phenyl-monobromopropionic acid described by Glaser (vi. 470, 962); but the success of the reaction appears to depend on peculiar conditions (Aronheim).

Normal phenyl-butylene, $C^4H^7.C^6H^5$, produced as above mentioned, by distillation of normal bromophenyl-butyl, boils at 186°, and forms with bromine the compound $C^{10}H^{12}Br^2$, which crystallises in white needles having a silky lustre, and melting at 70°–71°. On distilling this dibromide with lime, a mass is obtained, which after purification exhibits the odour, crystalline form, and melting point of naphthalene (Radziszewski, *Ber.* ix. 260).

PHENYL-CACODYLIC ACID, syn. with DIPHENYL-ARSINIC ACID (p. 1553).

PHENYL-CACODYL-CHLORIDES (Di- and Tri-), syn. with ARSENIOS and ARSENIC CHLORODIPHENIDES respectively (p. 1552).

PHENYLCARBAMATE, PROPYLIC, $C^6H^5.NH.CO.OC^3H^7$, is formed by the action of aniline in ethereal solution on propyl chlorocarbonate :

It crystallises in slender needles, easily soluble in alcohol, less soluble in water, melting at 57°–59° (H. Römer, *Ber.* vi. 1101).

PHENYL-CARBAMIDE, $NH^2.CO.NH(C^6H^5)$. On the crystalline form and other physical characters of this compound, see CARBAMIDES (p. 390).

Diphenyl-carbamide.—The symmetrical modification of this compound, $(C^6H^5)_2HN.CO.NH(C^6H^5)$, or carbanilide, is formed by the action of water on dibenzhydroxamic acid. See HYDROXAMIC ETHERS (p. 1080).

PHENYL-CARBODIIMIDOTHIACTIC ACID, $C^6H^{10}N^2SO^2 = C^6H^5.NH.C \begin{smallmatrix} NH \\ S \end{smallmatrix} .CH^2.COOH$. This acid is formed by the action of monochloroacetic acid on aniline thiocyanate, or a mixture of a metallic thiocyanate with aniline. The best yield is obtained by heating 1 mol. aniline dissolved in twice its weight of absolute alcohol on the water-bath with 1 mol. ammonium thiocyanate and 1 mol. chloroacetic acid. A brisk reaction then sets in, attended with evolution of gas, and crystals separate, increasing in quantity as the liquid cools: they may be purified by repeated crystallisation from absolute alcohol and boiling with ether. The compound thus obtained dissolves easily in hot water, alcohol, and acetic acid, sparingly in ether, and crystallises in flattened prisms, apparently orthorhombic, which melt at 148°–152°. Its aqueous solution has an acid reaction, but no salt or ethyl-compound of it has yet been obtained. The solution is coloured deep yellow by iron salts, and decomposed by prolonged boiling with alkalis and acids. Boiled for several hours with sulphuric acid (20 per cent.) it yields phenyl-carbamide and thioglycollic acid :

The corresponding *paratolyl-compound*, $C^{10}H^{12}N^2SO^2$, obtained in like manner by heating paratoluidine with ammonium thiocyanate and chloracetic acid, melts at 176° – 182° , and is resolved by boiling with sulphuric acid into thioglycollic acid and tolyl-carbamide (Jäger, *J. pr. Chem.* [2], xvi. 1).

PHENYL-CHLORACETAMIDE, $C^6H^5.NH.C^2H^2ClO$. See ACETAMIDES (p. 5).

PHENYL-CRESYLAMINES, $C^6H^4(CH^3).NH(C^6H^5)$. See TOLUIDINES.

PHENYL-CROTONIC ACID, $C^{10}H^{10}O^2 = C^6H^5.C^3H^4.CO^2H$. See CINNAMIC ACID, HOMOLOGUES OF (p. 500).

PHENYL-CYMYL-CARBAMIDE, $C^6H^5.NH.CO.NH.C^{10}H^{13}$. See CARBAMIDES (p. 392).

PHENYL-DIBENZAMIDE, $(C^6H^5)N(C^7H^5O)^2$, analogous to Hofmann's phenyl-diacetamide (vii. 946), is formed by the action of benzoic acid on phenyl-thiocarbimide at 130° – 150° :

(Losanitsch, *Ber.* vi. 176).

PHENYL-DIETHYL-AZONIUM BROMIDE, $C^6H^5.N^2H^2(C^2H^5).C^2H^5Br$. See HYDRAZINES (p. 1051).

PHENYL-DIPHENYLENE SULPHIDE, $C^{16}H^{12}S = \begin{array}{c} C^6H^5 - C^6H^5 \\ | \quad \quad | \\ C^6H^4 \quad S \end{array}$. This

appears to be the principal constituent of the higher-boiling portion of the crude diphenylene sulphide which Graebe obtained by passing the vapour of phenyl sulphide, $(C^6H^5)_2S$, through a red-hot tube filled with iron nails (p. 669).

PHENYLENE-CARBAMIDE, $C^6H^4(NH.CO.NH^2)^2$. See CARBAMIDES (p. 392).

PHENYLENE-DIAMINES, $C^6H^4N^2 = NH^2.C^6H^4.NH^2$. *Diamidobenzenes*.—These bases are obtained by the action of reducing agents on the corresponding dinitrobenzenes and nitroamidobenzenes (nitranilines), and by dry distillation of the corresponding diamidobenzoic acids (iv. 480; vii. 946). The following are their melting and boiling points, those of the *meta*- and *para*-modifications according to Hofmann, those of the *ortho*-modification according to Griess:

	Ortho	Meta	Para*
Melting points	99°	63°	147°
Boiling points	252°	287°	267°

Ortho-phenylene-diamine is also produced. (a). From *ortho*-nitrobromobenzene (p. 176), by heating that compound with alcoholic ammonia, whereby it is converted into *orthonitraniline*, and reducing the latter with tin and hydrochloric acid (Zincke a. Sintonis, *Ber.* vi. 637). (b). From *metabromorthonitraniline*, $C^6H^4N^2.NO^2.H.H.Br.H$ (p. 199), by reduction with tin and hydrochloric acid, and treatment of the resulting bromodiamido-benzene with sodium-amalgam (Wurster, p. 201).

Orthophenylenediamine is converted, by the action of a dilute solution of potassium nitrite slightly acidulated with sulphuric acid, into *amidazo-phenylene*, $C^6H^4N^3$, which crystallises in white nacreous needles melting at 98.5° (Ladenburg, *Ber.* ix. 219).

Methenyl-o-phenylenediamine, $C^7H^6N^2 = C^6H^4 \begin{array}{c} NH \\ \diagup \quad \diagdown \\ N \end{array} CH$, is obtained by heating *o*-phenylene diamine with formic acid for four hours in a flask connected with an upright condenser. It is a white crystalline body which melts at 167° , and boils at 360° , dissolves in alcohol, water, and acids, and is precipitated from acid solutions on the addition of ammonia. The hydrochloride, sulphate, nitrate, and acetate are extremely soluble in water. The *hydrochloride* has the composition $C^7H^6N^2.HCl + H^2O$. The *platinochloride*, $(C^7H^6N^2.HCl)_2PtCl_4$, crystallises with 2 mols. water, which it gives off at 160° . The *aurochloride*, $C^7H^6N^2.HCl.AuCl_3$, separates from solution in dilute hydrochloric acid in feathery groups of yellow anhydrous crystals (E. Wundt, *Ber.* xi. 826).

* The base melting at 63° was formerly regarded as the *para*-, and the base melting at 147° as the *meta*-modification (vii. 947); but recent investigation having shown that ordinary dinitrobenzene, from which the former is derived, is a *meta*-compound (p. 175), it follows that the original designations of these two bases must be reversed.

Ethenyl-o-phenylene-diamine, $C^6H^4N^2=C^6H^4\langle\begin{smallmatrix} NH \\ N \end{smallmatrix}\rangle C^6H^3$, prepared by boiling orthophenylenediamine with glacial acetic acid, melts at 175° , and distils without decomposition (Ladenburg, *Ber.* viii. 677).

Propenyl-phenylenediamine, $C^9H^{10}N^2=C^6H^4\langle\begin{smallmatrix} NH \\ N \end{smallmatrix}\rangle C^3H^3$, prepared by heating propionic acid with orthophenylenediamine, melts at 168.5° – 169° , and boils above 360° . It is very soluble in alcohol, ether, and acids, and is deposited from its aqueous solution in thin plates. All its salts, except the picrate, are very soluble in cold water. The picrate, $C^9H^{10}O^2.C^6H^4(NO^2)_3OH$, is deposited from a hot saturated aqueous solution, on cooling, in yellow needles (Wundt).

Anhydrobenzoyl-phenylenediamine, $C^{13}H^{10}N^2=C^6H^4\langle\begin{smallmatrix} NH \\ N \end{smallmatrix}\rangle C.C^6H^3$, is formed by the action of hydrogen on orthonitrobenzanilide:

Fuming nitric acid converts it into a mononitro-derivative, which is but feebly basic, melts at 196° , dissolves easily in hot alcohol and glacial acetic acid, and crystallises from the alcoholic solution in granular groups of needles. With tin and hydrochloric acid, it yields the bi-acid base, $C^{13}H^{12}N^3=NH^2.C^6H^3\langle\begin{smallmatrix} NH \\ N \end{smallmatrix}\rangle C.C^6H^3$, which separates from a saturated alcoholic solution in dense white granules, melting at 245° (Hübner a. Stöver, *Ber.* vii. 1814).

Amylanhydrobenzoyl-phenylenediamine, $C^{18}H^{20}N^2=C^6H^4\langle\begin{smallmatrix} N.C^5H^{11} \\ N \end{smallmatrix}\rangle C.C^6H^3$, is obtained as a hydriodide by heating the preceding compound with excess of amyl iodide at 180° (another compound crystallising in white laminae, insoluble even in hot water, being formed at the same time). The free base crystallises from alcohol in microscopic rhombic plates, melting at 270° . Its salts are crystallisable (Sennewald, *Ber.* ix. 775).

Ethylanhydrobenzoyl-phenylenediamine, $C^8H^4\langle\begin{smallmatrix} N.C^2H^5 \\ N \end{smallmatrix}\rangle C.C^6H^3$, is formed in like manner together with another compound. It is moderately soluble in water; its hydrochloride and basic sulphate crystallise in needles (Sennewald).

Metaphenylenediamine is formed by reduction of ordinary dinitrobenzene, and by distillation of either of the three metadiamidobenzoic acids (p. 273). It occurs also as a bye-product in the manufacture of aniline (p. 210). Boiled for five or six hours with oxalic acid and alcohol, it is converted into phenylene-oxamic acid, $NH^2.C^6H^4.NH.CO.COOH$ (p. 1457).

Chloro-m-phenylenediamine, $C^6NH^2.H.NH^2.Cl.H^2$, melting at 86° , is formed by the action of tin and hydrochloric acid on the corresponding dinitrochlorobenzene (m. p. 50°), p. 183 (Beilstein a. Kurbatow, *Ber.* xi. 1939).

Nitrochloro-m-phenylenediamine, $C^6NH^2.NO^2.NH^2.H.Cl.H$, is formed by the action of alcoholic ammonia on nitrochlorobenzene, $C^6.Cl.NO^2.Cl.H.Cl.H$ (m. p. 68°), (Beilstein a. Kurbatow, *Ber.* xi. 1978).

Tetramethyl-m-phenylenediamine, $(CH^3)^2N.C^6H^4.N(CH^3)^2$, is formed by the action of methyl alcohol and hydrochloric acid on metaphenylenediamine, and separates from the resulting solution on addition of caustic soda, as an uncrystallisable oil having a peculiar odour and boiling at 256° (corr.). Its hydrochloride forms hygroscopic crystals. The free base unites with methyl iodide to form the compound $C^6H^4[N(CH^3)^2]^2.CH^3I + H^2O$, which dissolves freely in water, but is less soluble in alcohol; it melts at 192° with decomposition into its constituents. Tetramethylmetaphenylenediamine forms a liquid dibromo-compound, and is converted by the action of nitric acid on its acetic acid solution into the nitrosamine of trinitrotrimethylmetaphenylenediamine, $C^6H(NO^2)^3N^2(CH^3)^3NO$, a yellow crystalline body, which dissolves in alcohol and in benzene, and melts at 132° (Wurster a. Morley, *Ber.* xii. 1814).

Paraphenylenediamine is formed: α . By the action of dry hydrogen chloride at 180° on paramidodimethylaniline:

β . As hydrochloride, together with the tin salt of diamidodiphenylcarbamide,

$\text{CO}(\text{NH} \cdot \text{C}_6\text{H}_4 \cdot \text{NH})^2 \cdot 2\text{HCl} \cdot \text{SnCl}_2$, by the action of tin and hydrochloric acid on the nitro-product (chiefly dinitrocarbanilide), obtained by the action of nitric acid on carbanilide. The hydrochloride of the phenylene-diamine is more soluble than the tin salt just mentioned (H. Schiff, *Liebig's Annalen*, clxxxix, 157). γ . By reduction of nitraniline from nitracetanilide with tin and hydrochloric acid (Biedermann a. Ledoux, p. 210).

Paraphenylene-diamine melts, according to Hofmann, at 140° , but according to Biedermann a. Ledoux, the perfectly pure base obtained by dry distillation of the hydrochloride with sodium carbonate, melts at 147° (p. 210).

Reaction with Calcium Hypochlorite.—When a solution of paraphenylenediamine hydrochloride slightly acidulated with hydrochloric acid is quickly stirred into an excess of a solution of bleaching powder (1 mol. of the hydrochloride to 3 mols. chlorine), a yellowish-white precipitate separates out, having the composition of dichlorodiimidobenzene, $\text{C}_6\text{H}_4\text{Cl}_2\text{N}_2 = \text{C}_6\text{H}_2(\text{Cl}_2)(\text{NH})^2$. This compound is soluble in alcohol, ether, benzene, and glacial acetic acid, sparingly in hot water. When slowly heated in an oil-bath it detonates at 124° , but if rapidly heated it may be melted without decomposition. By the action of reducing agents it is reconverted into phenylenediamine hydrochloride. Hydrochloric acid of sp. gr. 1.2 converts it into a substance which has the composition $\text{C}_6\text{H}_4\text{Cl}_4\text{N}_2$ or $\text{C}_6\text{H}_2\text{Cl}_4\text{N}_2$; crystallises in pale-red needles; is insoluble in water and in cold hydrochloric acid, but dissolves freely in alcohol, benzene, ether, and glacial acetic acid; and is converted by nitric acid into tetrachloroquinone (chloranil), which is likewise produced by passing chlorine into a solution of paraphenylene-diamine in glacial acetic acid.

Hydrobromic acid appears to act on dichlorodiimidobenzene similarly to hydrochloric acid.

Dichlorodiimidobenzene, dissolved in glacial acetic acid and treated with bromine and water, is converted into dichlorodibromoquinone, $\text{C}_6\text{Cl}_2\text{Br}_2\text{O}_2$, which separates in rhombic plates:

(A. Krause, *Ber.* xii. 47).

Dinitro-p-phenylenediamines, $\text{C}_6\text{H}_2(\text{NO}_2)^2(\text{NH})^2$.—Biedermann a. Ledoux obtained a body of this composition by heating diaceto-p-phenylenediamine with alcoholic ammonia: it crystallises in red needles melting at 294° (p. 210). Another modification (distinguished as β), first observed by Clemm (*J. pr. Chem.* [2], i. 145), is produced by heating [1 : 2 : 4 : 6] trinitraniline (picramide, p. 198) with alcoholic ammonium sulphide at 130° . It crystallises in long slender red needles melting at 210° . It unites with hydrochloric acid, forming the compound $\text{C}_6\text{H}_2\text{N}^4\text{O} \cdot \text{HCl}$, which however is decomposed by water. By the action of acetyl chloride it is converted into the *diacetyl-compound*, $\text{C}_6\text{H}_4(\text{C}^2\text{H}_3\text{O})^2\text{N}^4\text{O}_4$, which crystallises in slender bright yellow needles melting at 245° (Norton a. Elliott, *Ber.* xi. 327).

DIMETHYLPARAPHENYLENEDIAMINE, $\text{C}_6\text{H}^4\text{N}_2 = \text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{N}(\text{CH}_3)^2$ [$\text{NH}_2 : \text{N}(\text{CH}_3)^2 = 1 : 4$]. This base is prepared by the action of tin and hydrochloric acid on nitrosodimethylaniline (p. 1309), (Schraube, *Ber.* viii. 616; Wurster, *ibid.* xii. 522), or on tetramethyldiamidazoxybenzene (Schraube); also by similar reduction of nitrodimethylaniline (A. Weber, *ibid.* x. 760). To obtain the pure base, Wurster gradually adds the tin salt, which is the immediate product of the reaction, to an excess of warm soda-ley, whereupon the base separates as a brown oil which may be dried over calcium chloride and distilled, the distillate on cooling depositing the base in crystals, which may be pressed between paper and dissolved in a small quantity of warm benzene. On cautiously adding warm petroleum ether to this solution, an oil separates out containing all the impurities, and on subsequently adding cold petroleum-ether, the pure dimethyl-phenylenediamine separates in long white needles resembling asbestos.

Dimethylparaphenylenediamine melts at 41° and boils at 257° . When pure it does not change on exposure to the air, but the impure base turns red or violet. It dissolves freely in water, alcohol, benzene, and chloroform, but is less soluble in ether and in light petroleum.

When a 10 per cent. solution of bromine in glacial acetic acid is added to a somewhat more dilute solution of dimethylparaphenylenediamine in the same solvent, a green substance is precipitated, which has the composition $\text{C}_6\text{H}^4\text{N}_2\text{Br}$. The precipitate must be thoroughly washed with glacial acetic acid and with anhydrous ether, and may be rapidly recrystallised from hot alcohol, from which it is deposited in green scales, having a metallic lustre and melting at 146° . The aqueous and alcoholic solutions of this substance exhibit a deep red colour, which is destroyed by exposure to the air or by the addition of sulphurous acid (Wurster a. Sendtner, *Ber.* xii. 1803).

Acetyl-dimethyl-paraphenylenediamine, $(\text{CH}^3)^2\text{N}.\text{C}^6\text{H}^4.\text{NH}(\text{C}^2\text{H}^3\text{O})$, prepared by treating the base with acetic anhydride at ordinary temperatures, or boiling it with glacial acetic acid, crystallises in white needles or plates, melts at 130° , boils with slight decomposition at 355° , and dissolves in benzene, alcohol, and hot water (Wurster).

Dimethylparaphenylenediamine-oxamic acid,

The ethylic ether of this acid is obtained, together with diparamido-dimethylphenyl-oxamide, by heating 1 mol. dimethylparaphenylenediamine with rather more than 1 mol. ethyl oxalate, treating the product with ether to remove the excess of ethyl oxalate, and digesting the residue in warm alcohol, which dissolves out the oxamic ether, and leaves the phenyl-oxamide.

The acid, $\text{C}^1\text{H}^{12}\text{N}^2\text{O}^3$, crystallises in grey needles or plates which dissolve freely in boiling water, but only sparingly in boiling alcohol, and melt with decomposition at 192° . The *ethylic ether* crystallises in yellow needles or plates, melts at 117° , dissolves in hot water and hot alcohol, also in acids, forming crystalline salts. On adding alcoholic ammonia to an alcoholic solution of this ether, *monoparamido-dimethylphenyl-oxamide*, $(\text{CH}^3)^2\text{N}.\text{C}^6\text{H}^4.\text{NH}.\text{CO}.\text{CONH}^2$, crystallises out. This substance melts at 257° – 259° , dissolves in hot benzene, and unites with acids forming crystalline salts soluble in hot water (Sendtner, *Ber.* xii. 530).

Diparamidodimethylphenyl-oxamide, $[\text{CONH}.\text{C}^6\text{H}^4.\text{N}(\text{CH}^3)^2]^2$, forms a yellow crystalline powder which does not melt when heated to 270° . It is soluble in boiling benzene and chloroform. Its salts dissolve readily in water.

When a solution of ethylic dimethylparaphenylenediamine-oxamate in dilute hydrochloric acid is treated with *sodium nitrite*, a yellowish-red nitro-product, $(\text{CH}^3)^2\text{N}.\text{C}^6\text{H}^4.\text{N}(\text{NO}^2).\text{NH}.\text{CO}.\text{COOC}^2\text{H}^5$, collects on the surface. This substance, when recrystallised from acetic acid, forms red needles melting at 152° , freely soluble in benzene, less soluble in ether and in boiling water. On reduction with tin and hydrochloric acid, it yields oxalic acid and dimethyltriamidobenzene, $\text{C}^6\text{H}_3.\text{N}(\text{CH}^3)^2.\text{H}.\text{NH}^2.\text{NH}^2.\text{H}^2$, which crystallises in colourless prisms melting at 42° – 44° , boils at 298° , dissolves in water and in petroleum-ether, and forms an acetyl-derivative crystallising from water in transparent prisms or plates which contain 1 mol. H^2O , and begin to melt at 82° , resolidify at 120° , and then melt at 153° . From benzene anhydrous crystals are obtained which melt at 153° (Wurster a. Sendtner, *Ber.* xii. 1804).

Dimethylparaphenylenediamine-carbamides. — The dicarbamide, $\text{CO}[\text{NH}.\text{C}^6\text{H}^4.\text{N}(\text{CH}^3)^2]^2$, is formed by heating 1 pt. of urea with 4 pts. of dimethylparaphenylenediamine at 130° – 150° for three hours. The crude product is washed with alcohol, and purified by conversion into the sulphate. The dicarbamide crystallises in long needles soluble in boiling acetone. It melts with decomposition at 262° . The *sulphate*, $\text{C}^{12}\text{H}^{22}\text{N}^4\text{O}.\text{H}^2\text{SO}^4$, is sparingly soluble in water; the *hydrochloride*, $\text{C}^{12}\text{H}^{22}\text{N}^4\text{O}.\text{HCl}$, is very soluble.

The monocarbamide, $\text{NH}^2.\text{CO}.\text{NH}.\text{C}^6\text{H}^4.\text{N}(\text{CH}^3)^2$, obtained by mixing solutions of potassium cyanate and dimethylparaphenylenediamine, forms large white needle-shaped crystals (melting at 179°), soluble in boiling water. The sulphate and hydrochloride are easily soluble (F. Binder, *Ber.* xii. 535).

The thiodicarbamide, $\text{CS}[\text{NH}.\text{C}^6\text{H}^4.\text{N}(\text{CH}^3)^2]^2$, obtained by boiling the diamine with carbon bisulphide, is a white crystalline powder, melting at 186.5° , soluble in hot benzene and hot alcohol. The *hydrochloride*, $\text{C}^{12}\text{H}^{22}\text{N}^4\text{S}.\text{HCl}$, is a white powder soluble in alcohol. The *acetyl-derivative*, obtained by heating the thiocarbamide with acetic anhydride on the water-bath and then adding alcohol, crystallises on cooling in white nacreous laminae melting at 71° (A. Baur, *Ber.* xii. 533).

Sulphuretted Colouring Matters derived from Dimethylparaphenylenediamine (A. Koch, *Ber.* xii. 592–595). — The blue colouring matter formed by treating dimethylparaphenylenediamine first with sulphuretted hydrogen and then with ferric chloride (p. 211) may be precipitated by zinc chloride, and purified by dissolving it in water and reprecipitating with zinc chloride. When hydrochloric acid is added to an aqueous solution of this blue compound, dark blue plates having a strong metallic lustre slowly separate out. These crystals, after drying at 110° , have the composition $\text{C}^{16}\text{H}^{18}\text{N}^4\text{S}.\text{HCl}$, with $1\frac{1}{2}$ to 4 mol. H^2O . This compound is soluble in water and alcohol; it is bleached by reducing agents, and precipitated by potassium dichromate, zinc chloride, and mercuric chloride. When sulphuretted hydrogen is passed through its ammoniacal solution, a yellow precipitate is formed, which turns green on exposure to the air.

On evaporating the liquid from which the original blue colouring matter has been precipitated by zinc chloride, bronze-coloured needles separate out, having the composition $C^{16}H^{16}N^4S^4.2HCl.ZnCl^2 + 2H^2O$. This substance is soluble in water and alcohol. It is precipitated by mercuric chloride, and bleached by alkalis.

The formation of the original blue compound is represented by the equation $2C^8H^{12}N^2 + H^2S + O^4 = C^{16}H^{16}N^4S^4 + 4H^2O$, and that of the bronze-compound by the equation $2C^8H^{12}N^2 + 4H^2S + O^7 = C^{16}H^{16}N^4S^4 + 7H^2O$ (A. Koch, *Ber.* xii. 592).

TETRAMETHYLPARAPHENYLENE-DIAMINE, $(CH^3)^2N.C^6H^4.N(CH^3)^2$, which Hofmann obtained, together with other products, by the action of methyl iodide on the dimethylated base (iv. 481) is also produced by heating a mixture of dimethylparaphenylene-diamine with methyl alcohol and hydrochloric acid in sealed tubes, first at 180° , afterwards at 200° . On adding soda to the crude product, an oil separates out, which, when purified by distillation and crystallisation from dilute alcohol, deposits tetramethylparaphenylene-diamine in white plates. This base melts at 51° , and boils without decomposition at 260° ; dissolves in hot water and the other ordinary solvents. Oxidising agents colour its solution deep blue. The hydrochloride, sulphate, and platinochloride dissolve readily in water (Wurster, *Ber.* xii. 526).

By the action of *bromine* on a solution of tetramethylparaphenylenediamine in acetic acid, an unstable blue compound, $C^{10}H^{14}N^2$, is formed, which may be obtained in the form of a microscopic crystalline precipitate by adding ether to the mixture; its solution in water and in alcohol has a deep blue colour, which is destroyed by sulphurous acid. The substance can also be obtained as ferrocyanide, by adding potassium ferricyanide to tetramethylphenylenediamine sulphate, $C^{10}H^{16}N^2 + H^6Fe^3Cy^{12} = C^{10}H^{14}N^2.H^4FeCy^6 + H^4FeCy^6$. The ferrocyanide forms blue needle-shaped crystals, having a metallic lustre.

By the action of sodium nitrite on tetramethylparaphenylenediamine, *trimethylphenylenediaminenitrosamine* is obtained, and a blue colouring matter is produced, which, however, has not been isolated. The nitrosamine crystallises in greenish-yellow plates (m. p. 98°), soluble in benzene, chloroform, ether, and hot water. On reduction with tin and hydrochloric acid, it yields trimethylparaphenylenediamine, $N(CH^3)^2.C^6H^4.NH(CH^3)$, an oily liquid (b. p. 265°), sparingly soluble in water. The acetyl-derivative crystallises in hydrated prisms melting at 78° . The anhydrous crystals melt at 95° .

When an excess of sodium nitrite is added to an acid solution of tetramethylparaphenylenediamine, *nitrotrimethylparaphenylenediamine-nitrosamine*, $N(CH^3)^2.C^6H^3[N(CH^3.NO)(NO^2)]$, separates out in orange-coloured needles melting at 87° , soluble in benzene and chloroform, but insoluble in water. On reduction with tin and hydrochloric acid, this compound yields *trimethyltriamidobenzene*, $N(CH^3)^2.C^6H^3[NH(CH^3)].NH^2$, which crystallises in white needles, melts at 90° , boils at 294° , and dissolves in water. Its diacetyl-derivative crystallises in white plates melting at 184° (Wurster a. Schobig, *Ber.* xii. 1807).

The formation of the red and blue colouring matters obtained by the action of oxidising agents on di- and tetramethylparaphenylenediamine respectively may be represented, according to Wurster (*Ber.* xii. 1803) by the following equations:

DISUCCINYLPARAPHENYLENEDIAMINE, $C^{14}H^{12}N^2O^4 = C^6H^4(N.C^2O^2.C^2H^4)^2$ (R. Biedermann, *Ber.* ix. 1668). This compound is obtained by heating a mixture of paraphenylenediamine and succinic acid at 200° for about half an hour:

On boiling the fused mass with water, the succinyl-derivative remains as a substance slightly soluble in hot glacial acetic acid, and separating from this solution on cooling in small shining crystals. The best solvent for recrystallising it is fuming nitric acid.

Disuccinylphenylenediamine melts at a temperature above the range of the mercurial thermometer, and may be sublimed from a red-hot platinum crucible in white shining needles. It does not unite either with bases or with acids. By boiling with potash-ley, it is resolved into phenylenediamine and succinic acid. By a mixture

of strong nitric acid and strong sulphuric acid or phosphoric anhydride, it is converted into a yellow nitro-compound.

An action similar to that of succinic acid is exerted upon paraphenylenediamine by succinic anhydride and succinyl chloride. Phthalic anhydride and hydroxy-acids, salicylic acid, for example, appear also to act in like manner on para- and meta-phenylenediamine.

PHENYLENE-KETONIC COMPOUNDS (Gabriel a. Michael, *Ber.* x. 1559, 2199). **Ethineorthophenylenediketone** or **Ethinediphthalyl**,

is formed by heating a mixture of phthalic anhydride and succinic acid with sodium acetate, the mixture being kept in a state of fusion as long as carbon dioxide continues to escape:

On dissolving the residue in nitrobenzene, the diketone crystallises out in yellow needles melting at a temperature above 300° . When a solution of this compound in acetic acid is heated with bromine at 100° in a sealed tube, a molecule of water is taken up, and two of the hydrogen-atoms are replaced by bromine, producing the compound:

which is decomposed by fusion with alkalis.

Phenylene-ethyleneketone - carboxylic, or **Ethylene-benzoylcarboxylic acid**,

(Gabriel a. Michael, *Ber.* x. 2199). This acid is formed by the action of boiling dilute potash-ley on ethine-diphthalyl, $\text{C}^8\text{H}^{10}\text{O}^4$, and is precipitated from the resulting solution by hydrochloric acid:

When fused, it gives off 1 mol. water and yields an anhydride which melts at 228° – 230° . Heated to 163° in a sealed tube with hydrogen iodide and red phosphorus, it exchanges O^2 for 2H^2 , and is converted into ethylene-benzoylcarboxylic acid:

melting at 196° – 198° . Bromine converts it into dibromethylenebenzoyl-carboxylic acid, $\text{C}^8\text{H}^{12}\text{Br}^2\text{O}^6$, which crystallises in long white prisms and melts at 270° – 272° . By sodium-amalgam, ethylenebenzoylcarboxylic acid is converted into the anhydride of ethylenebenzoylcarboxylic acid:

which forms long needles having a silky lustre and melting at 208° – 210° .

PHENYLENE-OXAMIC ACID, $\text{NH}^2 \cdot \text{C}^6\text{H}^4 \cdot \text{NH} \cdot \text{C}^2\text{O}^2 \cdot \text{OH}$ [1 : 3]. See OXAMIC ACIDS (p. 1457).

PHENYL-ETHER, SULPHOPHENYLIC. See THIOPHENYLIC ETHERS.

PHENYL-ETHYL ALCOHOLS AND ETHERS. *Primary Phenyl-ethyl Alcohol*, $\text{C}^6\text{H}^5 \cdot \text{CH}^2 \cdot \text{CH}^2 \cdot \text{OH}$, is formed by the action of sodium-amalgam (2 p. c. Na) on an alcoholic solution of phenylacetaldehyde, $\text{C}^6\text{H}^5 \cdot \text{CH}^2 \cdot \text{COH}$ (prepared by distilling a mixture of the calcium salts of phenylacetic and formic acids) the liquid being neutralised from time to time with sulphuric acid. It is a colourless liquid having a sp. gr. of 1.0337 at 21° , boiling without decomposition at 212° , and oxidised by chromic acid mixture to phenylacetic acid. The acetate, $\text{C}^6\text{H}^5 \cdot \text{CH}^2 \cdot \text{CH}^2 \cdot \text{O}(\text{C}^2\text{H}^3\text{O})$, obtained by heating the alcohol with acetic anhydride at 150° , is a colourless liquid having a strong but agreeable odour, a sp. gr. of 1.0286, and boiling without decomposition at 224° . Treated with aqueous potash and a

small quantity of alcohol, it yields potassium acetate and phenylethyl alcohol (Radziszewski, *Ber.* ix. 372).

Secondary Phenyl-ethyl Alcohol or *Acetophenonic Alcohol*, $C^6H^5.CHOH.CH^3$ (b. p. 202° – 203°), formed by the action of sodium-amalgam on a dilute alcoholic solution of phenyl-methyl ketone, has been already described (vii. 936).

Radziszewski (*Ber.* vii. 140) prepares it by dissolving the corresponding bromide (*infra*) in twice its volume of glacial acetic acid, and mixing it with twice the quantity of dry silver acetate. The mixture becomes hot, and yields—together with silver bromide and a small quantity of cinnamene—secondary phenyl-ethyl acetate, which may be dissolved out from the silver bromide by prolonged washing with glacial acetic acid. This ether, warmed with aqueous soda-ley containing a little alcohol, yields secondary phenyl-ethyl alcohol boiling constantly at 202° – 204° , and converted by oxidation into phenyl-methyl ketone.

Secondary Phenyl-ethyl Bromide or *Bromethyl-benzene*, $C^6H^5.CHBr.CH^3$ (v. 1057; vi. 292), is obtained: 1. By the action of bromine on ethylbenzene at 140° , and may be purified by washing, drying, and cooling in a freezing mixture, whereupon the styryl bromide, $C^6H^5.CHBr.CH^2Br$, formed at the same time, crystallises out (Radziszewski, *Ber.* vi. 492; comp. Berthelot, *Compt. rend.* lxvii. 328). 2. By passing hydrogen bromide into cooled secondary phenyl-ethyl alcohol, to which a small quantity of calcium chloride is added to take up water formed at the same time. The product, freed from excess of hydrobromic acid by shaking with water, is a brown-yellow liquid which fumes and gradually becomes darker on exposure to the air, and cannot be distilled without considerable decomposition (Engler a. Bethge, *Ber.* vii. 1125). The *acetate*, obtained from it by means of silver acetate, is converted by saponification into secondary phenyl-ethyl alcohol. The *bromide*, heated with an alcoholic solution of potassium cyanide, yields cinnamene, metacinnamene, and—together with other products not yet examined—a small quantity of a nitril convertible by caustic potash into a liquid acid (Radziszewski, *ibid.* 140). A mixture of phenylethyl bromide and ethylbenzene heated with zinc-dust yields the hydrocarbon $C^{10}H^{18} = \begin{matrix} C^6H^5 \\ | \\ CH^3 \end{matrix} > CH.C^6H^4.CH^2.CH^3$, which when oxidised yields, as chief product, parabenzoylbenzoic acid, together with terephthalic, benzoic, and carbonic acids, and a ketonic compound, $C^6H^5.CO.CH^2.C^6H^4.C^2H^5$ or $C^6H^5.CH^2.CO.C^6H^4.C^2H^5$, which crystallises from ether in rhombic prisms melting at 120° , and smelling like fungi and bergamot oil (Radziszewski, *Ber.* vi. 494, 811; vii. 142).

PHENYLETHYLSULPHONIC ACID, $C^6H^5.SO^3H$. Cinnamene, C^8H^8 , treated with acid sodium sulphite, yields crystals consisting of the sodium salt of a phenethylsulphonic acid; but whether the acid thus produced contains primary or secondary phenyl-ethyl has not yet been ascertained (W. Miller, *N. Rep. Pharm.* xxiv. 1).

PHENYL-FURFUZIDE, $C^6H^5.N^2H.C^3H^4O$. See HYDRAZINES (p. 1054).

PHENYL-GLYCERYL ALCOHOL or **PHENYL-GLYCEROL**, $C^6H^{12}O^3 = C^6H^4(C^6H^5)(OH)^3$, and **ETHERS** (Grimaux, *Bull. Soc. Chim.* [2], xx. 48). When bromine (1 mol.) dissolved in chloroform is added by drops, so as to avoid heating, to a chloroform solution of cinnyl alcohol, styryl alcohol, or styrene, $C^6H^9.OH$ (i. 992; v. 447), and the liquid is then left to evaporate, phenyl-glyceryl-dibromhydrin, styceryl-bromhydrin, or styrene dibromide, $C^6H^2Br^2.OH$ or $C^6H^5.CHBr.CHBr.CH^2OH$, separates out as a hard crystalline mass, which, when purified by pressure and slow crystallisation from ether, forms broad white shining laminae or groups of slender needles. It melts at 74° , is insoluble in water, but dissolves readily in alcohol and ether.

Phenyl-glycerol, Phenoglycerin, or Stycerin, $C^6H^5.CHOH.CHOH.CH^2OH$, is formed, together with small quantities of other products, by boiling this dibromhydrin with water for twenty-four hours. The formation of the secondary products may be avoided by conducting the saponification in presence of silver acetate, so as to remove hydrobromic acid as fast as it is formed, then filtering, treating the filtrate with hydrogen sulphide, again filtering, concentrating the filtrate, and finally leaving it to evaporate in a vacuum. The phenyl-glycerol thus obtained is a gummy, light-yellow, bitter substance, easily soluble in water and alcohol, nearly insoluble in ether. It does not appear to alter in contact with the air, but its solution becomes brownish during evaporation. It decomposes when distilled. By distillation with formic acid, it yields carbon dioxide, water, and a thick oil (perhaps diphenyl-diallyl), boiling at about 300° .

Phenyl - glycerylacetodibromohydrin

or

Styceryl - acetodibromohydrin,

$C^6H^5.CHBBr.CHBBr.CH^2(OC^2H^3O)$, obtained by heating styrceryl dibromhydrin with acetyl chloride, evaporating the product over the water-bath, and crystallising it from ether, forms oblique prisms having a pleasant odour of flowers, soluble in alcohol and ether, melting at 85° – 86° . Heated for twenty-four hours at 100° with silver acetate and glacial acetic acid, it yields, together with silver bromide, an amorphous body soluble in ether, which appears to be the corresponding *triacetin*.

Phenyl-glyceryl-tribromhydrin or *Styrceryl-tribromhydrin*, $C^6H^5.CHBBr.CHBBr.CH^2Br$, is formed on repeatedly distilling the dibromhydrin with strong hydrobromic acid, and passes over into the receiver; also on adding bromine to a solution of styryl bromide in chloroform. It crystallises in small shining needles, melts at 124° , dissolves sparingly in alcohol and ether, more readily in chloroform.

The *chlorodibromhydrin*, $C^6H^5.CHBBr.CHBBr.CH^2Cl$, is obtained by adding bromine to styryl chloride, $C^6H^5.CH=CH.CH^2Cl$ (v. 447), and crystallises from ether in translucent laminæ, moderately soluble in chloroform, sparingly in cold ether, and melting at 96.5° .

PHENYL-GLYCOCINE, $C^6H^5.NO^2 = \begin{matrix} CH^2.NH(C^6H^5) \\ | \\ COOH \end{matrix}$. This compound, which

Michaelson a. Lippmann obtained by the action of aniline on bromacetic acid (vi. 644), is also produced from aniline chloracetate by prolonged heating with water and aniline (Schwabel, *Ber. x.* 2045), and apparently when phenylamidacetonitril, $NC.CH^2.NH(C^6H^5)$, is heated with strong potash-ley (Engler, *Ber. vi.* 1004).

Phenyl-glycoccine melts at 126° – 127° , and when heated to 140° – 150° , gives off 1 mol. water, and is converted into the indifferent compound $\begin{matrix} CH^2 \\ | \\ CO \end{matrix} > N(C^6H^5)$ (P. J.

Meyer, *Ber. viii.* 1152).

Phenyl-glycoccine dissolves recently precipitated cupric hydrate with deep green colour; the oxides of silver and mercury are not dissolved by it. With *mercuric chloride* and *stannous chloride* it forms white precipitates (Schwabel, *Ber. x.* 2045). Heated with excess of *aniline*, it yields needle-shaped diphenyloxethylene-carbamide, melting at 110° – 111° , together with small quantities of ethylic phenylamidoglycollate, $CH^2.NH(C^6H^5)—COOC^2H^5$, melting at 57° – 58° . Methylic phenylamidoglycollate, $CH^2.NH(C^6H^5)—COOCH^3$, formed in like manner, crystallises in needles or prisms melting at 48° (Meyer).

Phenylamidoglycollamide, $CH^2.NH(C^6H^5).CONH^2$, melting at 133° , is formed by heating monochloracetamide and aniline in molecular proportions, till the former melts. *Phenylamidoglycollanilide*, $CH^2.NH(C^6H^5).CONH(C^6H^5)$, produced in like manner from monochloracetanilide and aniline, melts at 110° – 111° ; *phenylamidoglycollotoluidide* crystallises in needles melting at 171° – 172° (Meyer).

Phenyl-glycoccine, heated with *urea* to 155° , is converted into phenyl-hydantoin (p. 1046); and the same conversion is effected by heating it to 40° in aqueous solution with potassium cyanate and ammonium sulphate (Schwabel).

PHENYL-GLYCOL, $C^6H^5.O^2 = C^6H^5(OH)^2 = C^6H^5.CHOH.CH^2OH$. *Phenyl-ethylene Alcohol*, *Styrolene Alcohol*, *Cinnamene Alcohol*.—This diatomic alcohol is prepared from styrolene dibromide, $C^6H^5.CHBBr.CH^2Br$, by means of silver nitrate or potassium acetate in acetic acid solution, or with potassium acetate or silver benzoate in alcoholic solution, and subsequent saponification of the corresponding ethers. It is very soluble in water, alcohol, ether, benzene, and glacial acetic acid, and is best purified by crystallisation from a mixture of benzene and ligroin, in which latter it is but sparingly soluble. It melts at 67° – 68° , and can be sublimed. The *diacetate*, $C^6H^5.CH(OC^2H^3O).CH^2(OC^2H^3O)$, prepared from the glycol by the action of acetic chloride or anhydride, is an oily liquid having a very faint aromatic odour; the *dibenzoate*, prepared in like manner, crystallises in slender, white, scentless needles, melting at 96° – 97° (Wachendorff a. Zincke, *Ber. x.* 1004).

PRODUCTS OF OXIDATION OF PHENYL-GLYCOL (Hunäus a. Zincke, *Ber. x.* 1486). By *chromic acid* and *potassium permanganate*, phenyl-glycol is converted into benzaldehyde, together with formic or carbonic acid; by nitric acid, on the other hand, first into benzoyl-carbinol and then into benzoyl-formic acid. With nitric acid of sp. gr. 1.35–1.38, the reaction takes place at ordinary temperatures, and on its completion, which for the preparation of benzoyl-carbinol takes place in a comparatively short time, the crude product is purified by treatment with sodium carbonate and the carbinol is extracted with ether.

(1). *Benzoyl-carbinol*, $C^6H^5.CO.CH^2OH$, crystallises from alcohol or ether in six-sided plates, from water or dilute alcohol in shining hydrated laminæ, from ligroin in prisms. The hydrated crystals melt between 73° and 74° ; the anhydrous

crystals between 85.5° and 86° ; they are partly decomposed by volatilisation, and form crystalline compounds with alkaline bisulphites. On ammoniacal silver solution and alkaline copper solution, benzoyl carbinol exerts a strong reducing action, attended with precipitation of metallic silver and cuprous oxide respectively. The *acetate*, $C^6H^5.CO.CH^2.CO^2C^2H^5O$, prepared by the action of acetic anhydride on the alcohol, or by the action of potassium acetate and ethyl alcohol on bromacetophenone (p. 1150), crystallises from ligroin in colourless shining rhombic tablets, melting at 49° – 49.5° , easily soluble in alcohol, ether, and chloroform. The *benzoate*, $C^6H^5.CO.CH^2.CO^2C^2H^5O$, obtained in like manner with benzoic anhydride, crystallises from hot dilute alcohol in small tablets, melts at 117° – 117.5° , and dissolves readily in ether, chloroform, and benzene. The same benzoic ether is obtained from bromacetophenone, $C^6H^5.CO.CH^2Br$ (p. 1150), by means of silver benzoate and toluene.

(2). *Benzoyl-formic acid*, $C^6H^5.CO.COOH$, prepared as above described, forms a *barium salt*, $(C^6H^5.CO.CO^2)^2Ba$, crystallising in prismatic laminæ. The *silver salt*, $C^6H^5.CO.COOAg$, crystallises from water in small flat needles or acuminate tablets. The same acid appears to be formed by the action of nitric acid on mandelic acid, $C^6H^5.CHOH.CO^2H$.

PHENYLGLYOXALIC and PHENOXYLIC ACIDS. These are two isomeric acids obtained by the action of acids on benzoyl cyanide, and represented by the formula $C^6H^5.CO.COOH$.

Phenylglyoxalic acid, discovered by Claisen (*Ber.* x. 429, 844, 1663), is produced by treating benzoyl cyanide at ordinary temperatures with twice its weight of hydrochloric acid (sp. gr. 1.19). The cyanide then gradually dissolves, with formation of the amide of phenyl-glyoxalic acid, and afterwards sal-ammoniac and oily phenyl-glyoxalic acid separate out:

and

The latter is taken up by ether, and purified, after expulsion of the ether, by dissolving it in potassium carbonate, shaking the solution with ether (which takes up any undecomposed amide that may still be present), then acidulating and again extracting with ether, which leaves the acid as an oil, solidifying in the exsiccator to colourless prismatic crystals. After further purification through the medium of the potassium or silver salt, it melts at 65° – 66° . At a higher temperature it is resolved for the most part into benzoic acid and carbon monoxide, a smaller portion being at the same time resolved into benzoic aldehyde and carbon dioxide. It is extremely soluble in water. Its *ethylic ether*, obtained by passing hydrogen chloride into the alcoholic solution of the acid, is a fragrant liquid, insoluble in water, and boiling at 250° – 255° under ordinary pressure, at 143° – 143.5° under a pressure of 29 mm. Alcoholic potash instantly converts it into the potassium salt, $C^6H^5O^2K$, which crystallises from hot alcohol in slender, flat, concentrically grouped prisms. The silver salt, $C^6H^5O^2Ag$, obtained by precipitation, crystallises from hot water, with slight decomposition, in small plates.

The acid is reduced by sodium-amalgam to mandelic acid, $C^6H^5.CHOH.COOH$, and by hydriodic acid and phosphorus to *o*-toluic (phenyl-acetic) acid; these reactions establish its constitution.

Phenyl-glyoxamide, $C^6H^5.CO.CO.NH^2$. Of this compound there are three modifications. The *α -amide* is obtained from the above-mentioned solution by precipitation with water, as a white powder, or by agitation with ether and slow evaporation, in prismatic crystals which may be purified by recrystallisation from carbon sulphide. It then melts at 90° – 91° , dissolves easily in ether, alcohol, benzene, and chloroform, slowly in water, and has a sharp and slightly bitter taste. It dissolves easily in dilute alkalis, and carbon dioxide throws down from the solution a crystalline precipitate consisting of the *β -amide*, which melts at 64° – 65° , and dissolves sparingly in cold water, scarcely at all in ether, easily in alcohol. The *γ -amide* is precipitated on dropping the *α -amide* into excess of dilute hydrochloric acid, as a white powder, melting at 130° , nearly insoluble in ether, benzene, and chloroform; easily soluble in alcohol, and crystallising from the latter in tufts of slender prisms, from hot water in small four-sided plates. On passing carbon dioxide into its alkaline solution, the *β -amide* is produced. The *β -* and *γ -amides* dissolve in strong sulphuric acid with deep yellow colour. All the three amides, when heated with alkalis as long as ammonia is thereby evolved, and then acidulated, are reconverted into the original phenyl-glyoxalic acid.

Phenoxylic acid, discovered by Hübner a. Buchka (*Ber.* x. 479), is obtained

by heating benzoyl cyanide to 140° in sealed tubes with glacial acetic acid saturated with dry hydrogen chloride. The first product of the reaction is the compound $(C^6H^5.CO.CN.H)^2O$, which separates, on diluting the contents of the tube, as a yellow-brown powder, and may be crystallised from alcohol or acetic acid. By boiling with water, or more quickly with alkalis or acids, it is converted into phenoxyllic acid, which melts at 111°, forms a *barium salt*, $(C^6H^5.CO.COO)^2Ba$, crystallising in tablets, and with lead acetate, small white needles of the *lead salt*, $(C^6H^5.CO.COO)^2Pb + 2H^2O$, which gives off its water at 200°.

PHENYL-HYDANTOIN, $C^6H^5.NO^2$. See HYDANTOIN (p. 1046).

PHENYL-HYDRAZINE, $C^6H^5.NH.NH^2$. See HYDRAZINES (pp. 1048-1057).

PHENYLIMIDOCHLORACETIC ETHER, $C^6H^5.N=CCl-COOC^6H^5$. See OXAMIC ETHERS (p. 1457).

PHENYLISOBUTANE, $C^6H^5.CH^2.CH(CH^3)^2$, is formed by the action of sodium on benzyl chloride and isopropyl iodide mixed with ether (Köhler a. Aronheim, *Ber.* viii. 508).

PHENYL-KETONES. See pp. 1149-1156. On *Phenylchloromethyl ketone* or *Chloracetophenone*, $C^6H^5.CO.CH^2Cl$, the following observations have been made by Dyckerhoff (*Ber.* ix. 1216; x. 119, 531). By treatment with potassium thiocyanate, the ketone is converted into phenyl-thiocyanomethyl ketone or thiocyanacetophenone, $C^6H^5.CO.CH^2SCN$, which separates in fine crystals melting at 72°-73°. Crystalline compounds are also formed by treating chloracetophenone with cyanide or cyanate of potassium.

Thiocyanacetophenone, boiled with tin and hydrochloric acid, is converted, with simultaneous emission of a strong odour of mercaptan, into an isomeric compound which forms slender needles sparingly soluble in all solvents, and melting at 203°-204°. The same body is formed by boiling the thiocyno-compound with hydrochloric acid. It dissolves in alkalis, and is reprecipitated by acids. The thiocyno-derivative is quickly oxidised by dilute nitric acid to carbonic, benzoic, and sulphuric acids.

Chloracetophenone is converted by *phosphorus pentachloride*, with separation of hydrochloric acid, into α - β -dichlorostyrolene, $C^6H^5.CCl=CHCl$, according to the equation:

If an excess of chlorine be used in the preparation of chloracetophenone, the chief product obtained is the dichloride, $C^6H^5.OCl^2=C^6H^5.CO.CHCl^2$, which boils between 250° and 255°. If the passage of the chlorine be further continued, a thick black greasy mass is obtained, yielding by distillation nothing but benzoyl chloride and less chlorinated products of higher boiling point (Dyckerhoff).

Acetophenone-ortho-carboxylic Acid, $C^6H^5O^3=C^6H^4\begin{smallmatrix} \diagup CO.CH^3 \\ \diagdown COOH \end{smallmatrix}$ (Michael a. Gabriel, *Ber.* x. 1555, 2199; xi. 1007). This acid is formed from benzoyl-aceto-(ortho-) carboxylic acid, $C^{10}H^8O^3$, by boiling the latter in aqueous or alkaline solution, or by keeping it for some time in a state of fusion: $C^{10}H^8O^3=C^6H^5O^3+CO^2$; also by heating phthalylacetic acid (*q.v.*) with water at 200°: $C^{10}H^8O^4+H^2O=C^6H^5O^3+CO^2$. It forms crystals having a vitreous lustre, a sweet taste, and melting at 114°. Its salts show but little tendency to crystallise.

When acetophenonecarboxylic acid is treated with *sodium-amalgam* ($1\frac{1}{2}$ p. c. Na), and the resulting solution is treated with hydrochloric acid, an oil is precipitated which distils over with vapour of water, and may be separated by agitation with ether. This oil solidifies below 0°, and melts at the heat of the hand. Its composition is represented by the formula

It is not dissolved by ammonia or by cold potash or soda-ley; it dissolves, however, in baryta-water, and silver nitrate added to the solution throws down slender crystals of the salt, $C^6H^4\begin{smallmatrix} \diagup CH(OH)CH^3 \\ \diagdown COOAg \end{smallmatrix}$. Stronger reducing agents, such as red phosphorus and hydriodic acid, convert acetophenonecarboxylic acid into ethylbenzoic acid,

Tribromacetophenone-o-carboxylic acid, $CBr^3.CO.C^6H^4.COOH$, formed by the action of bromine on a solution of phthalylacetic acid in dilute acetic acid, melts at 159°-

160°, and is resolved by alkalis into phthalic acid and bromoform. The corresponding chlorinated acid melts at 144°.

When, on the other hand, a mixture of bromine, glacial acetic acid, and acetophenone-carboxylic acid is heated in sealed tubes, bromomethylene-phthalyl, $C^6H^5BrO^2 = C^6H^5 \begin{smallmatrix} CO \\ CO \end{smallmatrix} CHBr$, is formed, according to the equation,

The contents of the tubes are heated on a water-bath to expel hydrobromic and acetic acids, and the residue is dissolved in hot alcohol. On evaporating the alcoholic solution, bromomethylenephthalyl crystallises out, and after diluting the mother-liquor with water, an oily liquid separates, which on boiling with water deposits a yellow crystalline mass which has the composition $C^6H^5O^3$, melts at 145°–146°, and begins to sublime at 100°. Bromomethylenephthalyl dissolves easily in benzene, chloroform, carbon bisulphide, glacial acetic acid, and hot alcohol, and crystallises in long flexible needles melting at 132°–133°.

PHENYL-LACTIC ACID, $C^6H^{10}O^3 = C^6H^5.CH^2.CHOH.CO^2OH$. On the formation of this acid by the action of water on hydrobromocinnamic acid, see p. 500.

PHENYL-METHANES. On DIPHENYL-METHANE, $CH^2(C^6H^5)^2$, see vii. 947; viii. 682. On TRIPHENYL-METHANE, vii. 948.

PHENYL-METHYL-OXAMIDE, $NH(CH^3).CO.NH(C^6H^5)$. See OXAMIDE (p. 1458).

PHENYL-OXAMETHANE, $C^6H^5.CO.NH.COOC^2H^3$. See OXAMIC ETHERS (p. 1457).

PHENYL-OKAZIDE. Syn. with OXALYL - DIPHENYLHYDRAZIDE, $(C^6H^5.N^3H^2)^2C^2O^2$. See HYDRAZINES (p. 1053).

PHENYL-OKYCROTIC ACID. Syn. with CINNAMOMANDELIC ACID, $C^{10}H^{10}O^3 = C^6H^5.CH=CH.CHOH.CO^2OH$ (p. 507).

PHENYL-PERCHLORETHYLENE, $C^6H^5Cl^3$, is formed, with evolution of hydrogen chloride, by distilling tetrachlorocinnamene, which latter is produced by the action of chlorine at ordinary temperatures on α - β -dichlorocinnamene:

(Dyckerhoff, *Ber.* x. 531).

PHENYL-PHOSPHINES. See PHOSPHINES.

PHENYL-PROPIONIC ACID, $C^6H^9O^2 = CH^2(C^6H^5).CH^2.CO^2OH$. *Hydrocinnamic acid* (vi. 468).—This acid is formed by oxidising phenyl-propyl alcohol dissolved in glacial acetic acid with somewhat less than the theoretical quantity of chromic acid. Its *calcium salt*, $(C^6H^5O^2)^2Ca + 1\frac{1}{2}H^2O$, crystallises in stellate groups of needles. The *benzylic ether*, $C^6H^5O^2.CH^2.C^6H^5$, formed by the action of sodium on benzyl acetate, has been already described (p. 1068). The *phenyl-propylic ether*, $C^6H^5O^2.C^3H^4(C^6H^5)$, obtained by the action of sodium-amalgam and water on styrcnyl tetrabromide, is a colourless mobile oil (W. v. Miller, *Ber.* ix. 274).

Phenyl-bromopropionic acid, $C^6H^9BrO^2$, and the corresponding *iodine-derivative*, discovered by Glaser (vi. 417), are respectively identical with hydrobromo- and hydriodo-cinnamic acid, but, according to F. Binder (*Ber.* x. 518), their reactions do not quite agree with those described by Glaser. The brominated acid is resolved at 143° into hydrobromic and cinnamic acids, and at 150° in a stream of air, the decomposition is complete. The same change takes place on boiling the brominated acid with water, but the greater part of it is converted into phenyl-lactic or phenyl-hydroxypropionic acid, $C^6H^9(OH)O^2$, which may be advantageously prepared by this reaction. Phenyl-iodopropionic acid reacts with water in a similar manner, the greater part of it being, however, resolved into hydriodic and cinnamic acids.

Phenyl-bromopropionic acid, treated with excess of dilute soda-ley, is immediately decomposed, with separation of cinnamene, small quantities of cinnamic and phenyl-lactic acids being formed at the same time. Phenyl-iodopropionic acid is decomposed in the same manner, excepting that it yields a larger proportion of cinnamene (70 per cent. of the theoretical amount). Now, as phenyl-lactic acid has the constitution $C^6H^5.CH^2.CH(OH).CO^2OH$, and consequently phenyl-bromopropionic acid must be $C^6H^5.CH^2.CHBBr.CO^2OH$, the above-mentioned formation of cinnamene shows that this hydrocarbon is an unsaturated compound represented by the formula $C^6H^5.CH^2.CH$ (Binder).

Phenyl-propionitril, $C^6H^5.CH^2.CH^2.CN$, is the principal constituent of the volatile oil of water-cress (Hofmann, p. 584).

PHENYL-PROPYL ALCOHOL, $C^9H^{12}O = C^6H^5.CH^2.CH^2.CH^2OH$ (Rüchheimer, *Ber.* vi. 214). This alcohol is obtained, together with a small quantity of allyl-benzene, C^9H^{10} , by treating a warm aqueous solution of styryl alcohol, $C^9H^{10}O$, with sodium-amalgam in a reflux apparatus heated in the water-bath, agitating with ether, and submitting the product to fractional distillation. It is a viscid, colourless, strongly refracting liquid, having a density of 1.008 at 18° , boiling at 255° (uncorr.), and not solidifying at -18° . It is only slightly soluble in water, but mixes in almost all proportions with alcohol, ether, and glacial acetic acid. When dissolved in a small quantity of the latter and oxidised with somewhat less than the calculated quantity of chromic acid, it is converted into phenyl-propionic acid.

Phenyl-propyl Acetate, $C^9H^{11}.O.C^2H^3O$, is formed, with violent reaction, on mixing the alcohol with acetyl chloride. It is a slightly yellow, nearly scentless liquid, much more mobile than the alcohol, boiling at 244° - 245° , not solidifying at -18° . The *benzoate*, prepared by heating the alcohol with benzoyl chloride, is a thick brownish liquid. The *phenyl-propionate*, $C^9H^{11}.C^8H^7O^2$, has been already described.

Phenyl-propyl Bromide, $C^9H^{11}Br = C^6H^5.CH^2.CH^2.CH^2Br$, formed by passing bromine-vapour into normal propyl-benzene heated to 150° - 160° , is resolved by boiling into hydrogen bromide and allyl-benzene, $C^6H^5(C^3H^3)$ (Radziszewski, *Compt. rend.* lxxviii. 1153).

Phenyl-propyl Ketones. See KETONES (p. 1152).

PHENYL-PROPYLGLYCOLLIC ACID,

(A. Raab, *Ber.* viii. 592). This acid, homologous with mandelic acid (p. 1261), is prepared by heating an alcoholic solution of cumic aldehyde to 120° - 130° for fifteen hours with hydrocyanic and hydrochloric acids:

The yield, however, is very small. The acid crystallises in small white needles, which melt at 158° , dissolve with moderate facility in water, very readily in alcohol and ether. The *barium salt*, $(C^{11}H^{13}O^3)^2Ba + 4H^2O$, is moderately soluble in boiling water, and crystallises therefrom in small rhombic plates. The *silver salt*, $C^{11}H^{13}O^3Ag$, separates from a mixture of the barium salt with silver nitrate in stellate groups of slender needles. The *lead salt*, $(C^{11}H^{13}O^3)^2Pb$, is a white nearly insoluble precipitate.

PHENYL - SEMICARBAZIDE, $C^6H^5.N^2H^2.CO.NH^2$. See HYDRAZINES (p. 1055).

PHENYL-SULPHACETIC, -SULPHINACETIC, and -SULPHON-ACETIC ACIDS. See SULPHALKYLACETIC ACIDS.

PHENYL-SULPHURIC ACID, $C^6H^5.O.SO^3H$. The potassium salt of this acid may be formed synthetically by heating a concentrated aqueous solution of potassium phenate with potassium pyrosulphate:

This salt is slightly soluble in cold, moderately soluble in hot alcohol, easily in water. When quickly heated to fusion and then dissolved in water, it gives a ruby-red colour with ferric chloride. It is decomposed by dilute hydrochloric acid, yielding phenol and sulphuric acid (E. Baumann, *Ber.* ix. 1715).

Potassium phenyl-sulphate is found in the urine after the introduction of phenol into the organism, being formed by the action of the phenol on potassium sulphate present therein. Phenyl-sulphates occur also in the urine of the horse and other mammalia, their formation being especially promoted by vegetable diet (Baumann, *Pflüger's Archiv. f. Physiologie*, xii. 69; xiii. 285; *Ber.* ix. 54; *Chem. Soc. J.* xxix. 726; xxx. 109, 212, 534).

On *Methyl-phenylsulphuric* or *Cresylsulphuric acid*, $C^6H^4(CH^3).O.SO^3H$, see p. 584.

PHENYL-THIOCARBAMIDE, $NH^2.CS.NH(C^6H^5)$. See CARBAMIDES (THIO-), (p. 396).

PHENYL-THIOCARBAZIDE. See HYDRAZINES (pp. 1055, 1056).

PHENYL-THIOCARBIMIDE, $CS=N-C^6H^5$. On the reaction of this compound with aldehyde-ammonia. see p. 399.

PHENYL-TOLUENE, $C^7H^7(C^6H^5)$. On the decomposition of this hydrocarbon by Heat, see Barbier (p. 1065).

PHENYL-(DI-) TOLYL-CARBAMIDE, $N(C^6H^5)_2.CO.N(C^6H^4.CH^3)$. See CARBAMIDES (p. 391).

PHENYL-URETHANE, $NH^2.CO.OC^6H^5$. See CARBAMATES (p. 384).

PHENYL-VALERIC ACID, $C^8H^8(C^6H^5)O^2$. The benzylic ether of an acid having this composition is obtained by the action of sodium on benzyl butyrate. This ether boils at 240° – 250° ; the acid obtained from it melts at 78° (Conrad a. Hodgkinson, *Ber.* x. 254).

PHENYL-XYLENE, $C^{14}H^{14} = C^6H^4(CH^3).CH^2.C^6H^5$, is formed by heating xylol chloride, $C^6H^4(CH^3).CH^2Cl$ (b. p. 192° – 196° , from coal-tar xylene), with 3 vol. benzene and zinc-dust. When purified by fractional distillation and rectification over sodium, it is a liquid boiling at 283° – 286° (corr.), having a density of 1.01 at 0° , a blue fluorescence, and a faint alliaceous odour. At a red heat it is quickly resolved into anthracene, xylene, benzene, and hydrogen (Barbier, *Compt. rend.* lxxix. 660; *Ann. Chim. Phys.* [5], vii. 516).

PHILLIPIUM. See YTTRIUM-METALS.

PHILLIPSITE. This mineral occurs, together with other zeolites, in the cavities of the basalt of the Limperichkopf, near Asbach, and of Geisnidda, Vogelsberg. In the former locality it is the oldest of the zeolites, being followed in order by natrolite and apophyllite; in the latter it follows gismondin, and is itself succeeded by chabasite (Weiss, *Jahrb. f. Min.* 1873, 319; Sandberger, *ibid.* 1874, 173). At Stempel, near Marburg, phillipsite occurs, together with natrolite and analcime, the natrolite being the oldest of the three zeolites, and the analcime the most recent (A. v. Koener, *ibid.* 75. 116). The occurrence of phillipsite, and other zeolites of recent formation, near Oran, in Algeria, has been observed by Daubrée (*Compt. rend.* lxxiv. 167; *Chem. Soc. J.* xxxi. 444).

According to A. Streng (*ibid.* 585), phillipsite, hitherto regarded as orthorhombic (iii. 13), belongs, as also does baryta-harmotome, to the monoclinic system; and this view is confirmed by the crystallographical and optical measurements of Trippke (*Jahrb. f. Min.* 1879, 681; *Chem. Soc. J.* xxxvi. 515).

Phillipsite from Richmond, Victoria, analysed by C. Newbery (*Jahrb. f. Min.* 1871, 75), was found to contain:

SiO ²	Al ² O ³	CaO	K ² O	Na ² O	H ² O
46.62	23.60	4.48	6.39	5.10	14.76 = 100.95

PHLOBAPHENE. This name is applied to certain red bodies, formed, together with glucose, when many tannins are heated with dilute sulphuric acid. By fusion with potash, they are resolved into protocatechuic acid, and another body, which is either a fatty acid, or phloroglucol, according to the kind of tannin employed (II. B. Procter, *Chem. News*, xxxix. 245; *Chem. Soc. J.* xxxvi. 979). According to C. Etti (*Dingl. pol. J.* cccxxviii. 354) the dark-red substance which remains on evaporating the yellowish alcoholic solution of lupulo-tannin from hops, has the composition $C^{20}H^{40}O^{25}$, and may be supposed to result from the expulsion of one molecule of water from 2 mols. of a tannic acid of the formula $C^{20}H^{20}O^{15}$. To obtain it, coarsely powdered hop flowers are placed in an extraction apparatus, and the mass, after being freed from resin and bitter principle as much as possible, is extracted with 20 per cent. alcohol. On evaporating to a small bulk and cooling, a red precipitate of lupulo-phlobaphene is formed; this is dissolved in 90 per cent. alcohol, evaporated to dryness, and heated at 120° – 130° . If it tastes bitter, the bitter-principle may be removed by ether. Lupulo-phlobaphene is easily soluble in alkalis, and is precipitated unchanged by dilute mineral acids. On boiling the freshly precipitated and not previously heated phlobaphene with dilute mineral acids, it is decomposed, glucose and 1 mol. of water being split off.

As the phlobaphene is easily prepared, is constant in composition, and precipitates gelatin solution completely, it may be estimated quantitatively like tannin, and used for standardising the solution employed.

PHLOGOPITE. See MICA (p. 1321).

PHLOREIN, $C^{18}H^{14}NO^7$ (R. Benedikt, *Ber.* vii. 445; *Liebig's Annalen*, clxxviii. 92). A colouring matter produced by the action of nitrous acid on phloroglucol. It is a dark green powder having a metallic lustre, insoluble in water, but dissolving easily in alcohol, ether, and acetic acid with dark brown colour, in alkalis and alkaline carbonates with deep purple colour. Benedikt deduced, from his first analyses of this body, the formula $C^{12}H^8O^5$, and represented its formation by the equation

$2\text{C}^6\text{H}^6\text{O}^3 = \text{C}^{12}\text{H}^8\text{O}^5 + \text{H}^2\text{O} + \text{H}^2$; but from subsequent analyses he infers that it contains nitrogen, and has the composition $\text{C}^{18}\text{H}^{11}\text{NO}^7$, according to which its formation may be represented by the equation:

For its constitution he proposes the formula

PHLORETIC ACID, $\text{C}^9\text{H}^{10}\text{O}^3$. H. Schiff (*Liebig's Annalen*, clxxii. 356) prepares phloretic acid, together with phloroglucol, by boiling phloretin in portions of 20 grams for about three hours in a reflux apparatus, with 150 c.c. of potash-ley of sp. gr. 1.20; saturates the liquid when cold with sulphuric acid; then adds sodium bicarbonate in very slight excess, and extracts the phloroglucol by repeated agitation with an equal volume of ether; a larger excess of the bicarbonate interferes with the complete extraction of the phloroglucol. The remaining alkaline liquid is finally supersaturated with sulphuric acid, and the phloretic acid extracted by agitation with ether four times repeated. The phloroglucol thus obtained is quite pure; the phloretic acid still retains a small quantity of phloroglucol (compare Hlasiwetz, iv. 489).

Phloretic acid treated with *phosphorus oxychloride* at about 60° dissolves, with evolution of hydrochloric acid; and after about an hour the whole solidifies to a white mass; and on washing this mass with ether, alcohol, and water, and dissolving it at boiling heat in glacial acetic acid, a solution is obtained which on cooling deposits white crystals of triphloretid, $\text{C}^{27}\text{H}^{26}\text{O}^7 = 3\text{C}^9\text{H}^{10}\text{O}^3 - 2\text{H}^2\text{O}$. This compound does not give the reactions of tannic acid (Schiff, *Ber.* vi. 759).

Methyl-phloretic acid, $\text{C}^{10}\text{H}^{12}\text{O}^3 = \text{C}^9\text{H}^9(\text{CH}^3)\text{O}^3$, is prepared by mixing the solutions of 1 mol. phloretic acid and $2\frac{1}{2}$ mols. potassium hydrate in methylic alcohol, and slowly evaporating to dryness. The product is then mixed with a quantity of dry methyl alcohol sufficient to form a thin paste, and methyl iodide (3 mols.) is gradually added, whereby a crystalline mass is obtained, consisting of potassium iodide and *methylic methylphloretate*, with some potassium methylphloretate. The methylic methylphloretate, which may be separated by dissolving the mass in water, and agitating with ether, crystallises in lustrous tables, which have a pleasant odour, resembling that of methyl anisate. It melts at 38° , and boils at 278° . This ether is easily decomposed by an aqueous solution of potassium hydrate, and the addition of hydrochloric acid then separates the methylphloretic acid in the crystalline state. The acid is only slightly soluble in cold water, more readily when heated, and very soluble in alcohol and ether. It crystallises in prisms, which sublime below 100° , and melt at 103.4° . The barium salt crystallises readily in thin plates; the potassium salt in tufts of needles.

Ethyl-phloretic acid, prepared in a similar manner with ethyl alcohol and ethyl iodide, crystallises in white lustrous scales melting at 106.5° ; in other respects it closely resembles the methyl derivative.

When methylphloretic acid is added to a cold mixture of potassium dichromate, sulphuric acid and water, a violent action takes place, resulting in the formation of methylparaoxybenzoic (anisic) acid; if the reaction be moderated, the corresponding aldehyde is obtained. Ethylphloretic acid similarly treated yields paraethoxybenzoic acid, $\text{C}^9\text{O}^2\text{H}^3\text{H}^3\text{H}^3\text{CO}^2\text{H}^2\text{H}^2$, melting at 195° (vi. 899). From these results it follows that phloretic acid has only one side-chain containing carbon, and must therefore have the constitution of phenoxypropionic acid, $\text{C}^6\text{H}^4(\text{OH})\text{CH}^2\text{CH}^2\text{COOH}$, or of phenoxyisopropionic acid, $\text{C}^6\text{H}^4(\text{OH})\text{CH} < \begin{smallmatrix} \text{CH}^3 \\ \text{COOH} \end{smallmatrix}$, the hydroxyl being in the para-position with respect to that side chain (Körner a. Corbetta, *Ber.* vii. 1731).

PHLORETIN, $\text{C}^{18}\text{H}^{14}\text{O}^5$. H. Schiff (*Liebig's Annalen*, clxxii. 356) prepares this compound by dissolving phlorizin (20 g.) in water (140 g.) heated nearly to boiling, adding 50 g. of 20 per cent. sulphuric acid previously heated nearly to boiling, and keeping the mixture nearly at the boiling heat. After a few minutes the liquid solidifies to a pulp of perfectly white crystals of phloretin.

PHLORIZIN. The formula $\text{C}^{21}\text{H}^{24}\text{O}^{10}$, usually assigned to this body, is founded on the analysis of Stas, which gives 57.47 per cent. carbon and 5.67 hydrogen, the calculated quantities being 57.79 C. and 5.51 H. (see Gmelin's Handbook, English Edition, xvi. 13). According to this formula, and those of phloretin and phloretic acid above given, the resolution of phlorizin into glucose and phloretin is represented

by the equation $C^{21}H^{24}O^{10} + H^2O = C^6H^{12}O^6 + C^{15}H^{14}O^5$; and that of phloretin into phloretic acid and phloroglucol under the influence of alkalis, by the equation $C^{15}H^{14}O^5 + H^2O = C^9H^{10}O^3 + C^6H^4O^3$ (iv. 489, 494). According to J. Löwe, on the other hand (*Zeitschr. anal. chem.* 1876, 28), the formula of phlorizin dried over sulphuric acid is $C^{23}H^{20}O^{14}$; of phlorizin dried at 100° – 105° , $C^{23}H^{20}O^{12}$; of phloretin, $C^{17}H^{14}O^6$; and of phloretic acid, $C^{11}H^{10}O^4$. Löwe finds also that phlorizin is not precipitated either by lead salts or by barium salts, and that it is resolved into phloretin and glucose when heated to 110° even in pure water, and when heated to 130° in the dry state. These decompositions he represents by the following equations:

and the resolution of phloretin into phloretic acid and phloroglucol by the equation:

It must be observed, however, that the percentages of carbon required by Löwe's formulæ of phlorizin, phloretin, and phloretic acid are lower than those found by all other chemists who have examined these bodies (see Gmelin's Handbook, xiii. 308; xv. 8, 11), and that the formula $C^9H^{10}O^3$ for phloretic acid is supported by the composition of methyl- and ethyl-phloretic acids (p. 1569). Moreover, it is not easy to see how Löwe's formula for phloretic acid can be reconciled with the formation of anisic acid by oxidation of methyl-phloretic acid.

Phlorizin gives a dark blue colour with ammonium sulphomolybdate (p. 1335).

A solution of 0.046 grm. phlorizin in 100 c.c. alcohol, or of 0.039 grm. in 100 c.c. wood-spirit, has a specific rotatory power of +52 for the yellow ray (Oudemans, *Pogg. Ann.* cxlviii. 337).

PHLOROBROMIN, C^6HBr^9O (Benedikt, *Liebig's Annalen*, clxxxix. 165). When bromine (10 pts.) is gradually added to an aqueous solution of phloroglucol (1 pt.), tribromophloroglucol is first formed, and subsequently converted into phlorobromin:

and

To obtain the latter compound pure, the liquid is decanted from the hard lumps formed in the reaction; these are left to dry in the air and crystallised from chloroform; the prisms thus obtained are heated on the water-bath with water and excess of bromine till the bromine is driven off; and the residue is recrystallised from chloroform.

Phlorobromin thus obtained crystallises in colourless orthorhombic prisms, $0P.\infty P.\infty \bar{P}\infty$, having the axial ratio $a : b = 1 : 1.188$, and the angles $\infty \bar{P}\infty : \infty P = 39^\circ 55'$; $\infty P : \infty P = 79^\circ 50'$ and $100^\circ 10'$. The crystals melt at 152° ; decompose at a higher temperature, are insoluble in water, and are not attacked either by boiling potash-ley, boiling nitric acid, or sodium-amalgam.

When phlorobromin is dissolved in warm alcohol, and the solution, after standing for some hours, is mixed with a large quantity of cold water, an oil is precipitated together with slender needles of pentabromacetone melting at 76° (vi. 27).

Phlorobromin is decomposed by aqueous ammonia at ordinary temperatures, yielding, together with bromoform, a body having the composition $C^5Br^4H^4N^2$, which may be purified by precipitation from the ammoniacal solution with excess of sulphuric acid, extraction with ether, evaporation of the ethereal solution, and recrystallisation of the residue from water with the aid of blood-charcoal. It then forms large white crystals or transparent laminæ melting at 124° . It is decomposed by potash, with formation of ammonia and bromoform, and converted into a brominated acid by heating to 120° for several hours with dilute sulphuric acid.

PHLOROGLUCOL, $C^6H^6O^3 = C^6H^4(OH)^2$. *Phloroglucin*.—This triatomic alcohol is formed: 1. Together with another substance, by fusing resorcinol ($C^6H^6O^2$) with sodium hydrate, the phloroglucol constituting from 60–70 per cent. of the product (Barth a. Schreder, *Ber.* xii. 503). 2. Together with small quantities of other products, by fusing resorcinoldisulphonic acid with potassium hydrate; soda yields a less favourable result (Tedeschi, *Ber.* xii. 1267). 3. Together with hesperetic acid, by heating hesperitin to 100° with potash (E. Hoffmann, *Ber.* ix. 685):

Reactions.—1. When a solution of *potassium nitrite* is added to a very dilute solution of phloroglucol mixed with *nitrate of toluidine* (or *aniline*), the liquid, which is at first clear, becomes brownish-yellow, then orange-red, and ultimately deposits a cinnabar-red precipitate. This is a very delicate test for phloroglucol. A similar reaction is however produced by *maclurin*, *catechin*, *decoction of fustic*, and *extract of hops* (Weselsky, *Ber.* ix. 216). See also Procter (*Chem. News*, xxxix. 245; *Chem. Soc. J.* xxxvi. 979).

2. By the action of *chlorine* and *water*, phloroglucol is converted into dichloro-acetic acid (Hlasiwetz a. Hubermann, *Liebigs Annalen*, clv. 120):

3. With *bromine* and *water*, it yields tribromophloroglucol, afterwards converted into phlorobromin, $\text{C}^6\text{HBr}^3\text{O}$.

4. With *nitrous acid* it yields phlorein, $\text{C}^{12}\text{H}^8\text{O}$ (p. 1568).

Trinitrosophloroglucol, $\text{C}^6(\text{NO})^3(\text{OH})^3$ (Benedikt, *Ber.* xi. 1374). When a concentrated well-cooled solution of potassium nitrite is added to a solution of phloroglucol in dilute acetic acid covered with a layer of ether, the mixture becomes dark-brown, and after some minutes an acid potassium salt begins to separate. On supersaturating the solution with potash, and adding alcohol, the neutral potassium salt is thrown down in beautiful green needles amounting to about 70 per cent. of the theoretical yield. As this *potassium trinitroso-phloroglucol*, $\text{C}^6(\text{NO})^3(\text{OK})^3$, cannot be recrystallised without great loss, it must be dissolved in water and precipitated with alcohol, to which some potash has been added. It is easily soluble in water, with difficulty in dilute potash, quite insoluble in weak alcohol. It may be heated to above 130° without decomposition, but explodes at a high temperature. A drop of sulphuric or nitric acid will also occasion violent explosion. A lead salt of trinitroso-phloroglucol is obtained by precipitating a dilute solution of the potassium salt with lead acetate, and falls as a yellow precipitate. When dried it forms a light cinnamon-brown powder, exploding with violence when heated. Nitroso-phloroglucol can be isolated by cautious decomposition of this lead salt mixed with alcohol, by means of sulphuric acid. On filtering and evaporating the alcoholic solution, groups of needles are obtained, which are easily soluble in water and alcohol, insoluble in ether.

The number of nitrosyl-groups that can be introduced into a phenol is—so far as can be judged from the small number of examples at present known—equal to the number of hydroxyl-groups contained therein. The introduction of the NO-group into the hydrocarbons (benzene and naphthalene) is difficult and can be effected only by indirect means, whereas the monhydric phenols, phenol, thymol, and naphthol, take up one NO-group with ease; the dihydric phenols, resorcinol, and orcinol, give dinitroso-derivatives; and the trihydric phenol, phloroglucol, yields trinitroso-phloroglucol.

Trinitro-phloroglucol, $\text{C}^6(\text{NO}_2)^3(\text{OH})^3 + \text{H}^2\text{O}$ (Benedikt, *loc. cit.*) On adding powdered potassium nitroso-phloroglucol in very small quantities at a time to a mixture of nitric acid and sulphuric acid, oxidation takes place at the ordinary temperature, and finally yellow needles of trinitro-phloroglucol separate out. The mass is then diluted with water, exhausted with ether, and the product recrystallised from boiling water. It crystallises in hexagonal prisms modified by combination with the pyramid and prism of the second order, the combination being represented by the formula $\infty \text{P} \cdot \text{P} \cdot \infty \text{P}^2$.

Trinitro-phloroglucol loses its crystallisation-water at 100° . At 130° it begins to sublime; at 158° it melts without decomposition, but explodes on further heating. It is easily soluble in hot water, alcohol, and ether, and is decomposed by sulphuric acid only at a high temperature. Like picric acid, it possesses great tinctorial power for animal matters, the tint, however, being richer and more beautiful. It gives the isopurpuric acid reaction with potassium cyanide. On reduction with hydrogen sulphide or tin and hydrochloric acid, it appears to form the compound analogous to picramic acid. On boiling the tin solution it becomes decolorised, but does not appear to yield the corresponding triamido-compound.

Salts of Trinitro-phloroglucol.—This body decomposes carbonates readily, and forms with metals three series of salts containing 1, 2, and 3 equivalents of metal. All are explosive. The *potassium salts* are formed by saturating 2 mols. of the nitro-compound with 1, 2, or 3 mols. of potassium carbonate, working with a solution as concentrated as possible. The compound $\text{C}^6(\text{NO}_2)^3(\text{OK})^3$ forms orange-red shining needles often an inch long, whilst $\text{C}^6(\text{NO}_2)^3(\text{OK})^2\text{OH}$ is of a deep-yellow colour, and not so shining as the preceding. The compound $\text{C}^6(\text{NO}_2)^3(\text{OK})(\text{OH})^2 + \text{H}^2\text{O}$ forms long, silky, sulphur-yellow needles, losing water at 100° , and becoming dull. All three potassium-derivatives are sparingly soluble in cold water. The *neutral ammonium derivative* behaves like the corresponding potassium compound. The *barium compound*

formed by adding baryta-water to an aqueous solution of trinitro-phloroglucol, consists of microscopically small, sulphur-yellow needles, insoluble in cold or boiling water.

Lead acetate gives, in an aqueous solution of the acid, an amorphous, flocculent precipitate of *plumbic trinitro-phloroglucol*.

Phloroglucic Anhydride, or **Phloroglucide**, $C^{12}H^{10}O^5 = C^6H^3(OH)^2 \cdot O \cdot C^6H^3(OH)^2$, is obtained: 1. By the action of heat on phloroglucol, $2C^6H^3O^3 - H^2O = C^{12}H^{10}O^5$ (Piccard, *Ber.* vii. 891). 2. By heating phloroglucol with concentrated aqueous hydriodic or hydrochloric acid (Hlasiwetz, vi. 928). 3. By heating phloroglucol for several hours with phosphorus oxychloride. On distilling off the excess of the latter, treating the residue first with water, then with alcohol, and finally washing it with ether as long as the ether is thereby coloured red, the phloroglucide is obtained in scales unctuous to the touch (H. Schiff, *Liebig's Annalen*, clxxii. 358). It dissolves in hot water, and separates therefrom as a white tasteless powder (Piccard).

Phloroglucolsulphonic Acid, $C^6H^3SO^6 = C^6H^3O^3(SO^3H)$, produced by the action of pyrosulphuric acid on phloroglucol, forms very soluble salts with the alkalis and alkaline earths, and is coloured deep violet by baryta-water and ferric chloride. By the action of phosphorus oxychloride, it is converted into an amorphous anhydride which may be purified by washing it, first with ether, then repeatedly with water, and finally dissolved in water at 50° – 60° . The resulting yellow solution reacts with albumin, gelatin, alkaloids, acids, salts, and iodide of starch, exactly like tannic acid. It is precipitated by hydrochloric acid, and on repeating this operation several times, there is obtained a yellow precipitate of the formula $C^{12}H^{10}S^2O^{11} = 2C^6H^3SO^6 - H^2O$, which dissolves readily in water, and when boiled with dilute acids is reconverted into phloroglucolsulphonic acid, which exhibits none of the reactions of tannic acid. Lastly, there is precipitated a highly carbonised body, $C^{24}H^{18}S^2O^{15}$, which also reacts like tannin, but does not decolorise iodide of starch. This body may be formed from the sulphonic acid of phloroglucol according to the equation $2C^{12}H^{10}O^5(SO^3H) - H^2O = C^{24}H^{18}S^2O^{15}$ (H. Schiff, *Ber.* vi. 26).

PHLOROL, $C^6H^{10}O = C^6H^3(OH)$. This phenol, first noticed as a constituent of beech-tar creosote by Marasse (vi. 928), and afterwards by Tiemann a. Mendelssohn (p. 580 of this volume), has been further examined by the last-mentioned chemists (*Ber.* x. 57). To determine its constitution, it was first converted into methyl-phlorol, for which purpose the ether-alcoholic mother-liquors, obtained in the preparation of potassium-cresol from the portion of the creosote boiling between 200° and 230° , were evaporated on the water-bath; the aqueous residue was acidulated with hydrochloric acid and exhausted with ether; and the ethereal extract was evaporated, whereby an oil (b. p. 220°) was obtained which was boiled for several hours in a reflux apparatus with potassium hydrate, methyl iodide, and methyl alcohol. On heating the product of this reaction over the water-bath to remove methyl alcohol, and then adding water, an oil was obtained separable by rectification into two portions, one boiling at 215° , the other at about 200° . The latter, which is the crude methyl-phlorol, gave, when suspended in 20 pts. water and boiled in a reflux apparatus with potassium permanganate (1 : 40), a mixture of acids, which was fused for a short time with potassium hydrate to remove the methyl-groups contained in it; and the substance afterwards separated from the melt by hydrochloric acid, was found to be identical with hydroxyphthalic or hydroxybenzene-orthodicarboxylic acid, $C^6H^3(OH)(COOH)^2$ (p. 1531). From these results, Tiemann a. Mendelssohn infer that the phlorol of beech-tar is a hydroxy-xylene, $C^6H^3(CH^3)^2OH$. The phlorol prepared by distillation of calcium phloretate (p. 1569) they regard as an ethylphenol.

PHLOROSE, $C^6H^{12}O^6$. A sugar obtained by the action of sulphuric acid on phlorizin (see SUGARS).

PHOLERITE. A mineral from India, named *Meerschallummit* by Ross, has been shown by Maskelyne a. Flight (*Chem. News*, xxii. 260) to contain 43.144 per cent. SiO_2 , 41.073 Al_2O_3 , and 15.783 H_2O , and to be identical with pholerite (iv. 496).

Frenzel regards the pholerite, nacrite, and lithomarge of the Saxon and Bohemian tin-mines as varieties of gilbertite (p. 860).

PHONOLITE. The following are analyses of this volcanic rock: (1 and 2). From the Wolf Rock near the Land's End, Cornwall: exhibits small sanidines enclosed in a compact grey matrix. Sp. gr. 2.54 (Allport, *Jahrb. f. Min.* 1874, 38; analysed by A. Phillips). (3). From the Ravin de l'Usclade, Auvergne. Sp. gr. 2.54. Analysed by C. v. Bonhorst (*ibid.* 1872, 337). (4 and 5). Nosean-phonolites from the Hohentwiel in the Högau. 4. Fresh rock: 55.9 per cent. soluble; 44.1 insoluble. Sp. gr. 2.54. 5. Weathered: 39 per cent. soluble; 61 insoluble. Sp. gr. 2.41:

	SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	K ² O	Na ² O	H ² O	
1.	56.46	22.29	2.70	0.97	1.47	—	2.81	11.13	2.05	= 99.88

PHORONE, C⁶H¹⁴O. This name has been given to at least two isomeric bodies, one, which is the ketone of camphoric acid (also called *camphorone*) being formed by distillation of calcium camphorate (i. 733; vii. 949), the other (also called *acephorone*) being produced by the condensation of acetone under the influence of strong hydrochloric acid: 3C³H⁶O - 2H²O = C⁶H¹⁴O (i. 23; vi. 26); and by heating nitrosotriacetoneamine (p. 29) with potash:

The action is best commenced over the water-bath, and completed by boiling the liquid in a reflux apparatus, and the phorone thus produced may be extracted with ether and purified by distillation (Heintz, *Liebig's Annalen*, clxxxvii. 250).

Camphorone is a liquid boiling at 208° (Gerhardt); at 206°-215° (Kachler); acephorone crystallises in large yellowish prisms, melts at 28°, boils at 140°-191° (Claisen, *Liebig's Annalen*, clxxxiv. 163).

The phorone produced by the action of alkaline reagents on acetone (i. 29) appears to be identical with camphorone. A liquid having the composition of phorone, and boiling at 230°-235°, is obtained, together with camphor, by distilling the calcium salt of camphic acid with calcium formate (J. de Montgolfier, *Compt. rend.* lxxxviii. 816).

Acephorone is very readily attacked by *oxidising agents*; dilute nitric acid converts it into acetic and oxalic acids. By dehydration with *phosphoric anhydride*, it is converted chiefly into pseudocumene, C⁶H¹² (p. 1284). Its solution in carbon sulphide readily absorbs *bromine*, forming a well-crystallised tetrabromide, C⁶H¹⁴O.Br⁴, easily soluble in ether, sparingly in cold water, melting at 86°-88°. With *sodium-amalgam* acephorone yields only imperfectly crystallised resinous products; but when its alcoholic solution is left in contact with zinc and sulphuric acid, it takes up hydrogen and is converted into deoxyphorone, C¹²H²⁰O, related to it in the same manner as pinacolin to acetone, and deoxybenzoïn to benzaldehyde. This compound crystallises in short colourless four-sided prisms, melts at 108°, sublimes well, and volatilises easily with vapour of water. The same compound is formed by treating the above-mentioned tetrabromide with zinc and hydrochloric acid. By strong *sulphuric acid*, acephorone is for the most part converted into mesitylene (Claisen, *Ber.* xi. 1168; *Liebig's Annalen*, clxxx. 1).

Acephorone unites with *hydriodic acid*, forming the compound C⁶H¹⁶I²O, which crystallises in needles, melts at 13°, is partly decomposed by boiling, but not decomposed by water, and is reconverted into phorone by alcoholic potash (Kasaneff, *Ber.* viii. 435).

Camphorone being the ketone of camphoric acid, probably forms a closed chain, as represented by Kachler's formula (vii. 949); but acephorone, according to the preceding reactions and its formation from nitrosotriacetoneamine by removal of N² and H²O (p. 1572), appears to have the constitution of an open chain with two double linkings. The two formulæ of nitrosotriacetoneamine give for phorone the three following formulæ:

Either of these three phorone-molecules with two pairs of doubly linked carbon-atoms may take up 4 at. bromine, and form the tetrabromide, which may accordingly be represented by one of the three following formulæ:

PHORONIC ACID, $\text{C}^9\text{H}^{16}\text{O}^2$. A crystallisable acid, obtained under certain circumstances by oxidation of camphic acid with potassium permanganate (Montgolfier, *Compt. rend.* lxxv. 961), the usual product being hydroxycamphic acid, $\text{C}^{10}\text{H}^{16}\text{O}^3$ (p. 372).

PHOSENE, or **PHOTENE**. According to Barbier (*Ann. Chim. Phys.* [5], vii. 526), the substance so-called by Fritzsche (vi. 176) is a mixture of anthracene and phenanthrene.

PROSGENITE. A mineral discovered by Sella in the lead mines of Monte Poni; found also at Gibbus. The crystals are hexagonal, exhibiting the combination $\infty \text{P} . \infty \text{P}2 . 0\text{P} . 2\text{P}2 . 2\text{P} \infty . \infty \text{P} \infty$, the faces ∞P being vertically striated. Axial ratio $a : c = 1 : 1.08758$ (Hansel, *Jahrb. f. Min.* 1878, 754).

PHOSPHAM. This name is given to the nitril of phosphoric acid, PHN^2 , which Rose obtained by passing ammonia gas over phosphorus pentachloride and heating the product in a stream of carbon dioxide (iv. 497). M. Salzmänn (*Ber.* vii. 494), by passing ammonia gas over moderately heated phosphorus pentachloride, obtained a product which, after successive treatment with hot water, hydrochloric acid, potash, and ether, formed a white amorphous powder scarcely acted upon by acids or alkalis, and giving by analysis numbers leading to the improbable formula $\text{P}^3\text{H}^4\text{N}^2$, possibly a mixture of several compounds.

PHOSPHANILATE, DIPHENYLIC, $\text{C}^{16}\text{H}^{16}\text{NPO}^3 = \text{PO} \left\{ \begin{array}{l} (\text{OC}^6\text{H}^5)^2 \\ \text{NH} \cdot \text{C}^6\text{H}^5 \end{array} \right.$ (Wallach a. Heymer, *Ber.* viii. 1235). This ether is obtained by dropping a mixture of equal parts of phenol and aniline on the calculated quantity of phosphorus pentachloride, and treating the semi-solid product with water and soda-ley. It crystallises in six-sided tablets melting at 127° – 128° ; dissolves both in acids and in alkalis, sparingly in water, readily in alcohol and ether; has a neutral reaction, and is decomposed by distillation, giving off aniline and phenol.

PHOSPHENYL BROMIDES (Michaelis a. Köhler, *Ber.* ix. 519). The *Dibromide*, *Phosphorus Phenylidibromide*, or *Phosphorus Dibromophenide*, $\text{C}^6\text{H}^5\text{PBr}^2$, is formed by passing hydrogen bromide dried with phosphoric anhydride into boiling phosphenyl dichloride (*infra*), whereupon the gas is completely absorbed, streams of hydrochloric acid gas carrying benzene with them are given off, and small quantities of phosphorus separate out. The product, after saturation with hydrogen bromide and rectification in a stream of carbon dioxide, consists essentially of phosphenyl dibromide, together with small quantities of phosphorus chloride and bromide, monobromobenzene, and diphenyl. It may be freed from dissolved phosphorus by heating it to 250° – 300° in a sealed tube, the phosphorus then separating out in the red amorphous state. The diphenyl is very difficult to remove. Phosphenyl dibromide may, however, be obtained free from diphenyl, but in small quantity only, by the action of phosphorus bromide on mercury-diphenyl:

Phosphenyl dibromide is a colourless liquid, boiling at 255° – 257° ; it soon turns yellow, and on exposure to sunlight becomes turbid and deposits a red substance. It is decomposed by water into hydrobromic acid, phosphenylous acid, and phenyl-phosphine.

Phosphenyl Tetrabromide, *Phosphoric Phenyltetrabromide* or *Tetrabromophenide*, $\text{C}^6\text{H}^5\text{PBr}^4$, formed, with great rise of temperature, by direct combination of the dibromide with bromine, is a yellow-red mass which, when heated, sublimes in yellow-red needles melting at 207° . It fumes strongly in the air, and is converted by water into hydrobromic and phosphenylous acids. It unites with bromine, forming a *heptabromide*, $\text{C}^6\text{H}^5\text{PBr}^7$, which sublimes at 110° in dark-red needles, and is decomposed by water, yielding bromine, hydrobromic acid, and phosphenylous acid.

PHOSPHENYL CHLORIDES. *Dichloride*, *Phosphorus Phenyl-dichloride* or *Dichlorophenide*, $\text{C}^6\text{H}^5\text{PCl}^2$.—To prepare this compound, the mixed vapours of benzene and phosphorus trichloride are passed through a hot tube filled with fragments of pumice, the vapour of that portion of the condensed liquid which distilled below 80° being again repeatedly passed through the tube; and the

portion of the product which boils above 80° is subjected to fractional distillation. Phosphenyl dichloride thus obtained is a colourless, very stable, strongly refractive liquid, having a sp. gr. of 1.319 at 20°, and boiling at 222° (Michaelis, *Ber.* vi. 601, 816). It is converted by chlorine into phosphenyl tetrachloride, by hydrogen iodide into phosphenyl di-iodide, by oxygen and sulphur into phosphenyl oxychloride and sulphochloride respectively, by cooled zinc-ethyl into diethylphenylphosphine, $P(C^6H^5)_3(C^6H^5)$.

Phosphenyl Tetrachloride, Phosphoric Phenyl-tetrachloride or *Tetrachlorophenide*, $C^6H^5PCl_4$, is obtained, by passing chlorine into the dichloride well cooled by cold water, as a dry mass, the yellow colour of which is due to excess of chlorine, and may be removed by crystallisation from phosphorus trichloride or phosphenyl dichloride. It melts at 73° to a clear liquid which solidifies to a crystalline mass on cooling. At a higher temperature it partly sublimes unaltered and is partly resolved into the dichloride and free chlorine (Michaelis, *loc. cit.*) When heated in a tube, it exhibits no alteration at 100°, but melts at 140°, and is resolved at 180° into PCl_3 ; boiling at 78°, monochlorobenzene, and other products boiling at higher temperatures (Michaelis a. Kammerer, *Ber.* viii. 1306). Water decomposes it with violent hissing, forming at first phosphenyl oxychloride as an oily liquid, which is further converted into phosphenylic acid (Michaelis). With phosphorous acid, it yields phosphenyl dichloride and oxychloride in the quantities required by the following equation, without a trace of phosphorus trichloride:

This tends to show that phosphorous acid has the constitution represented by $OPH(OH)^2$, since if it were correctly represented by the formula $P(OH)^3$, it should yield with phosphenyl tetrachloride, not phosphenyl oxychloride and dichloride together with phosphorus oxychloride, but phosphenyl oxychloride and phosphorus trichloride: thus

(Michaelis a. Ananoff, *Ber.* vii. 994). With *phenol*, phosphenyl tetrachloride gives off hydrochloric acid, and yields, together with monochlorobenzene, white needles of phenyl phosphenylate, $C^6H^5PO^2(C^6H^5)^2$ (Michaelis a. Kammerer, *Ber.* viii. 1306).

Phosphenyl Chlorobromide, $C^6H^5PCl^2Br^2$, is obtained by adding 1 mol. bromine to 1 mol. well-cooled phosphenyl dichloride, as a dry yellow-red solid mass which melts at about 208° to a dark-brown liquid, but sublimes even at 130° without decomposition in fan-shaped groups of yellow-red crystals. With a sufficient quantity of water it yields, as final products, hydrochloric, hydrobromic, and phosphenylic acids (Michaelis).

Phosphenyl Chlorotetrabromide, $C^6H^5PCl^2Br^4$, is formed, with brisk reaction, on adding 1 mol. bromine to the chlorobromide just described. The mixture, which is pasty at first, quickly solidifies to a dry bright-red mass which is decomposed by water, yielding phosphenylic, hydrochloric, and hydrobromic acids, and free bromine (Michaelis).

Phosphenyl Oxychloride, $C^6H^5PCl^2O$, is formed by direct combination of oxygen with phosphenyl chloride, the action being greatly facilitated by heat; also by the action of oxalic acid, and of phosphorous acid (*supra*) on phosphenyl tetrachloride. It is a colourless thickish liquid, having a faint odour, a density of 1.375 at 20°, and boiling, not quite without decomposition, at 260° (uncorr.) By water it is slowly resolved into hydrochloric and phosphenylic acids (Michaelis).

Phosphenyl Thiocchloride, $C^6H^5PCl^2S$.—Sulphur dissolves quietly in phosphenyl dichloride at ordinary temperatures, but on heating the solution, it suddenly assumes a darker colour, and the two substances enter into chemical combination, attended with violent ebullition, and when considerable quantities are present, with inflammation. The thiocchloride thus formed is a colourless liquid, boiling under ordinary pressure at 270°, with partial decomposition; under a pressure of 130 mm. at 205°. Sp. gr. = 1.376 at 13°. Its odour is aromatic at ordinary, pungent at higher temperatures. It fumes slightly in the air, and is decomposed by prolonged boiling with water, into hydrochloric, hydrosulphuric, and phosphenylic acids. Strong potash-ley attacks it violently; dilute potash-ley only after prolonged boiling. On evaporating the resulting solution and treating the residue with alcohol, potassium chloride remains undissolved, and a salt which crystallises in small needles, and probably consists of potassium thiophosphenylate, $C^6H^5PS(OK)^2$, passes into solution. The alcoholic solution thus formed acquires when somewhat concentrated an odour like that of mercaptan. The corresponding lead salt is a white precipitate, which blackens when boiled with water (Köhler a. Michaelis, *Ber.* ix. 1053).

PHOSPHENYL DIIODIDE, $C^6H^5PI_2$, is formed, with rapid evolution of hydrogen chloride, when dry hydrogen iodide is passed into the corresponding chloride (p. 1574). The liquid becomes heated and darker in colour, begins to deposit a crystalline body, then gradually becomes thicker, and finally solidifies completely to a dry dark-coloured mass, which still for awhile rapidly absorbs hydrogen iodide. The *iodide of phosphenyl and hydrogen* thus formed distils, with copious evolution of hydrogen iodide, at a temperature above the boiling point of mercury, and is decomposed by water and more readily by alcohol, yielding phenyl-phosphine, $PH^2(C^6H^5)$.

PHOSPHENYL SULPHIDES. Köhler a. Michaelis (*Ber.* x 815), by treating phosphenyl dichloride, heated nearly to boiling, with dry hydrogen sulphide, obtained a thick, colourless, disagreeably-smelling liquid, very much like the sulphide of phenyl-phosphine, and having the composition C^6H^5PS . This substance, heated with nitric acid, yields diphenylphosphinic acid, together with phosphoric acid; hence its constitution is probably $(C^6H^5)_2P.S.PS$. Köhler a. Michaelis call it *isophosphenyl sulphide*. Together with this compound, which dissolves readily in ether, there is also formed *tetraphenylphosphotrisulphide*, $(C^6H^5)_4P^3S^3$, which crystallises from warm ether in white crystals melting at 192° – 193° , and yielding by oxidation diphenylphosphinic acid.

PHOSPHENYLIC ACID, $C^6H^5.PO(OH)^2$. *Phenyl-phosphoric*, *Phenyl-phosphinic*, or *Benzenephosphinic Acid* (Michaelis, *Ber.* vi. 816; Michaelis a. Mathias, *ibid.* vii. 1070). This acid is the final product of the decomposition by water of all the derivatives of phosphenyl dichloride above described. It is best prepared by adding phosphenyl tetrachloride in successive small portions to water, and warming the liquid for some time to complete the decomposition of the phosphenyl oxychloride formed in the first instance. On evaporating the resulting solution which contains hydrochloric acid, the phosphenylic acid crystallises in colourless clinorhombic laminae having a vitreous lustre. In pure water the acid is much more soluble, so that the solution requires to be much more highly concentrated before it will begin to crystallise, the whole then solidifying to a pulp of small felted laminae, enclosing a large quantity of mother-liquor. 100 pts. by weight of water at 15° dissolve 23.5 pts. of the crystallised acid; it dissolves readily also in alcohol. It melts at 158° , and when quickly heated to about 250° is resolved into benzene and metaphosphoric acid, a decomposition exactly analogous to that of tribasic phosphoric acid into metaphosphoric acid and water, and to that of aromatic carboxylic acids into CO^2 and hydrocarbons.

Phosphenylic acid slowly heated above its melting point gives off water, and leaves a residue of condensed phosphenylic acids. At 200° , two mols. of $C^6H^5.PO^3H^2$ lose 1 mol. H^2O , leaving di- or pyro-phosphenylic acid, $(C^6H^5)_2(PO)^2O(OH)^2$, and at 210° three mols. of the acid are converted, by loss of $2H^2O$, into triphosphenylic acid, $(C^6H^5)_3(PO)^3O^2(OH)^2$.

1 mol. phosphenylic acid heated to 100° in a sealed tube with 1 mol. bromine in presence of water, yields—together with a small quantity of oil and unaltered phosphenylic acid—paradibromobenzene (m. p. 89°), hydrobromic acid, and phosphoric acid (Benzinger a. Michaelis, *Ber.* viii. 550).

Phosphenylicates.—Phosphenylic acid is a powerful bibasic acid, forming acid and neutral salts. The free acid precipitates neither barium chloride nor silver solutions, but on addition of a little ammonia, white precipitates are thrown down. The addition of sodium acetate also determines the precipitation of the silver salt.

The *neutral potassium salt*, $C^6H^5PO^3K^2$, is uncrystallisable and very soluble. The *acid salt*, $C^6H^5PO^3KH$, is precipitated from its aqueous solution by alcohol as a crystalline powder. *Neutral sodium phosphenylate*, $C^6H^5PO^3Na^2.12H^2O$, resembles the corresponding sodium phosphate. The *acid salt* crystallises less easily in similar forms.

Calcium phosphenylate, $C^6H^5PO^3Ca.2H^2O$, is a white, amorphous precipitate, soluble though with difficulty, in acetic acid. By evaporating this solution, the *acid salt*, $(C^6H^5PO^3)^2H^2Ca^2$, is obtained, crystallised in beautiful shining scales, which are anhydrous. The *acid strontium salt*, $(C^6H^5PO^3)^2H^2Sr.H^2O$, resembles the calcium salt. *Zinc phosphenylate* has the formula $C^6H^5PO^3Zn.H^2O$. *Copper phosphenylate* is $C^6H^5PO^3Cu$. *Silver phosphenylate*, $C^6H^5PO^3Ag^2$, is a light white powder, not changed by light. *Ferric phosphenylate*, $(C^6H^5PO^3)^3Fe^2.2\frac{1}{2}H^2O$, is a yellowish white precipitate.

Phosphenylic Ethers. *Ethyl-phosphenylic acid*, $C^6H^5.PO(OC^2H^5)(OH)$, is formed on adding phosphenyl tetrachloride to absolute alcohol, and leaving the solution to evaporate first on the water-bath, then over lime. It is a thick, heavy,

oily, non-volatile liquid having a fruity odour, and is quickly decomposed by water into alcohol and phosphenylic acid. Its *silver salt*, $\text{C}^6\text{H}^5\cdot\text{PO}(\text{OC}^2\text{H}^5)(\text{OAg})$, separates, on mixing the alcoholic solutions of the free acid and silver nitrate, as a yellowish-white precipitate, quickly blackening on exposure to light; it is quickly decomposed by water, with separation of phosphenylic acid and silver phosphenylate; ammonia and nitric acid dissolve it readily, though not without decomposition (Michaelis a. Mathias).

Ethylphosphenylic acid is also formed by the action of water on the normal ether (*infra*). It unites with water, forming an unstable hydrate consisting of scaly crystals, which liquefy and give off their water even over sulphuric acid at ordinary temperatures. By prolonged contact with water, the acid ether is converted into phosphenylic acid (Köhler a. Michaelis, *Ber.* x. 816).

Normal Ethyl Phosphenylate, $\text{C}^6\text{H}^5\text{P}(\text{OC}^2\text{H}^5)_2$, is formed by the action of sodium ethylate on phosphenyl dichloride. The reaction is rather violent, so that it is best to drench the sodium ethylate with ether, and gradually add the phosphenyl chloride, keeping the retort well cooled. This ether is a colourless, very mobile liquid, having an intensely disagreeable odour, a density of 1.032 at 16°, and boiling at 235°.* It is insoluble in water, and is gradually decomposed thereby, yielding alcohol and ethylphosphenylic acid (Köhler a. Michaelis).

Phenyl Phosphenylate, $\text{C}^6\text{H}^5\cdot\text{PO}(\text{OC}^6\text{H}^5)_2$, is formed, together with monochlorobenzene and hydrochloric acid, by the action of phosphenyl tetrachloride on phenol:

It crystallises in thin white needles melting at 63.5°; is insoluble in water, but dissolves readily in alcohol, ether, and benzene; is scarcely attacked by aqueous potash, but easily resolved by hot alcoholic potash into phenol and phosphenylic acid.

Phenyl phosphenylate is also formed, together with the chloride, $\text{C}^6\text{H}^5\cdot\text{PO}(\text{OC}^6\text{H}^5)\text{Cl}$, by the action of phosphorus oxychloride on phenol. This chloride is converted by boiling water into phenylphosphenylic acid, $\text{C}^6\text{H}^5\cdot\text{PO}(\text{OH})(\text{OC}^6\text{H}^5)$, and may thus be separated from the normal ether. The acid ether forms long capillary needles melting at 57°, dissolves sparingly in water, easily in alcohol, ether, benzene, and alkalis. Its ammonium salt forms colourless needles; the silver salt needles having a silky lustre (Michaelis a. Kammerer, *Ber.* viii. 48).

Nitrophosphenylic Acid, $\text{C}^6\text{H}^4(\text{NO}^2)\cdot\text{PO}(\text{OH})_2$, is obtained by heating phosphenylic acid to 100° with fuming nitric acid, and purified from unaltered phosphenylic acid by conversion into the barium salt (*infra*). It crystallises from ether in radiate groups of white needles, from water in cauliflower-like masses; deliquesces in moist air; melts at 132°, resolidifies at 105°, and explodes when heated above 200°.

The *normal barium salt*, $\text{C}^6\text{H}^4(\text{NO}^2)\cdot\text{PO}\cdot\text{O}^2\text{Ba} + 2\text{H}^2\text{O}$, is prepared by agitating the cold solution of the crude acid with barium carbonate, filtering, and treating the undissolved substance with cold water as long as the filtrate gives a reaction of barium. Nitrophosphenylate of barium then dissolves, while the phosphenylate remains behind. This salt is more soluble in cold than in hot water, 100 pts. water dissolving 0.844 pts. of it at 22° and 0.646 at 100°. The *acid barium salt*, $(\text{C}^6\text{H}^4\text{NO}^2\text{PO}^3)^2\text{Ba} + 2\text{H}^2\text{O}$, crystallises in white laminæ much more soluble than the normal salt. The *calcium salt*, $\text{C}^6\text{H}^4(\text{NO}^2)\cdot\text{PO}\cdot\text{O}^2\text{Ca} + \frac{1}{2}\text{H}^2\text{O}$, is a yellowish-white amorphous powder. The *silver salt*, $\text{C}^6\text{H}^4(\text{NO}^2)\cdot\text{PO}(\text{OAg})_2$, obtained by precipitation, is a yellowish-white powder, easily soluble in ammonia and in nitric acid, sparingly in water, and separating therefrom in white laminæ. The *lead salt*, $\text{C}^6\text{H}^4(\text{NO}^2)\cdot\text{PO}\cdot\text{O}^2\text{Pb}$, is a white pulverulent precipitate.

Solutions of sodium nitrophosphenylic acid give with ferric chloride a reddish, with cupric sulphate, on warming, a green flocculent precipitate; with cobalt nitrate a violet precipitate; with mercuric, bismuth, and zinc solutions, white precipitates (Michaelis a. Benziger, *Ber.* viii. 1310; *Lieb. Ann.* clxxxviii. 275).

Amidophosphenylic Acid, $\text{C}^6\text{H}^4(\text{NH}^2)\cdot\text{PO}(\text{OH})_2$ (Michaelis a. Benziger, *Ber.* ix. 513; *Lieb. Ann.* clxxxviii. 275). When nitrophosphenylic acid is treated with tin and hydrochloric acid, stannous nitrophosphenylic acid first separates as a bulky yellow precipitate, which is subsequently reduced to amidophosphenylic acid; and the liquid freed from tin by hydrogen sulphide leaves on evaporation a red viscid mass, from which, by washing with alcohol, amidophosphenylic acid is obtained as a greyish-white powder.

This acid, when recrystallised from hot water, forms thin, white, glistening

* In a former paper by Benziger a. Michaelis (*Ber.* viii. 1310), it is stated that normal ethyl phosphenylate obtained by the action of ethyl iodide on silver phosphenylate, boils at 267°, and the methylic ether similarly prepared at 247°.

needles, which at 280° acquire a bluish-green colour, and undergo decomposition 100 pts. of water dissolve 0.43 pt. of the acid at 20° , and 0.52 pt. at 100° ; in alcohol. it dissolves but sparingly, and in ether not at all. Heated with soda-lime, it yields aniline and phosphoric acid. It dissolves readily in hydrochloric acid, forming a solution which is coloured permanently red by bleaching-powder.

Sodium Amidophosphénylate, $C^6H^4(NH^2)PO^2Na^+ + 3H^2O$, obtained by reducing the nitro-acid with sodium-amalgam, crystallises in white prisms, which effloresce over sulphuric acid. The *silver salt*, $C^6H^4(NH^2)PO(OAg)^2$, is a pale yellow precipitate, freely soluble in ammonia and nitric acid. The *copper salt*, $C^6H^4(NH^2)PO^2Cu$, is a bluish-green powder soluble in acetic acid. The *lead salt*, $C^6H^4(NH^2)PO^2Pb$, is a white amorphous precipitate.

Diazophosphénylic Acid. When a hot solution of the amido-compound in nitric acid is treated for some time with nitrous acid and then concentrated, the nitrate of diazophosphénylic acid, $C^6H^4.N^2.NO^2PO^2H^2 + 3H^2O$, separates out, and may be purified by pressing and crystallisation from nitric acid. It forms white prisms, is freely soluble in water and alcohol, sparingly in ether. It contains three molecules of water. It gives off 2 mols. H^2O at 130° , melts at 188° , and explodes at a few degrees higher. The *potassium salt*, $C^6H^4.N^2.O^2PO^2K^+ + H^2O$, is obtained as a precipitate consisting of small yellow needles. The *barium salt*, $C^6H^4.N^2.O^2PO^2Ba + 3H^2O$, crystallises from water in reddish-yellow glistening needles, which lose their water at 130° ; it is very explosive. The *silver salt*, $C^6H^4.N^2.O^2PO^2Ag^2$ is a red, amorphous, very sparingly soluble powder. The *lead salt*, $C^6H^4.N^2.O^2PO^2Pb$, is a yellow powder. The aqueous solution of the free acid is very stable, and does not give off nitrogen on boiling; it does not show the reaction of nitric acid until boiled with an alkali (Michaelis a. Benziger, *loc. cit.*)

PHOSPHENYLOUS ACID, $C^6H^5PO^2 = C^6H^5.P(OH)^2$ (Michaelis a. Ananoff, *Ber.* vii. 1688). This acid is formed when phosphényl dichloride is allowed to drop gradually into water, and separates on heating the liquid product to boiling, and filtering, either as an oil or in white leaflets:

100 pts. of boiling water dissolve 211 pts. of phosphénylous acid, while 100 pts. of cold water dissolve only 7.23 pts. The acid is readily soluble in alcohol, and melts at 70° , but decomposes at a higher temperature (170° – 250°) in accordance with the equation

Probably this decomposition takes place in two stages, thus:—

Phosphénylous acid is monobasic, and reduces mercuric chloride to calomel, sulphurous acid to sulphur, and silver nitrate to the metallic state.

The following salts have been obtained:— $C^6H^5PO^2KH + 2H^2O$, deliquescent needles; $C^6H^5PO^2H(NH^4)$, deliquescent rhombic tables; $(C^6H^5PO^2H)^2Ca$, foliated crystalline mass; $(C^6H^5PO^2H)^2Ba + 4H^2O$, shining rhombic crystals; $(C^6H^5PO^2H)^2Pb$, slightly soluble needles; $(C^6H^5PO^2H)^2Fe$, white amorphous precipitate.

When phosphénylous acid is treated with phosphorus pentachloride, an action takes place, resulting in the formation of phosphényl oxychloride, thus:

This reaction points to the conclusion that phosphénylous acid is correctly represented by the constitutional formula $OPH(OH)C^6H^5$, and phosphorous acid by the corresponding formula $OPH(OH)^2$, as already inferred from the action of that acid on phosphényl tetrachloride (p. 1575).

When phosphénylous acid is subjected to the action of *chlorine*, the H-atom attached to the phosphorus is not replaced by chlorine, but a brisk reaction takes place, resulting in the formation of pyrophosphénylous acid and phenyl-phosphine, the latter being subsequently carbonised by the excess of chlorine.

PHOSPHIDES. On Hydrogen Phosphide, see PHOSPHINES.

Metallic Phosphides.—Many of these compounds are decomposed by heat, and cannot therefore be obtained by the action of phosphorus on metals at high temperatures under ordinary atmospheric pressure. Complete union, however, may frequently be effected by heating the metals in the form of wire or foil with phosphorus in sealed glass tubes, protected by enclosing them in iron tubes filled with

magnesia, a dull red heat being kept up for eight to ten hours, and the tubes being opened in an atmosphere of carbon dioxide.

Copper phosphide, CuP , thus prepared, is a pulverulent silvery mass, of sp. gr. 5.14, insoluble in hydrochloric acid, oxidised by nitric acid. *Magnesium phosphide* is a bluish-green very unstable substance, oxidising rapidly to phosphate on exposure to the air. *Silver phosphide*, AgP , is black and very brittle; leaves metallic silver when ignited. *Cadmium phosphide*, Cd_2P , is a greyish or sometimes silver-white mass, dissolving in hydrochloric acid with evolution of phosphine. *Zinc phosphide*, Zn_2P_2 , is a crystalline mass. No other phosphide of zinc was obtained by the process above described (comp. v. 1073; vi. 1134; vii. 1214).

Tin phosphides, SnP , and SnP_2 , were obtained according to the proportion of phosphorus used. The first is tin-white; the second black and brilliant, and splits into thin plates. Sp. gr. of $\text{SnP}_2 = 4.91$ at 12° . This compound is not attacked by hydrochloric acid. Aluminium and mercury were not attacked when heated with phosphorus as above described; iron only superficially (Emmerling, *Ber.* xii. 152).

On the preparation of Metallic Phosphides by precipitation, see vii. 949.

PHOSPHINES. *Phosphine*, or *Gaseous Hydrogen Phosphide*, PH_3 , may be obtained in the pure state by decomposing phosphonium iodide with water, or by the action of sodium ethylate on phosphorus in alcoholic solution; aqueous or alcoholic solutions of ammonia yield only traces of phosphine. The formation of spontaneously inflammable phosphine by the action of aqueous alkalis on phosphorus is not prevented by the presence of glycerol.

Phosphine reduces *sulphuric acid* with extraordinary energy, but without at first producing any visible alteration; as soon however as the acid is saturated with the gas, it suddenly becomes so hot that the phosphine is set on fire. If the liquid be cooled, sulphurous acid is formed and sulphur deposited. With an alcoholic solution of *mercuric cyanide*, phosphine produces a yellow precipitate extremely sensitive to light and containing mercury, cyanogen, phosphorus, and hydrogen. A similar, but red-brown, and still more easily alterable precipitate, is formed in an alcoholic solution of mercuric cyanide by *arsine*, AsH_3 . *Stibine*, SbH_3 , reduces mercuric cyanide even more energetically, throwing down nothing but metallic mercury (W. R. Hodgkinson, *Chem. News*, xxxiv. 14, 67, 167).

Phosphine is slowly decomposed by *sulphur* in sunshine, yielding reddish-yellow phosphorus sulphide and hydrogen sulphide: $2\text{PH}_3 + 6\text{S} = \text{P}_2\text{S}_3 + 3\text{H}_2\text{S}$ (F. R. Jones, *Chem. Soc. J.* xxix. 648).

On the preparation of *Phosphine Hydriodide*, or *Phosphonium Iodide*, PH_4I , see A. W. Hofmann (vii. 951). On the reaction which takes place in the formation of this compound, see K. Lissenko (*Ber.* ix. 1313; *Chem. Soc. J.* xxxi. 46).

Liquid Hydrogen Phosphide, P^2H_4 .—The following method of preparing this compound for lecture experiments is described by Hofmann (*Ber.* vii. 531). A thick-walled U-tube, three or four millimeters in diameter, and provided with a stop-cock on each arm, is surrounded by a freezing mixture (16° to 20°), and receives the phosphoretted hydrogen prepared from 30 to 50 grams of freshly made calcium phosphide. A wide glass tube in the cork of the generating flask, dipping beneath the surface of the water (at about 60°), serves for the introduction of the phosphide. While the liquid is being collected, spontaneously inflammable phosphoretted hydrogen escapes; and on displacing this by a stream of carbon dioxide, the bright flame is replaced by a scarcely luminous green flame, of so low a temperature that a taper cannot be lighted at it. This flame is caused by the liquid phosphoretted hydrogen in the stream of carbon dioxide coming in contact with the air. The carbon dioxide may be replaced by a stream of some combustible gas, e.g. hydrogen, and a luminous flame again obtained.

On Isopropyl-, Isobutyl-, and Isopentyl- or Amyl-phosphines, see vii. 955.

Trimethylphosphine Hydriodide, $\text{P}(\text{CH}_3)_3\text{HI}$, is formed by heating 1 pt. carbon disulphide with 3 pts. phosphonium iodide in a sealed tube at 150° :

On cooling, the contents of the tube solidify to a brown crystalline mass mixed here and there with red needles; and this product, mixed with soda-ley and agitated with ether, yields trimethylphosphine with all its characteristic properties (iv. 609). The red crystals contain phosphorus, sulphur, and iodine (Drechsel, *J. pr. Chem.* [2], x. 180).

Phenylphosphine, $\text{C}_6\text{H}_5\text{PH}_2$. *Phosphaniline* (Michaelis, *Ber.* vii. 6; Köhler a. Michaelis, *ibid.* x. 807). This base is formed, together with phosphenylic and

phosphenylous acids, by the action of alcohol on phosphenyl-hydrogen iodide, according to the equation,

the phosphenylous acid being further resolved on heating into phosphenylic acid and phenylphosphine:

The residue left after distilling off the alcohol yields, when heated above 250° , a mixture of water, benzene, and phenylphosphine, the phosphenylic acid being first resolved into water and pyrophosphenylic acid, $2\text{C}^6\text{H}^5\text{PO}^3\text{H}^2 = \text{H}^2\text{O} + \text{C}^{12}\text{H}^4\text{P}^2\text{O}^3$, and the latter at higher temperatures into benzene and P^2O^3 , which with the water forms metaphosphoric acid. Phenylphosphine may also be prepared by adding phosphenyl dichloride (p. 1575), holding phosphorus in solution, gradually, and with agitation, to excess of alcohol, and distilling the filtrate in a stream of carbon dioxide.

Phenylphosphine is a colourless, highly-refractive liquid, having a pungent odour, a density of 1.001 at 15° , and boiling at 160° – 161° . With free oxygen it combines energetically to phosphenylous acid, the action being attended with inflammation unless the liquid is cooled. It also unites directly with sulphur, forming phenylphosphine sulphide, $\text{C}^6\text{H}^5\text{PH}^2\text{S}$, a thick liquid, which on continued heating breaks up into isophosphophenyl sulphide (p. 1575), phenylphosphine, and hydrogen sulphide: $2\text{C}^6\text{H}^5\text{P}^2\text{SH} = \text{C}^6\text{H}^5\text{PS} + \text{C}^6\text{H}^5\text{PH}^2 + \text{H}^2\text{S}$. The action of sulphur on phenyl phosphine likewise gives rise to a crystalline substance, insoluble in ether, which appears to be triphosphenyl sulphide, $(\text{C}^6\text{H}^5\text{P})^3\text{S}$; it melts at 138° , is also soluble in hot nitric acid, and does not separate on cooling.

Phenylphosphonium iodide, $\text{C}^6\text{H}^5\text{PH}^2\text{I}$, is produced by direct combination of phenylphosphine with dry hydrogen iodide. It forms white needles, which, by heating in an indifferent gas, or by contact with water, are resolved into hydriodic acid and phenylphosphine.

Phenylphosphine is but slightly soluble in concentrated hydrochloric acid, but the solution mixed with platinum chloride yields phenylphosphonium platinumchloride, $(\text{C}^6\text{H}^5\text{PH}^2\text{Cl})^2\text{PtCl}_4$.

Diethylphenylphosphine, $\text{C}^6\text{H}^5\text{P}(\text{C}^2\text{H}_5)^2$ (Michaelis a. Ananoff, *Ber.* viii. 493). The zinc-chloride of this base is formed by gradually adding phosphenyl dichloride to zinc-ethyl, both being diluted with benzene; and remains on removing the solvent by distillation as a viscous liquid which, when decomposed by sodium carbonate and then saturated with caustic potash, yields the free base in the form of an oily layer.

Diethylphenylphosphine is a colourless pungent liquid, boiling at 221.9° (corr.), and having a specific gravity of 0.9571 at 13° . It is but slowly oxidised in the air, but if heated in oxygen, it explodes and deposits carbon. Pure chlorine causes its ignition, but chlorine diluted with air converts it into the normal chloride, $\text{PC}^6\text{H}^5(\text{C}^2\text{H}_5)^2\text{Cl}^2$, and sulphur unites with it, forming the corresponding sulphide. Diethylphenylphosphine, though a distinctly characterised base, does not yield well-defined salts. With hydrochloric acid, it yields a solid monohydrochloride and a liquid dihydrochloride, both unstable and ill defined; platinum chloride added to the hydrochloric solution of the base throws down a crystalline yellow salt, containing $[\text{PC}^6\text{H}^5(\text{C}^2\text{H}_5)^2\text{HCl}]^2\text{PtCl}_4$.

Diethylphenylphosphine chloride, $(\text{C}^2\text{H}_5)^2\text{C}^6\text{H}^5\text{P}^2\text{Cl}^2$, is produced as above indicated, and forms a thick oily liquid which fumes slightly in the air, and has a faint but not disagreeable odour. Heat decomposes it, with separation of carbon, but if strongly cooled, it becomes solid and crystalline; when dissolved in cold water, it yields an opalescent solution which becomes clear on heating.

Diethylphenylphosphine oxide, $(\text{C}^2\text{H}_5)^2\text{C}^6\text{H}^5\text{PO}$, is very slowly formed by direct oxidation, but can be readily prepared by evaporating an aqueous solution of the chloride and removing the last trace of hydrochloric acid by means of silver oxide. The crude oxide when distilled condenses to a crystalline solid, which has a fruity odour, is very soluble and deliquescent, melts at 55° – 56° , and boils above 360° .

Diethylphenylphosphine sulphide is a viscous substance, formed by the direct combination of the base with sulphur. It is almost insoluble in water, has an unpleasant smell, solidifies in a freezing mixture, and boils above 360° .

Triethylphenylphosphonium iodide, $(\text{C}^2\text{H}_5)^3\text{C}^6\text{H}^5\text{PI}$, is produced by the direct union of diethylphenylphosphine and ethyl iodide, and forms white needles which melt at

115°, and are not decomposed by aqueous potash, but silver oxide acts on it, with production of the hydroxide, a white crystalline alkali, capable of precipitating aluminium or copper salts. The *platinochloride*, $[\text{PC}^6\text{H}_5(\text{C}^6\text{H}_5)_2\text{Cl}]^2 + \text{PtCl}_4$, crystallises in orange-yellow leaflets, melting below 100°.

Methyl-diethylphenylphosphonium iodide, $(\text{CH}_3)(\text{C}^6\text{H}_5)_2\text{C}^6\text{H}_5\text{PI}$, prepared in the same manner as the corresponding triethyl-compound, methyl iodide being used in the place of ethyl iodide, forms snow-white crystals, which melt at 95°. The *hydroxide* and *platinum salt* resemble those of the ethyl-base.

Dimethylphenylphosphine, $(\text{CH}_3)_2\text{PC}^6\text{H}_5$, prepared like the diethyl compound, forms a colourless, highly refracting liquid, insoluble in water, boiling at 192° (corr.), and having a specific gravity of 0.9768 at 11°. It has a much more powerful odour than the diethyl-base; oxidises quickly in the air; and forms a solid mono- and a liquid di-hydrochloride.

The iodides, hydroxides, and platinochlorides of ethyldimethylphenylphosphonium and trimethylphenylphosphonium have likewise been prepared.

PHOSPHINIC ACIDS. These acids, represented by the formulæ PH^2RO^3 and PHER^2O^3 , or $\text{PO}(\text{OH})^2\text{R}$ and $\text{PO}(\text{OH})\text{R}^2$, R denoting a monatomic alcohol-radicle, are formed from the primary and secondary phosphines by fixation of 3 and 2 atoms of oxygen, and may be regarded as orthophosphoric acid, $\text{PO}(\text{OH})^3$, in which one or two of the OH-groups is replaced by an alcohol-radicle. The phosphinic acids of the fatty series have already been described (vii. 956); also phenylphosphinic acid, $\text{PO}(\text{OH})^2\text{C}^6\text{H}_5$, at p. 1576 of this volume under the name of *phosphenylic acid*.

Diphenylphosphinic acid, $\text{PO}(\text{OH})(\text{C}^6\text{H}_5)_2$, is formed by heating 1 mol. phosphenyl dichloride with 2 mols. mercury-diphenyl and benzene to 160°. It dissolves in boiling hydrochloric acid, and crystallises from boiling nitric acid in long needles. It is insoluble in water, slightly soluble in cold alcohol, and melts at 174°. Its silver salt crystallises in white silky needles (Michaelis a. Graff, *Ber.* viii. 922, 1304).

PHOSPHOBENZENE, or DIPHOSPHENYL, $\text{C}^{12}\text{H}^{10}\text{P}^2 = \text{C}^6\text{H}_5\cdot\text{P}=\text{P}\cdot\text{C}^6\text{H}_5$, is prepared by adding phosphenyl dichloride (16 gr.) in drops to phenylphosphine (20 gr.) in a reflux apparatus through which a stream of dry hydrogen is passed:

At the end of the reaction, which must be assisted by gentle heating to remove the last traces of hydrochloric acid, a residue is obtained consisting of diphosphenyl in the form of a yellowish powder insoluble in hot water, also in alcohol and in ether. This compound, on exposure to air, is oxidised to diphosphenyl oxide, or

By oxidation with *nitric acid* it is converted into phosphenylous or phosphenylic acid. *Chlorine* acts violently on phosphobenzene, producing inflammation; when diluted with carbon dioxide it acts more regularly, forming phosphenyl dichloride; oxyphosphobenzene similarly treated yields the dichloride and oxychloride of phosphenyl. *Hydrochloric acid* converts phosphobenzene into phenylphosphine and phosphenylic acid. *Strong sulphuric acid* decomposes it, with evolution of sulphur dioxide; dilute sulphuric acid and alkalis do not act upon it.

PHOSPHOMOLYBDATES. See MOLYBDENUM (p. 1335).

PHOSPHORITE. See PHOSPHATES (p. 1597).

PHOSPHORUS. *Occurrence in Ancient Iron.*—A scoria produced in Roman or Etruscan times from the specular iron ore of Elba, was found to contain 0.34 per cent. P^2O^3 , which is about eight times as great as the proportion in the natural ore, usually 0.04 per cent. A piece of metallic iron from the same district gave 0.096 per cent. P, other specimens from 1.08 to 1.10 per cent. (A. E. Arnold, *Chem. News*, xl. 138). On the proportion of phosphorus in Belgian iron ores and in the pig-iron and malleable iron prepared therefrom, see p. 1111.

Determinations of the Specific Gravities and Expansion-coefficients of phosphorus in the solid and liquid states have been made by Pisati a. De Franchis (p. 935). According to the same authorities phosphorus melts at 44.4°–44.5°, and boils under 762 mm. at 278.3°.

On the *Phosphorescence* of phosphorus, see Joubert (*Compt. rend.* lxxviii. 1853).

Crystals of Phosphorus.—W. D. Hermann (*Ber.* vi. 1415) has obtained crystals of phosphorus by placing a piece of phosphorus at one end of a tube, exhausting the air with a Sprengel pump, then melting the phosphorus, and keeping it in the dark. After a few hours, a row of shining points becomes visible, and these in two or three days

grow to distinct crystals, attaining in a month or six weeks a diameter of 3 to 5 mm. They are colourless and transparent, with diamond lustre and great refracting power, but become yellow and opaque on exposure to light. According to Maskelyne's measurements, they exhibit the faces of the cube, octohedron, dodecahedron, tetrakis-hexahedron, triakis-octohedron, and ikositetrahedron.

Red phosphorus may be obtained in the crystalline state by heating ordinary phosphorus nearly to the softening point of difficultly fusible glass (about 503°). The allotropic phosphorus thus obtained had in the compact state the aspect of a violet-black fused body, with conchoidal fracture and translucent edges, and the crystals were found in cavities of this mass (Troost a. Hautefeuille, *Compt. rend.* lxxvi. 1175). The same authors also find (*ibid.* lxxviii. 748) that the density and heat of combustion of red phosphorus vary continuously according to the temperature at which it has been prepared, and it is only in the crystallised state, obtained as above, that red phosphorus exhibits the characters of a definite chemical species. Its density in this state is 2.34 at 0°, and 1 gram in burning evolves 5272 gram-degrees of heat. Phosphorus prepared by heating for 650 hours in an oil-bath at 265° has a density of 2.148 at 0°, and 1 gram in burning gives out 320 heat-units more than crystallised red phosphorus; ordinary red phosphorus gives out 580 units more; the product obtained at 360° has a density of 2.19, and gives out 290 units more; that prepared at 500° has a density of 2.293 and likewise a greater heat of combustion, whereas the heat of combustion of the fused product obtained at 180° is less by 50 units than that of crystallised red phosphorus. Hittorf, by heating red phosphorus to 530° in a vacuum tube and allowing the vapour to condense in the upper part heated only to 447°, obtained it in red crystals which he describes as rhombohedrons approaching very nearly to the cube (vi. 933).

The phenomena attending the conversion of ordinary into red phosphorus are analogous to those observed in the conversion of liquid cyanic acid into cyanilide (vi. 518). The vapour of the phosphorus first acquires the maximum tension corresponding with the temperature at which the change takes place; and this tension gradually diminishes during the formation of the red phosphorus, till it attains a certain value representing the transformation-tension at the same temperature. The following table shows the two tensions observed at different temperatures:

Temperature	Maximum-tension	Transformation-tension
360	3.2	0.12 atm.
440	7.5	1.75
487	—	6.80
494	18.0	—
503	21.9	—
510	—	10.8
511	26.2	—
531	—	16.0
550	—	31.0
577	—	56.0

The black phosphorus, obtained, according to Blondlot (iv. 503), by sudden cooling of melted phosphorus, previously distilled in a stream of hydrogen, is, according to E. Ritter (*Compt. rend.* lxxviii. 192), a mixture of phosphorus with phosphide of arsenic. From pure phosphorus Ritter was unable to obtain a black modification; but after fusion under a solution of arsenious or arsenic acid, and remaining for some time in contact with the solution, it became black; and on treating it with carbon sulphide, the pure phosphorus dissolved out, and phosphide of arsenic was left in the form of a shining black powder having nearly the composition As₂P.

Reactions. Detection. Estimation.—Pure phosphorus precipitates gold, copper, and palladium from solutions of their salts in the metallic state; silver as phosphide; whereas platinum, uranium, nickel, iron, zinc, cadmium, and cobalt are not precipitated by phosphorus (Böttger, *Chem. Centr.* 1878, 208; compare iv. 506).

On the detection and estimation of Phosphorus in Iron and Steel, see IRON (p. 1102). For the detection and separation of phosphorus in *Food-residues*, and other fatty substances, A. von Bastelaer proposes a method depending on the solubility of phosphorus in ether, and its complete indifference to a strong solution of ammonia. The substance to be tested, after being mixed with water to a thin paste, is briskly agitated several times with ether; the ether is left to evaporate at the ordinary temperature in a shallow dish; and the residue is carefully treated with warm water at 50°–60°, whereupon the phosphorus, with part of the fat, collects together under the water, to a liquid spherical mass from which the fat may be dissolved out by strong aqueous ammonia (*N. Jahrb. Pharm.* xl. 24; *Pharm. J. Trans.* [3], iv. 322).

Detection and Estimation of Phosphoric Acid.—Small quantities of free phosphoric acid in solution may be detected by introducing a ring of platinum wire, wetted with the liquid, into a colourless hydrogen-flame close to the end of the efflux-tube, where-upon, if phosphorus is present, the flame immediately becomes green. The presence of soda interferes with the reaction; if metallic or earthy-alkaline phosphates are present, it may be developed by moistening the loop of wire with sulphuric acid (F. Selmi, *Gazz. chim. ital.* 1876, 34).

The following method of detecting and estimating phosphoric acid by the blow-pipe, depending on the opalescence imparted to a borax-bead by a certain quantity of phosphoric acid, is described by A. W. Ross (*Chem. News*, xxxii, 217). This opalescence is directly produced by the phosphates of the alkali-metals and heavy metals, also by cast-iron, many tourmalines, axinite, and similar minerals. Its strength may be determined by comparison with a bead of the same size, to which the same degree of opalescence has been imparted by a standard solution of phosphoric acid. The phosphates of the alkaline earths form white beads like snow-balls; those of the earths form amorphous fragments which float in the transparent borax-bead. To set free the phosphoric acid from these compounds, and develop the opalescence, the borax-bead is fused with about a third of its volume of magnesium sulphate, and the white opaque bead thus produced is made clear again by cautious addition of a small quantity of potassium carbonate. If now into a bead thus prepared there be introduced the smallest quantity of a phosphate, it will be decomposed on heating, and as the bead cools, the characteristic opalescence will appear, and may be compared with that of a standard bead prepared in a similar manner.

Estimation as Ammonio-magnesium Phosphate.—The degree of accuracy attainable by this method has been carefully investigated by T. R. Ogilvie (*Chem. News*, xxxi, 274; xxxii, 5, 12, 70). The experiments were made on a quantity of hydro-disodic phosphate containing 0.2021 gram P^2O_5 , with a magnesia mixture containing in 1 c.c. 0.0613 gram $MgCl_2$, 0.1401 gram NH_4Cl , and 0.0191 gram NH_3 , the same excess of free ammonia being present in each experiment. The volume of solution was in every case about 100 c.c., and the time allowed for precipitation six hours. When the excess of magnesia used did not exceed 58 per cent. of that required, the results were absolutely correct; with a large excess of magnesia the results became rather excessive. When sulphate of magnesium was substituted for the chloride, accurate results were obtained with an excess of 13 per cent., but with 58 per cent. and upwards they became too high. Chloride of ammonium, up to 2.5 grams, diminished but very slightly the weight of precipitates obtained with an excess of 13 and 58 per cent. of magnesia. Sulphate of ammonium, up to 0.5 gram, had no effect with an excess of 58 per cent. magnesia. Oxalate and citrate of ammonium, or mixtures of the two, considerably diminished the precipitate when a small excess of magnesia was present, but with a large excess of magnesia the results were much too high. There is thus for every proportion of oxalate and citrate a proportion of magnesia which will give an accurate result by a balance of errors. When the solution contained 0.035 gram ferric oxide, 0.013 gram alumina, 0.5 gram ammonia, and 1 gram of citric acid, the results with an excess of 58 per cent. and upwards of magnesia were rather too high. With the quantities of ferric oxide, alumina, and citric acid doubled, the results with the same magnesia were distinctly too low. The citric acid in both cases was sufficient to yield a precipitate free from iron. When the alumina was increased to 0.26 gram, and the citric acid to 4 grams, the results became very low. In the last two cases an increase in the proportion of magnesia did not increase the precipitate. The removal of the mother-liquor, and the solution and reprecipitation of the ammonio-magnesian phosphate, is attended with loss if the original precipitate is pure, but if it contains an excess of magnesia the result may be correct, the excess of magnesia hindering the solvent action of the ammonium salts. Precipitation at the boiling heat gives accurate results with pure solutions and a small excess of magnesia, but with a large excess of magnesia the results are higher than in the cold. In presence of ammonium oxalate and the other salts mentioned above, the results obtained at boiling heat are more irregular, and generally higher than in the cold.

The general conclusion drawn from these experiments is that the opposite errors due to the solubility of ammonio-magnesium phosphate in oxalate and citrate of ammonium, and to the precipitation of basic salts in presence of excess of magnesia, are the cause of a wide range of results in commercial analyses, and that accuracy can be obtained only when the phosphoric acid exists as an alkaline salt, or is brought into this condition by the molybdic method.

In a paper read by E. M. Dixon, before the Philosophical Society of Glasgow, January 18, 1875, it is shown that the presence of large quantities of sodium or ammonium sulphate increases the weight of the ammonio-magnesian phosphate. Also

that oxalate and citrate of ammonium retard precipitation; that, in the case of the oxalate, precipitation is complete in twenty-four hours: but that with a large proportion of citrate, and a small excess of magnesia, precipitation is incomplete even then. As the solvent action of the oxalate is certainly, and that of the citrate probably, removable by the use of excess of magnesia and long standing, Dixon suggests such a procedure as the first stage of the determination, the impure precipitate to be finally redissolved and reprecipitated, in presence of a very small excess of magnesia.

J. Hughes (*Chem. News*, xxxi. 209) observes that the magnesia-method, when applied to the analyses of native phosphates, is apt to give results in excess, unless the original hydrochloric acid solution of the mineral has been previously evaporated to dryness, as in the contrary case the ammonia-magnesium phosphate may become mixed with more or less magnesium silicate.

As Phosphomolybdate.—O. Hehner (*Analyst*, 1879, 23) gives a review of all that has been previously contributed towards the estimation of phosphoric acid, either directly as phospho-molybdate, or indirectly by dissolving this precipitate in ammonia, precipitating with magnesia mixture, and weighing as magnesium pyrophosphate. The objection to weighing the dried phospho-molybdate precipitate is that it is found to contain percentages of phosphoric anhydride varying from 3.14 to 3.90. The explanation given by Lipowitz, that this variation is due to MoO_3 accompanying the precipitate in varying proportions, is confirmed by Hehner, who also finds that the quantity of MoO_3 precipitated increases with the temperature at which the precipitation took place. Hence low temperatures (30° – 35° C.) should be employed. The molybdic solution is best prepared according to the directions of Fresenius, by dissolving 1 pt. of molybdic acid in 4 pts. of ammonia of 0.96 sp. gr., and pouring this solution slowly into 15 pts. of nitric acid of 1.2 sp. gr., avoiding all rise of temperature. When the precipitate was thrown down by means of the above molybdate solution in a solution previously nearly neutralised by addition of ammonia, and at a low temperature, it was found to be free from molybdic acid. It was soluble in 21,186 pts. of water, in 8,117 of strong alcohol, and in 13,513 of dilute alcohol: hence this precipitate may be washed with dilute alcohol without sensible loss, and this liquid is to be preferred to water, because it does not cause the precipitate to pass through a good filter. Direct experiment showed that no one of these three liquids dissolved the precipitate sensibly when used for washing.

To obtain the precipitate in a form suited for weighing, the phosphate is precipitated with the precautions already mentioned, avoiding too great concentration of the solution, which encourages the simultaneous precipitation of molybdic acid. This precipitate is washed with dilute alcohol, leaving as much of the precipitate as possible in the beaker, the precipitate is dissolved from the beaker and filter by ammonia solution, and this solution is evaporated to dryness on the water-bath, the evaporation being several times repeated after the successive addition of small quantities of water. The precipitate then consists of ammonium phosphate and acid ammonium molybdate. It may be dried at 100° and weighed, a constant weight being quickly obtained, since all the ammonia which ordinarily escapes during the drying process has been removed by the repeated evaporations. The weight of this precipitate divided by 23.5 gives the weight of the phosphoric anhydride present. Comparative results obtained by this method and by weighing as magnesium pyrophosphate were closely concordant. The precipitation requires only two or three hours, and the estimation may be easily completed in a day. The molybdic acid may be recovered from the residues by acidifying with nitric acid, adding sodium phosphate, dissolving the precipitate formed on heating in ammonia, precipitating the phosphate with magnesia mixture, and the molybdic acid from the filtrate by nitric acid. The molybdic acid is then filtered, washed, and dried.

See also Finkener (*Ber.* x. 1638; *Chem. Soc. J.* xxxvi. 275).

According to R. W. Atkinson (*Chem. News*, xxxv. 127), silica, if present, must be separated previous to the precipitation of phosphoric acid by ammonium molybdate; according to E. H. Jenkins, on the other hand (*Sill. Am. J.* [3], xi. 204), the presence of silica does not interfere with the result.

O. Kerschelt (*Dingl. pol. J.* cccxxv. 158) precipitates phosphoric acid with a solution of *potassium molybdate* prepared by dissolving 1 pt. MoO_3 in 2 pts. KHO in 12 pts. hot water, mixing the cooled liquid with a solution of 1 pt. tartaric acid in 4 pts. water and with 15 pts. nitric acid, then boiling and filtering. The precipitate of *potassium phospho-molybdate* dried at 120° contains 3.956 per cent. P_2O_5 .

As Uranic Phosphate (iv. 544).—According to A. Kitchen (*Chem. News*, xxvii. 199), this salt is least soluble and is precipitated most quickly when the solution contains a sufficient quantity of ammonium acetate, and only a slight excess of acetic acid. After washing, drying, and ignition, the precipitate should be repeatedly

moistened with nitric acid and re-ignited till its colour is no longer green, but pure yellow. Its composition is represented most nearly by the formula $U^2P^{2O}^{11}$ or $2UO^3.P^{2O}^3$ [$U = 240$].

Belohoubek (*Böhm. Ges. Ber.* 1876, Heft. 4), after precipitating the phosphoric acid with uranic acid, reduces the precipitate to uranous phosphate, determines the quantity of uranium in the resulting acid solution by means of a standard solution of permanganate, and thence deduces the amount of phosphoric acid present.

As Bismuth Phosphate.—E. Dransard (*Amer. Chem.* vi. 401) recommends a modification of Chancel's method (iv. 543), which consists in carefully neutralising the acid solution with sodium carbonate before adding the bismuth nitrate, and fusing the dried precipitate of bismuth phosphate and other basic bismuth salts with sodium carbonate in a small porcelain crucible, whereby sodium phosphate and metallic bismuth are formed. The sodium phosphate is dissolved out by water, the solution acidulated, and the phosphoric acid precipitated by ammoniacal solution of calcium chloride as calcium phosphate, which is then treated in the usual way.

Volumetric Methods.—An acidimetric method for the estimation of phosphoric acid and the quantity of alkali which must be added to a mixture of soluble alkaline phosphates to bring it up to trisodic phosphate, Na^3PO^4 , is described by Maly a. Hinterberger (*Zeitschr. anal. Chem.* 1876, 417). The solution is first made alkaline with excess of soda-ley, so as to ensure the formation of trisodic phosphate, and barium chloride is then added, whereby the whole of the phosphoric acid is precipitated as barium phosphate, and it only remains to determine the excess of alkali added by back titration, which may be done with normal hydrochloric acid, using corallin as indicator. The liquid must be kept hot, but it is not necessary to remove the barium phosphate by filtration. The method is especially applicable to free phosphoric acid and alkaline phosphates, but the solution must not contain any salts of the heavy metals.

J. Macagno (*Gazz. chim. ital.* 1874, 567) estimates phosphoric acid volumetrically by precipitating it as ammonium phosphomolybdate, reducing the molybdic acid therein contained to Mo^2O^3 with zinc and sulphuric acid, and reoxidising this oxide after removal of the zinc with a standard solution of permanganate.

A modification of Liebig's volumetric method of estimating phosphoric acid, viz. precipitation in acetic acid solution with a standard solution of ferric chloride, with potassium ferrocyanide as indicator, has been proposed by W. Stoddart (*Amer. Chem.* v. 235), consisting in the substitution of *thiocyanate* for the ferrocyanide, whereby the recognition of the end-reaction is greatly facilitated.

Comparison of various Methods.—M. Joulin (*Chem. News*, xxvii. 228, 309, 314) has made comparative experiments on the various methods in use for the estimation of phosphoric acid, from which he draws the following conclusions. The precipitation of phosphoric acid by *ammonia and a magnesium salt*, in presence of an excess of ammonium citrate, affords an excellent method of separating phosphoric acid from the bases usually associated with it, but the results obtained by direct weighing of the precipitate are too high. The separation of phosphoric acid by *uranic nitrate* from a solution slightly acidulated with acetic acid, gives results which are too low, if lime, ferric oxide, or alumina is likewise present. The most exact results are obtained by precipitating the phosphoric acid with a solution containing 400 grams citric acid and 20 g. magnesium carbonate in 200 litres of water mixed with 500 c.c. ammonia of 22° B. This liquid is to be diluted with water to 1 litre. In the resulting precipitate the phosphoric acid is estimated by titration with uranium solution.

Experiments on the relative accuracy of various methods of estimating phosphoric acid have also been made by Abesser, Jani a. Märcker (*Zeitschr. anal. Chem.* 1873, 239; *Chem. Soc. J.* xxvii. 387), who find that in the precipitation with magnesia-mixture, exact results are obtained only when this mixture is prepared with chloride instead of sulphate of magnesium, as in the latter case, the precipitate is always mixed with a certain quantity of basic magnesium sulphate which, if not compensated by the solubility of the ammonio-magnesium phosphate, is likely to make the results too high. With regard to the time required for complete precipitation of the phosphoric acid, they find that with a solution containing 0.1 to 0.15 g. phosphoric acid in 110 c.c. three or four hours standing is quite sufficient. For the separation of phosphoric acid from the alkaline earths or heavy metals, they recommend precipitation with ammonium molybdate, the digestion being continued from four to six hours.

Among volumetric methods of estimating phosphoric acid, Abesser, Jani a. Märcker have especially examined the uranium method and the results yielded by it with acid calcium phosphates, which, as a rule, they find to be lower than those obtained by gravimetric methods.

Fresenius, Neubauer, and Luck (*Zeitschr. f. anal. Chem.* x. 138) found that from a warm acetic acid solution of calcium phosphate, especially if the solution be too concentrated, calcium phosphate may separate as such, and thus escape titration with uranium acetate; and they proposed to modify the reaction so as to add the phosphatic solution to a measured quantity of uranium solution as long as potassium ferrocyanide gives a reaction (vii. 969). Abesser, Jani a. Märcker used solutions of phosphates in cold acetic acid, and applied heat only when nearly the whole of the phosphoric acid had been precipitated by the uranium acetate. They found, however, that the quantity of P_2O_5 in aqueous extracts from superphosphates, when determined gravimetrically by means of magnesium chloride mixture, differed on an average by +29 per cent. from that obtained by a uranium solution titrated with a solution of sodium phosphate. On examining the latter precipitate for lime, after separating the phosphoric acid by Reissig's method, and the uranium by means of ammonium sulphide, 4.15 per cent. of CaO were found. Hence they inferred that the strength of the uranium solution used in estimating phosphoric acid in superphosphates should be determined by a solution of the latter instead of by sodium phosphate. For this purpose they employ tricalcic phosphate free from neutral phosphate and other admixtures, dissolved in the least possible excess of nitric acid, the strength of the solution being determined as above, by evaporation and ignition and weighing of the residual tricalcic phosphate. They further observe that in presence of ammonia salts, the titration of the phosphoric acid may come out somewhat too low, but that this error may be avoided by using a solution of uranic acetate instead of nitrate, or by titrating the solution of uranium nitrate with calcium phosphate, with addition of ammonium salts. Solutions of uranic acetate containing excess of acetic acid are not altered by light.

For the estimation of 'soluble' phosphoric acid—in case the process of washing out is found to be too tedious, and recourse must be had to digestion—it is recommended that the time of digestion be shortened as much as possible, in order to avoid increase or diminution of the quantity of soluble phosphoric acid during the process.

Separation of Phosphoric Acid from Ferric Oxide and Alumina.—The various methods proposed for the separation of phosphoric acid from these bases have been subjected to comparative examination by W. Flight (*Chem. Soc. J.* xxviii. 592) with the following results: The method of separating phosphoric acid from alumina by means of *silica* or *potassium silicate*, proposed by Berzelius and by Fuchs (iv. 548), not only presents great difficulties, but gives results which are too low. That of Otto, which consists in precipitating with *magnesia-mixture* while the alumina and ferric oxide are held in solution by *tartaric acid* (iv. 547), is likewise inexact, because the precipitated ammonio-magnesium phosphate is apt to get mixed with a magnesium salt of the organic acid; and further, as shown by Knapp (*Zeitschr. anal. Chem.* iv. 151), and confirmed by Pribram (*ibid.* v. 208), because the ammonio-magnesium phosphate is soluble in excess of tartaric acid, especially when alumina is present. The method is not improved by the substitution of citric for tartaric acid. Wackenroder's method of digesting the hydrochloric acid solution of ammonia and phosphoric acid with *barium carbonate* and then with *potash-ley* (*Arch. Pharm.* [2], lvii. 17), also gives inexact results, inasmuch as the phosphoric acid is not wholly carried down in the baryta-precipitate. The *molybdic acid method*, as proposed by Sonnenschein (iv. 546) and modified by Ogilvie (p. 1583), yields sufficiently accurate results, but it requires a nitric acid solution, which is not always available. Rose's method of separating phosphoric acid from ferric oxide by fusion with an *alkaline carbonate* always yields an iron oxide still retaining phosphoric acid. Reynoso's method, modified by Reissig, of precipitating the phosphoric acid as *stannic phosphate*, cannot be used in presence of large quantities of iron oxide or alumina; it is, moreover, affected with an error arising from the contamination of commercial tin with arsenic. Rose's method with *mercurous nitrate* (iv. 543) is likewise defective on account of the difficulty, already pointed out by Schweizer (*Ber.* iii. 310), of completely expelling the nitric acid by evaporation, and even as modified by Munroe (vii. 967), it is not applicable to the separation of phosphoric acid from ferric oxide. The method of precipitating the phosphoric acid and ferric oxide together by ammonia, and digesting the precipitate with *ammonium sulphide*, requires, according to Schweizer, a repetition of the treatment, and even then does not yield exact results. The *bismuth-method* (p. 1585) is likewise inapplicable; that of Chancel, which consists in precipitating the phosphoric acid with *nitrate*, or better with *carbonate of silver*, is also inexact in presence of iron oxide or alumina, inasmuch as these oxides are precipitated at the same time, and the silver phosphate cannot be completely dissolved out from the precipitate by ammonia.

The following is, according to Flight's experiments, the best method of separating phosphoric acid from ferric oxide and alumina: (1). From Ferric oxide. The

slightly acid solution is completely reduced by a stream of hydrogen sulphide, then treated with excess of ammonium sulphide, heated nearly to boiling, filtered, and the precipitate is washed with water containing hydrogen sulphide. The whole of the phosphoric acid is then found in the filtrate. (2). From Alumina. The solution of the aluminium phosphate is mixed with an excess of caustic soda sufficient to keep the whole of the alumina in solution, and then treated with a quantity of barium chloride sufficient to throw down all the phosphoric acid in the form of barium salt. The liquid is left at rest for some hours, and protected from access of carbonic acid, then filtered, and the precipitate is washed with water containing soda, the addition of which is necessary, as the barium phosphate would be decomposed by pure water, and the estimation of the phosphoric acid would then come out much too low. (3). From Ferric Oxide and Alumina together. The solution, not too acid, is mixed, according to Chancel's method (i. 154), with excess of sodium thiosulphate, boiled for some time, and filtered, whereupon the whole of the iron remains in solution, together with part of the phosphoric acid, whilst the alumina is precipitated together with the rest of the phosphoric acid. The separation may then be effected by the methods (1) and (2) above described. If the phosphoric acid is not in excess with respect to the alumina, the whole of it will be found in the precipitate, and the iron-solution will be free from it.

The precipitates formed by excess of phosphoric acid in ferric and aluminic solutions are represented by the formulæ $7Al^2O^3 \cdot 6P^2O^5$ and $7Fe^2O^3 \cdot 6P^2O^5$.

H. Pellet (*Bull. Soc. Chim.* [2], xxvii. 106) estimates phosphoric acid, alumina, and ferric oxide when they occur together in solution as follows: 1. The solution is mixed with excess of ammonia and calcium chloride, whereby a precipitate is formed consisting of alumina, ferric oxide, and calcium phosphate. This precipitate is ignited and weighed; the residue is dissolved in hydrochloric acid; the phosphoric acid is determined in one portion of the solution with uranium; the ferric oxide in another by stannous chloride; and the alumina is estimated by difference.

F. Jean (*Compt. rend.* lxxviii. 1305) estimates phosphoric acid, in presence of lime, iron oxide, alumina, &c., by dissolving the phosphate under examination in strong nitric acid, mixing the filtered solution with a slight excess of ammonia, redissolving the precipitate in acetic acid, and precipitating the phosphoric acid with uranium acetate. The resulting precipitate after washing, drying, and ignition contains 20.05 per cent. P^2O^5 .

A. Classen separates phosphoric acid from certain bases by precipitation with *potassium oxalate*. This method is applicable to salts whose bases, like calcium, are at once completely precipitated by soluble oxalates; also to salts of manganese, zinc, cobalt, and nickel, the metals of which are precipitated as double oxalates easily decomposed by excess of acetic acid, which dissolves the alkaline oxalate and completely precipitates the oxalate of the heavy metal. For the details of this method, see *Zeitschr. anal. Chem.* 1879, 189, 373; *Chem. Soc. J.* 1879, xxxvi. 979 and 1054-1056.

B. W. Gerland (*Chem. News*, xxxiii. 133) modifies the oxalic acid method commonly used in the analysis of phosphorites on the ground that the presence of oxalic acid hinders the precipitation of ferric and aluminic phosphates by means of alkaline acetates. The weighed sample of phosphorite is dissolved in nitric or hydrochloric acid; the liquid, neutralised as nearly as possible without formation of a permanent precipitate, is boiled, and mixed with a slight excess of an oxalate; acetate of sodium or ammonium is then added; and the liquid is removed from the source of heat. On cooling, the whole of the lime separates as an oxalate in the form of a heavy powder. The iron and aluminium are best removed from the filtrate by precipitation with ammonium sulphide at a gentle heat. The precipitate consists of iron sulphide and aluminium phosphate, together with silica, which obstinately adheres to it. The determination of the phosphoric acid in it is effected by the molybdc method.

Haloid Compounds of Phosphorus.

Chlorides. An elaborate investigation of the action of these compounds on the acids of phosphorus has been made by A. Geuther (*J. pr. Chem.* [2], viii. 359).

1. *Action of Phosphorus Oxychloride on Orthophosphoric Acid.*—When these substances are mixed in accordance with the equation, $2PO^4H^3 + POCl^3 = 3PO^3H + 3ClH$, no apparent change is produced until the mixture is heated on the water-bath, the reaction then taking place in the manner just indicated. The use of a smaller proportion of phosphorus oxychloride leads to the formation of pyrophosphoric acid:

Pyrophosphoric acid is however produced when metaphosphoric acid and orthophos-

phoric acid are heated together, and hence it is probable that in the above case the pyrophosphoric acid may result from a secondary reaction between metaphosphoric acid and orthophosphoric acid.

2. *Action of Phosphorus Pentachloride on Orthophosphoric Acid.*—The following reaction takes place in the cold :

but, if excess of phosphoric acid is employed, the action recommences on the application of heat, the phosphorus oxychloride then acting on orthophosphoric acid according to the equation previously given.

3. *Action of Phosphorus Trichloride on Orthophosphoric Acid.*—When a gentle heat is employed, the principal reaction appears to be as follows :

but free phosphorus and pyrophosphoric acid are also produced, probably owing to secondary reactions.

4. *Action of Phosphorus Pentachloride on Metaphosphoric Acid.*—The reaction, $\text{PO}^3\text{H} + 2\text{PCl}^5 = 3\text{POCl}^3 + \text{ClH}$, takes place when these substances are heated on a water-bath; and even when a smaller proportion of pentachloride is employed, the reaction is the same, no chloride analogous to metaphosphoric acid being produced. Metaphosphoric acid is not attacked when digested with phosphorus oxychloride or phosphorus trichloride.

5. *Action of Phosphorus Pentachloride, Phosphorus Trichloride, and Phosphorus Oxychloride on Pyrophosphoric Acid.*—The following reactions take place on the application of heat :—

When pyrophosphoric acid is treated with a small proportion of phosphorus pentachloride, the reaction is—

6. *Action of Phosphorus Oxychloride and Phosphorus Pentachloride on Phosphorous Acid.*—The reactions which are represented by the following equations are regarded by Geuther as evidence that the true formula of phosphorous acid is $\text{P}(\text{OH})^3$, and not $\text{O}=\text{PH}(\text{OH})^2$.

7. *Action of the Chlorides of Phosphorus on Hypophosphorous Acid.*—Phosphorus trichloride acts energetically on hypophosphorous acid, the reaction being apparently as follows :

Orthophosphoric acid is also produced, but probably arises from the action of phosphorus trichloride on phosphorous acid. These results indicate $\text{PH}(\text{OH})^2$ as the formula of hypophosphorous acid. All attempts to obtain the chloride of this acid were fruitless.

The action of phosphorus oxychloride is similar to that of the trichloride, but more energetic, and after it has ceased, a fresh reaction may be produced by heating the mixture to 100° . The two stages may be represented as follows :—

The former reaction is probably the resultant of the following :—

Hypophosphorous acid thus behaves like a mixture of PH^3 and $\text{P}(\text{HO})^3$; when heated to 110° – 115° , it is decomposed into these substances, but when the heat reaches 250° the phosphorous acid decomposes. The action of phosphorus pentachloride on hypophosphorous acid is energetic, red phosphorus being deposited; but after sufficient of the pentachloride has been added, and the mixture has been heated, nothing remains but phosphorus oxychloride and phosphorus trichloride. The reactions are probably as follows :—

- (1.) $3\text{PH}(\text{OH})^2 + 6\text{PCl}^3 = 6\text{POCl}^3 + \text{PCl}^3 + 2\text{P} + 9\text{HCl}$.
- (2.) $6\text{PH}(\text{OH})^2 + 6\text{POCl}^3 = 6\text{PO}^3\text{H} + 2\text{PCl}^3 + 4\text{P} + 12\text{HCl}$.
- (3.) $6\text{PO}^3\text{H} + 12\text{PCl}^3 = 18\text{POCl}^3 + 6\text{ClH}$.
- (4.) $6\text{P} + 9\text{PCl}^3 = 15\text{PCl}^3$.

ultimate result:

The action of the chlorides of phosphorus on the Ethylic Ethers of Phosphorous and Phosphoric Acids, has been examined by E. Chambon (*Jenaische Zeitschrift*, [2], iii.; 2nd Suppl. p. 97).

1. *Ethyl Phosphite and Phosphorus Trichloride*.—These substances react upon each other to form ethylphosphorous chloride (phosphorus oxethylchloride), in accordance with the equation:

but the product is further acted on by the ethyl phosphite present, as is seen in the following reaction.

2. *Ethyl Phosphite and Phosphorus Oxethylchloride*.—When these bodies are mixed together in molecular proportions and gradually heated to 120° , ethyl chloride is given off, whilst free phosphorus and ethyl phosphate are left behind:

3. *Ethyl phosphite and phosphorous acid* do not act upon each other at 200° .

4. *Phosphorus Oxethylchloride and Phosphorous acid* heated together evolve ethyl chloride and hydrogen chloride, free phosphorus and phosphoric acid remaining in the retort:

5. *Phosphorus Oxethylchloride and Phosphorus Trichloride* do not act upon each other even when boiled together.

6. *Phosphorus Oxethylchloride* heated to 165° in a sealed tube is resolved into ethyl chloride, phosphorus trichloride, free phosphorus, and phosphoric anhydride:

7. *Phosphorus Oxethyloxychloride (ethylphosphoric chloride)* heated to 140° in sealed tubes is resolved into ethyl chloride, phosphorus oxychloride, and phosphoric anhydride:

8. *Ethyl Phosphate and Phosphorus Oxychloride* heated to 110° in a sealed tube combine together to form phosphorus oxethyloxychloride, in accordance with the equation:

The following reactions related to those just described have been observed by Geuther (*ibid.* 104).

Phosphorus Oxethylchloride and Phosphorus Pentachloride do not act upon each other at the ordinary temperature, but when they are heated together in the water-bath, the following reaction takes place:

Phosphorus Oxethylchloride and Phosphorus Pentabromide, when heated together, yield phosphorus oxybromochloride, phosphorus tribromide, and ethyl bromide:

Ethyl Phosphite and Phosphorus Pentachloride react upon each other in the manner indicated by the equation:

Phosphorus Oxethyloxychloride and Phosphorus Pentabromide react to form phosphorus oxybromochloride, phosphorus oxybromide, and ethyl bromide:—

The foregoing reactions all point to the conclusion that phosphorus pentachloride and pentabromide, in their action on the oxethyl-compounds of trivalent phosphorus, behave like mixtures of trichloride and free chlorine, and of tribromide and free bromine, respectively.

Trichloride, PCl_3 .—Ira. Remsen (*Sill. Am. J.* [3], xi. 365) finds that this compound is easily converted into POCl_3 by the action of ozone, and regards this reaction as affording an additional proof of the quinquivalence of phosphorus.

According to Michaelis (*Ber.* viii. 504), when phosphorus trichloride in small quantities is added without cooling to water at ordinary temperatures, the liquid at first remains perfectly clear, but as soon as a certain quantity of the trichloride has been decomposed, and the temperature has consequently risen, the liquid becomes turbid, and a small quantity of phosphorus separates out. When, on the contrary, the trichloride is dropt into boiling water, not a trace of phosphorus separates out. Ice-cold water, into which phosphorus trichloride is dropt, also remains clear, but becomes turbid and deposits a small quantity of phosphorus when heated. According to Geuther, on the other hand (*Jenaische Zeitschrift* [2], iii. 2nd Suppl. 116), the precipitation observed by Michaelis takes place only when the phosphorus chloride contains arsenic, and the solid body thus separated is not phosphorus but arsenic.

The action of phosphorus chloride on *potassium thiocyanate* gives rise to the formation of a compound, $\text{C}^2\text{H}^{15}\text{N}^4\text{S}^2\text{O}$, which crystallises in white slender needles (*Lössner, J. pr. Chem.* [2], vii. 474).

Oxychloride, POCl_3 , and *Ethoxychloride*, $\text{PO}(\text{OC}^2\text{H}^5)\text{Cl}^2$.—On the reactions of these bodies with the acids and other compounds of phosphorus, see p. 1587-9.

Pentafluoride, PF_5 (T. E. Thorpe, *Liebig's Annalen*, clxxxii. 201-205).—When phosphorus pentachloride is gradually added to arsenic trifluoride (obtained by heating arsenic trioxide with fluorspar and sulphuric acid), a violent reaction takes place, resulting in the formation of arsenic trichloride and phosphorus pentafluoride, in accordance with the equation :

Phosphorus pentafluoride is a colourless gas, having a very pungent odour, and attacking the mucous membranes. It fumes in the air, and reacts with water forming phosphoric and hydrofluoric acids. Its density is 6.23, that of hydrogen being 1 (theory requires 6.3). Under the pressure of 12 atmospheres at 7° , it exhibits no marked deviation from Boyle's law.

The gas neither burns nor supports combustion. It is not affected by the passage of electric sparks through it, either when pure, or when mixed with hydrogen or oxygen. It combines with dry ammonia to form a yellowish-white solid body, represented by the formula $2\text{PF}_5 \cdot 5\text{NH}_3$. A solution of the gas in aqueous ammonia deposits, on evaporation, crystals of ammonium phosphate, $\text{H}^2(\text{NH}_4\text{P})\text{O}^4$, and ammonium and hydrogen fluoride, $\text{HF} \cdot \text{NH}_4\text{F}$.

ACIDS OF PHOSPHORUS.

The Melting Points, and the Heats of Fusion, Solution, and Formation of these acids, have been determined by J. Thomsen (*Ber.* vii. 966) with the following results:—

<i>Heat of Fusion.</i>		
	Melting point	Heat of fusion
PO^4H^3	38.6°	2520 gram-degrees
PO^3H^3	70.1	7070
PO^2H^3	17.4	2400
<i>Heat of Solution.</i>		
	Crystallised acid	Fused acid
$(\text{PO}^4\text{H}^3, \text{Aq})$. . .	+ 2690 gram-degrees	5210 gram-degrees
$(\text{PO}^3\text{H}^3, \text{Aq})$. . .	— 130	2940
$(\text{PO}^2\text{H}^3, \text{Aq})$. . .	— 200	2200
<i>Heat of Formation.</i>		
Crystallised acid . . .	$\left\{ \begin{array}{l} (\text{P}, \text{O}^4, \text{H}^3) \\ (\text{P}, \text{O}^3, \text{H}^3) \\ (\text{P}, \text{O}^2, \text{H}^3) \end{array} \right.$	$\left\{ \begin{array}{l} 302560 \text{ gram-degrees} \\ 227680 \\ 139950 \end{array} \right.$
Fused acid	$\left\{ \begin{array}{l} (\text{P}, \text{O}^4, \text{H}^3) \\ (\text{P}, \text{O}^3, \text{H}^3) \\ (\text{P}, \text{O}^2, \text{H}^3) \end{array} \right.$	$\left\{ \begin{array}{l} 300040 \\ 224610 \\ 137550 \end{array} \right.$

HYPOPHOSPHOROUS AND PHOSPHOROUS ACID. 1591

On the reactions of these acids with the Haloid compounds of Phosphorus, see pp. 1587-1589.

Hypophosphorous Acid, $\text{H}^3\text{PO}^2 = \text{HP}(\text{OH})^2$. On the crystallisation of this acid, see vii. 965. The barium salt, $\text{BaH}^2\text{P}^2\text{O}^4 + \text{H}^2\text{O}$, forms monoclinic crystals, having the axial ratio $a : b : c = 2.0017 : 1 : 1.5760$, and the angle $ac = 80^\circ 27'$ (Topsoë, *Wien. Akad. Ber.* 2 Abth. lxi. 261). Compare Rammelsberg (*Chem. Soc. J.* 1873, 5). Sp. gr. 2.718 at 10° , and 2.891 at 17° ; of the *magnesium salt*, $\text{MgH}^2\text{P}^2\text{O}^4 + 6\text{H}^2\text{O}$, 1.5886 at 12.5° , and 1.5681 at 14.5° (C. A. Mohr, *Sill. Am. J.* [3], xiv. 281).

Reactions.—When perfectly dry *hydrogen iodide* is passed over hypophosphorous acid, a violent reaction takes place, accompanied by great rise of temperature. The products are phosphorous acid and phosphonium iodide:

2. Dry *sulphur dioxide* reacts with hypophosphorous acid in the manner indicated by the equation:

the chief products being phosphorous acid and free sulphur. At the same time, however, hydrogen sulphide is evolved, and some phosphoric acid is formed. The former of these bye-products is due, as found by direct experiment, to the action of free sulphur on hypophosphorous acid; the latter to the action of sulphur dioxide on phosphorous acid at high temperatures.

3. *Nascent hydrogen* does not act either on free hypophosphorous acid or on its alkaline salts (Ponndorf, *Jenaische Zeitschrift*, [2], iii. 2nd Suppl. p. 45).

By prolonged boiling of normal *lead hypophosphite* with lead hydrate, $3\text{PbO} \cdot \text{H}^2\text{O}$, a basic lead salt, $\text{P}^2\text{O}^2\text{H}^4\text{Pb}^3$, is obtained in the form of a homogeneous yellowish-grey powder made up of microscopic needle-shaped transparent crystals:

The constitution of this salt may be represented by the formula

and affords further evidence of the correctness of the formula $\text{HP}(\text{OH})^2$ usually assigned to hypophosphorous acid, according to which it contains an atom of trivalent phosphorus associated with 1 at. hydrogen and two hydroxyl-groups (Ponndorf).

Phosphorous Acid, PH^3O^3 . Of the two constitutional formulæ by which this acid is represented, viz. $\text{P}'''(\text{OH})^3$ and $\text{OP}^*\text{H}(\text{OH})^2$, the first certainly affords the readiest explanation of the formation of the acid by the action of water on phosphorus trichloride, and of most of the reactions between the halogen-compounds and acids of phosphorus investigated by Geuther (p. 1588). On the other hand, Michaelis a. Ananoff infer, from the action of phosphorus pentachloride on phosphenyloous acid, and of phosphenyl tetrachloride on phosphorous acid, that the latter is correctly represented by the formula $\text{OPH}(\text{OH})^2$ (p. 1578). Geuther, however, points out (*Jenaische Zeitschrift* [3], iii. 2nd Suppl. 116) that the former of these reactions, which gives rise to phosphenyl oxychloride, $\text{POCl}^2 \cdot \text{C}^6\text{H}^5$, together with POCl^3 , PCl^3 and HCl , may be satisfactorily explained on the hypothesis that phosphenyloous acid has the constitution $\text{P}(\text{C}^6\text{H}^5)(\text{OH})^2$, [analogous to $\text{P}(\text{OH})^3$], and that the phosphorus pentachloride acts like a mixture of PCl^3 and Cl^2 , thus:

A similar explanation is given by Geuther of the action of phosphenyl tetrachloride on phosphorous acid, based on the known fact that phosphenyl tetrachloride is resolved by heat into chlorine and the corresponding dichloride, thus:

It must be admitted, however, that the explanation of these reactions given by Michaelis a. Ananoff is more simple and direct.

Crystallised phosphorous acid may be prepared by heating the trichloride to 60° and passing the vapour by means of a current of dry air through two flasks each

containing about 100 grams of water cooled to 0° . In about four hours the contents of the first flask are found to be saturated with the phosphorous chloride and converted into a thick crystalline mass of phosphorous acid. The adhering liquid may then be drained off, and the crystals washed with small quantities of ice-cold water, and finally dried in a vacuum (Grosheintz, *Bull. Soc. Chim.* [2], xxvii. 433).

Metallic Phosphites. For the analysis of these salts, Kraut a. Precht (*Liebig's Annalen*, clxxvii. 274) recommend Rose's process, which consists in dissolving the phosphite in hydrochloric acid, adding an excess of pulverised mercuric chloride, and heating the mixture on a water-bath till the resulting mercurous chloride is completely deposited, collecting the deposit on a weighed filter, drying it at 100° , and weighing. If the filtrate be then freed by hydrogen sulphide from mercury and other bases which interfere with the determination of phosphoric acid, the amount of that acid produced may be estimated by precipitation with magnesia mixture, and a verification of the result thereby obtained.

Barium Phosphite, according to Kraut (*Lieb. Ann.* clxxvii. 274) and Rammelsberg (*Ber.* ix. 1877), has the composition BaHPO_3 , and not $\text{Ba}^2\text{H}_4\text{P}_2\text{O}_7$, formerly assigned to it (vi. 937). It is apt to retain small quantities of phosphate—acid phosphate, $\text{BaH}^2\text{P}_2\text{O}_8$, according to Rammelsberg—which may disguise its true composition. Rammelsberg also finds by new experiments that the barium salt, like other phosphites, gives off hydrogen, and leaves a residue of phosphide and pyrophosphate, a result which throws light on a long-established error respecting the composition of the phosphites of the alkaline-earths and of nickel as well as the abnormal results obtained in the analysis of the magnesium and zinc salts (vi. 937).

Trisodic Phosphite, PO_3Na^3 .—To obtain this salt, a concentrated solution of disodic phosphite, $\text{PO}_3\text{Na}^2\text{H}$, is first prepared by mixing pure phosphorous acid with sodium hydroxide to slight alkaline reaction, and to this solution is added a quantity of strong aqueous soda-solution equivalent to 4 mols. NaHO . The mass is then left to itself for two hours, after which strong alcohol is added, the supernatant alcoholic liquid is separated from a viscid syrup which settles down, and the latter, consisting of pure trisodic phosphite, is purified by repeatedly pouring strong alcohol upon it, and working it up therewith, and finally dried in a vacuum over sulphuric acid (C. Zimmermann, *Liebig's Annalen*, clxxv. 1).

Triethylic Phosphite, $\text{PO}_3(\text{C}^2\text{H}^5)^3$.—This compound, which Railton obtained by the action of phosphorus trichloride on dry sodium ethylate (iv. 533), is prepared by Zimmermann as follows: The sodium ethylate, after being brought to a constant weight by heating it at 180° – 200° , is pulverised and mixed with ether free from alcohol and water; the mixture is well cooled; and the phosphorous chloride is added by drops with constant agitation. When the action is complete, the ethereal solution is decanted from the resulting sodium chloride, the ether is distilled off, and the remaining liquid is rectified at the heat of an oil-bath in a stream of hydrogen till it boils constantly at 188° .

Triethylic phosphite saponified with caustic potash is converted into phosphorous acid. By gradual oxidation with nitric acid it yields phosphoric together with oxalic acid. Heated in oxygen gas it is gradually oxidised to triethylic phosphate, $\text{PO}(\text{OC}^2\text{H}^5)^3$. This last reaction is effected by filling a small flask containing the phosphorous ether with oxygen, closing it, passing in a fresh portion of the gas after the first has been absorbed, and repeating this treatment several times. At a high temperature triethylic phosphite is resolved into phosphine, phosphoric acid, and probably ethylene. From these reactions Zimmermann infers that triethylic phosphite has the constitution $\text{P}(\text{OC}^2\text{H}^5)^3$, and not $\text{PO}(\text{C}^2\text{H}^5)(\text{OC}^2\text{H}^5)^2$, as in that case it should yield by saponification, not phosphorous acid, but ethyl-phosphinic acid, $\text{PO}(\text{C}^2\text{H}^5)(\text{OH})^2$.

Hypophosphoric Acid, $\text{H}_2\text{P}_2\text{O}_6 = (\text{HO})^2\text{OP}=\text{PO}(\text{OH})^2$ (T. Salzer, *Liebig's Annalen*, clxxvii. 322; xciv. 28). This acid, intermediate in composition between phosphorous and metaphosphoric acids, is one of the constituents of the acid liquid (Pelletier's *acide phosphatique*) formed when phosphorus partially covered with water is exposed to the air (iv. 499). It may be separated in the form of a sparingly soluble sodium salt by treating the mixed acids with sodium carbonate or acetate.

Pure hypophosphoric acid is best obtained by treating the lead-salt suspended in water with hydrogen sulphide. Its aqueous solution is strongly acid, colourless, and inodorous, and may be boiled without decomposition, but when evaporated to a syrupy consistence, it is resolved by heat into phosphorous and phosphoric acids. In its behaviour with reagents, it is intermediate between phosphorous and phosphoric acids, which circumstance accounts for its having been so long overlooked in a mixture of these acids.

The acid is perfectly stable in aqueous solution, and is not affected by strong acids in the cold, but when boiled with dilute sulphuric or nitric acid, it is resolved, at a certain state of concentration, into phosphorous and phosphoric acids. The solution of the acid is not oxidised by dilute hydrogen peroxide when boiled therewith, and is not affected by potassium chromate, chlorine, or iodine, even at the boiling heat; neither does it reduce mercuric, auric, or platinic chloride. It produces in solutions of silver a white precipitate, which does not blacken on boiling. The solution is oxidised by potassium permanganate, slowly in the cold, and very rapidly when heated, being converted into phosphoric acid. It is not affected by hydrogen sulphide, sulphur-trioxide, or nascent hydrogen.

Hypophosphoric acid is quadribasic. Its salts mostly react like those of hypophosphorous and phosphorous acids, but are much more stable. At high temperatures they give off hydrogen or phosphine, leaving a metallic phosphide or phosphate.

The *tetrasodic salt*, $\text{Na}^4(\text{PO}^3)^2 + 10\text{H}^2\text{O}$, obtained by gradually adding a solution of 1 pt. sodium carbonate to a solution of 1 pt. of the trisodic salt in 50 pts. water, separates in needle-shaped monoclinic crystals exhibiting the faces 0P , $2\text{P}\infty$, ∞P , $\frac{1}{2}\text{P}$. Cleavage parallel to $\infty\text{P}\infty$. Axes $a : b : c = 2.0435 : 1 : 1.9055$. Angle $ac = 35.55^\circ$. Twin-lamellæ according to the basal face are of somewhat frequent occurrence. The plane of the optic axes is the plane of symmetry: the acute bisectrix passes through the obtuse angle between 0P and $2\text{P}\infty$. The crystals dissolve in 50 times their weight of water. The cold saturated solution turns turmeric paper dark brown, and when mixed with a strong solution of sodium carbonate, deposits the normal salt unaltered.

Trisodiohydric Hypophosphate, $\text{Na}^3\text{H}(\text{PO}^3)^2 + 9\text{H}^2\text{O}$, is obtained by acting with less than one part by weight of crystallised sodium carbonate on one part of the acid sodium hypophosphate in solution. Its solution has an alkaline reaction. It loses its water of crystallisation at 100° , and at higher temperatures suddenly takes fire, and burns with a steady flame, giving off phosphoretted hydrogen gas, and leaving a white enamel. The crystals are monoclinic and have a strong vitreous lustre. Combination 0P . — P , 6P , 3P . — $6\text{P}\infty$, $\infty\text{P}\infty$, $4\text{P}\infty$, $5\text{P}\infty$, $20\text{P}\infty$, $4\text{P}\infty$, $6\text{P}\infty$; mostly tabular through predominance of 0P , sometimes also elongated in the direction of the orthodiagonal, and in that case broadly wedge-shaped, from predominant development of the lower face 0P and the front face — $6\text{P}\infty$. Some crystals exhibit twin-formation parallel to a face normal to the clinodiagonal, the crystals having then a rhombic habit. Axes $a : b : c = 1.5788 : 1 : 0.4348$, Angle $ac = 60^\circ 43'$. The plane of the optic axes is perpendicular to the plane of symmetry, acute bisectrix nearly perpendicular to 0P . Axial angle large.

Disodio-dihydric Hypophosphate, $\text{Na}^2\text{H}^2(\text{PO}^3)^2 + 3\text{H}^2\text{O}$, is formed on adding sodium acetate in excess to the syrupy liquid produced by the oxidation of moist phosphorus in the air. It crystallises in oblique rhombic prisms, which dissolve in 45 pts. of cold and 5 parts of boiling water. When gently warmed it loses its water of crystallisation, and afterwards gives off inflammable hydrogen phosphide, leaving metaphosphate. At ordinary temperatures, both the salt and its aqueous solution are perfectly stable.

Acid Potassium Hypophosphate, $\text{K}^2\text{H}^2(\text{PO}^3)^2 + \text{H}^2\text{O}$.—Hypophosphoric acid neutralised with potassium carbonate and evaporated to syrupy consistency, gave crystalline nodules, which were not analysed. On adding an equal quantity of acid, crystals of the above salt were obtained. It is soluble in twice its weight of water at ordinary temperatures, but is insoluble in alcohol. When heated, it decomposes and gives off hydrogen which burns, whilst insoluble potassium metaphosphate is left behind. It crystallises in the orthorhombic system. The crystals are small, transparent, and colourless, and a combination of the prism ∞P and the pyramid, $2\text{P}2$, with $\infty\text{P}\infty$, $\text{P}\infty$ and 0P subordinate. Cleavage parallel to $\infty\text{P}\infty$. Axes $a : b : c = 0.6792 : 1 : 0.8508$.

The *normal potassium salt* could not be obtained pure. A concentrated solution of this salt will detect 0.003 grm. soda dissolved in 1 c.c. of water, and existing as chloride or sulphate.

In a solution of *lithium carbonate*, hypophosphoric acid produces a crystalline precipitate very sparingly soluble in water, easily soluble in excess of hypophosphoric acid.

Normal Ammonium Hypophosphate, $(\text{NH}^4)^4(\text{PO}^3)^2 + \text{H}^2\text{O}$, is obtained by heating a 5 per cent. solution of the acid with excess of ammonia. The crystals begin to effloresce immediately after drying. They appear to consist of quadratic prisms, with pyramidal end-faces, like those of zircon; they dissolve in thirty times their weight of water, forming a strongly alkaline solution, which on evaporation gives off ammonia, soon acquires an acid reaction, and ultimately leaves acid ammonium hypophosphate. The normal salt loses ammonia even on standing in the air, the clear crystals assuming

a turbid or milky appearance. When heated, they melt, with strong evolution of ammonia, and at last with combustion of the liberated hydrogen. This latter property is peculiar to the acid hypophosphates.

Acid Ammonium Hypophosphate, $(\text{NH}_4)^2\text{H}_2(\text{PO}^3)^2$.—If the solution of the previous salt be boiled until ammonia ceases to escape, the acid ammonium salt is formed, and may be obtained in needles; it is isomorphous with the acid potassium salt.

Normal Barium Hypophosphate, $\text{Ba}_2(\text{PO}^3)^2$, is thrown down from a solution of the normal sodium salt by barium chloride as an apparently amorphous precipitate. It is very sparingly soluble in water and in acetic acid, more soluble in hydrochloric and hypophosphoric acids. It is anhydrous, and when heated changes into reddish barium pyrophosphate without any appearance of combustion. Even by very rapid heating of the damp neutral barium salt, it is not possible to effect the oxidation of the hypophosphoric acid by means of the oxygen of the water.

Acid Barium Hypophosphate, $\text{BaH}_2(\text{PO}^3)^2 + 2\text{H}_2\text{O}$, is prepared from the acid sodium salt by precipitation with barium chloride. On mixing hot solutions of 4 pts. of the acid sodium salt in 180 pts. of water, and of 5 pts. of barium chloride in 10 pts. of water, and immediately filtering, beautiful crystals were obtained on cooling. They belong to the monoclinic system, and are needles formed of 0P and ∞P , with ∞P at the end. $a:b = 1.8480:1$. Angle $ac = 57^\circ 4'$. They are transparent, but become turbid when heated under water. With 1000 pts. of cold water, they give a solution which has an acid reaction, and becomes turbid on boiling, in consequence of the separation of neutral or basic barium hypophosphate. The crystals scarcely suffer any loss in weight by heating at 100° , but at 140° they slowly lose the 2 mols. of water of crystallisation, and at higher temperatures pass, with combustion of escaping hydrogen, into barium metaphosphate, which melts to a white bead.

Normal Calcium Hypophosphate, $\text{Ca}_2(\text{PO}^3)^2 + 2\text{H}_2\text{O}$.—In neutral calcium solutions, neutral sodium hypophosphate, even of 200,000-fold dilution, gives rise to a perceptible turbidity. With greater concentration the solution becomes alkaline after all the calcium has been precipitated. On the contrary, on adding calcium chloride to the sodium salt, the alkaline reaction disappears with completed precipitation of the hypophosphoric acid.

After washing, the originally very gelatinous precipitate quickly becomes denser and granular, and appears under the microscope as rounded but non-crystalline particles, and by continued washing suffers another change, whereby it becomes so finely divided as to go through the thickest double or triple filters. It is insoluble in water and almost insoluble in acetic acid, but easily soluble in hydrochloric and hypophosphoric acids. The crystallisation-water is very difficult to determine, as it begins to pass off at 100° , although the salt must be brought to 200° before all can be driven off, and then slight decomposition (*i.e.* oxidation) ensues.

Acid Calcium Hypophosphate could not be obtained in the solid form, as neither dilute nor concentrated hypophosphoric acid dissolves as much neutral calcium salt as is necessary for the formation of the acid salt. As only one calcium compound of this acid appears to exist, neutral calcium solutions may be titrated with normal sodium hypophosphate after addition of red litmus tincture. Alkaline reaction sets in after completed precipitation. The same remark applies to the hypophosphates of lead and other metals.

Phosphoric Acid (Ortho-), $\text{PO}(\text{OH})^3$. *Preparation.*—In preparing this acid by the oxidation of phosphorus with nitric acid, the best results are obtained, according to Krauthausen (*Arch. Pharm.* [3], x. 410), by using nitric acid having exactly the sp. gr. 1.197. With stronger acid, the action is too violent; with weaker, the oxidation of the phosphorus is very slow.

G. F. Markoe (*ibid.* ix. 531) adds to the mixture of phosphorus and nitric acid a small quantity of bromine, or better of bromine and iodine together, whereby phosphorus pentabromide is first formed, and then decomposed by the water present into hydrobromic and phosphoric acids, $\text{PBr}_5 + 4\text{H}_2\text{O} = 5\text{HBr} + \text{PO}_4\text{H}_3$. The hydrobromic acid thus formed is immediately decomposed by the nitric acid, yielding free bromine, nitrogen dioxide, and water:

and the free bromine acts on fresh quantities of phosphorus in the same manner as before. As a convenient proportion of the several materials, Markoe recommends 1 pt. phosphorus, 6 pts. nitric acid of sp. gr. 1.42, 1 pt. water, and enough bromine to give 1 pt. of that substance to 50 pts. of phosphorus. The phosphorus is first added to the mixture of nitric acid and water, and the bromine is then added by drops, the liquid being well cooled to prevent too violent action and consequent explosion. The

danger of explosion may, however, be more effectually guarded against by using a quantity of water three times as great as that above recommended, and bringing the phosphorus and bromine together before adding the nitric acid.

Crystallised phosphoric acid melts at 41.75° (at 38.6° according to Thomsen, p. 1590), and remains liquid till cooled down to 38° , at which point it solidifies, the temperature rising simultaneously to 40.5° (Berthelot, *Bull. Soc. Chim.* [2], xxix. 3).

On the Heat of Fusion, Solution, and Formation of Orthophosphoric Acid, according to Thomsen, see p. 1590.

METALLIC PHOSPHATES. Aluminium Salts. Millot (*Bull. Soc. Chim.* [2], xxii. 242) has prepared the salts $P^2O^5 \cdot Al^2O^3 \cdot 5H^2O$, $3P^2O^5 \cdot 2Al^2O^3 \cdot 20H^2O$, and $2P^2O^5 \cdot Al^2O^3 \cdot 8H^2O$ in the same manner as the corresponding ferric salts (p. 1599).

Barium Phosphate. According to Duvillier (*Compt. rend.* lxxxi. 1251), this salt [also the arsenate] is decomposed by nitric acid, yielding free phosphoric [or arsenic] acid and barium nitrate. If the nitric acid be so strong that the resulting nitrate will not dissolve in it, the decomposition will be complete.

Calcium Phosphates. Tricalcic Phosphate, $Ca_3(PO^4)^2$.—A solution of this salt in aqueous carbonic acid, which is used for therapeutic purposes, may be readily prepared by passing washed carbon dioxide into water in which the recently precipitated phosphate is suspended. The filtered solution becomes turbid on exposure to the air, and more quickly when heated, from loss of carbonic acid. The clear solution has an alkaline reaction, and gives all the reactions of orthophosphates (M. Chevrier, *Compt. rend.* lxxviii. 1184).

Experiments on the action of water on tricalcic phosphate, in continuation of those already noticed (vii. 974), have been made by R. Warrington (*Chem. Soc. J.* 1873, 983). By prolonged boiling, the tricalcic phosphate is converted into the salt $2Ca^2(OH)(PO^4)^2 = 3Ca^2(PO^4)^2 + Ca(OH)^2$. The solubility of tricalcic phosphate varies between 35,000 and 110,000 pts. water for 1 pt. of the phosphate. The decomposition of the salt by water begins at ordinary temperatures.

On the action of Water and other Solvents on Calcium Phosphate, gelatinous and ignited, and on Bone-substance, see BONE (p. 338).

The action of sulphuric acid on tricalcic phosphate has been examined by H. P. Armsby (*J. pr. Chem.* [2], xiii. 333), whose experiments show that when these compounds are mixed in molecular proportions, the acid acts upon only half the phosphate, forming monocalcic phosphate, thus:

and that the monocalcic phosphate then acts on the other half of the tricalcic salt, producing insoluble dicalcic phosphate, $Ca^2H^2(PO^4)^2$, thus:

See further SUPERPHOSPHATE (p. 1596).

On the composition of Bone Phosphate, see BONE (p. 337).

Dicalcic Phosphate, $Ca^2H^2P^2O^8$ or $CaHPO^4 = (OH)OP\begin{smallmatrix} O \\ \diagup \diagdown \\ O \end{smallmatrix}Ca$, is obtained by treating the monocalcic salt with hot water or alcohol (Erlenmeyer); also by precipitating calcium chloride with ordinary disodic phosphate; the latter is the mode of preparation usually employed in pharmacy. According to Hirschsohn (*Russ. Zeitschr. Pharm.* xvi. 385), it is essential, in preparing this salt by precipitation, to add an excess of calcium chloride. In this way, not much more than half of the calcium chloride used is converted into phosphate, but if the sodium phosphate be poured not too slowly into the solution of calcium chloride kept at ordinary temperature, and the resulting calcium phosphate, immediately after precipitation, be collected on a filter, washed, and dried at a moderate heat, the whole of the sodium phosphate will be utilised, and a preparation obtained which fully satisfies the conditions of constant composition, crystalline structure, and ready solubility in dilute acids. Under the influence of strong bases it is converted into the tricalcic salt.

Hydrated Dicalcic Phosphate, $CaH^2PO^6 = CaHPO^4 \cdot 2H^2O$, or, according to Erlenmeyer, $(OH)^4P.O.Ca(OH)$, is obtained by the action of cold water on monocalcic phosphate; also by triturating 1 mol. air-dried tricalcic phosphate with 1 mol. crystallised monocalcic phosphate, the conversion being completed in about a month. When heated at 100° , it loses water very gradually, 150 hours' heating being required to bring it to a constant weight. If moistened with water four or five times a day, it attains a constant weight in about 60 hours. Heated at 100° in a stream of dry air for 36 hours, it gives off 2 mols. water; when boiled with water, it loses the same quantity in half an hour. After 24 hours' boiling in a reflux apparatus, the water

exhibited only a faint acid reaction. After an hour's boiling in a reflux apparatus with absolute alcohol, the salt remained unaltered. When heated in a sealed tube placed in a water-bath, it lost after a certain time $1\frac{1}{2}$ mol. water, and it was only after 7 hours' heating that the quantity of water given up amounted to 2 mols. (Erlenmeyer).

Monocalcic Phosphate.—According to Erlenmeyer (*loc. cit.*), this salt, when prepared by the action of cold aqueous phosphoric acid on the tricalcic salt, has the composition $\text{CaH}^2\text{P}^2\text{O}^6 = \text{CaH}^1\text{P}^2\text{O}^5 \cdot \text{H}^2\text{O}$, or $(\text{OH})^1\text{P}^2\text{O}^5 \cdot \text{Ca} \cdot \text{O} \cdot \text{P}(\text{OH})^2$, and separates from the resulting solution on spontaneous evaporation in thin rhomboïdal plates, leaving when ignited a somewhat porous white opaque mass, which, when heated in the blowpipe-flame, melts at the edges only to enamel-like globules. The crystallised salt contains 1 mol. water, which it gives off at 100° , but recovers on exposure to the air. According to Erlenmeyer, it is not hygroscopic, although, as observed by Birnbaum (*Jahresb. f. Chem.* 1871, 281), it takes up water and deliquesces when placed near water under a bell-jar: for on subsequent exposure to the air it gives up this water again, and acquires a constant weight. According to Birnbaum, on the otherhand (*Ber.* vi. 898), it gives up only part of its water when thus exposed, and the proportion retained depends essentially on the state of humidity of the air, a maximum of atmospheric moisture corresponding to a minimum amount of phosphoric acid in the air-dried salt. The maximum difference between the amounts of phosphoric acid in the dry salt and that which had been altered by absorption of water from the air amounted to 8.8 per cent. The same variation in weight was observed under similar circumstances in a 'Noxana Superphosphate' from the manufactory of Packard and Co. in Ipswich. When drenched with somewhat less than 100 times its weight of water, it is resolved into the dicalcic salt and free phosphoric acid, $\text{CaH}^2\text{P}^2\text{O}^6 = \text{PO}^4\text{H}^3 + \text{CaHPO}^4 + \text{H}^2\text{O}$; but when a small quantity of it is introduced quickly and with agitation into 100 pts. of water, it dissolves completely in a short time. The precipitate formed on treating it with only 10 pts. water, redissolves completely in about three weeks if shaken up with the liquid every day; and that which is formed with 40 pts. water redissolves on similar treatment in a few days. But all these liquids, even that which is obtained with 1 pt. salt to 100 water, deposit a precipitate on boiling. When monocalcic phosphate was treated with cold absolute alcohol, nothing but phosphoric acid was found in solution after two days, and the residue contained lime and phosphoric anhydride in the proportion of $6\text{CaO} : 5.7\text{P}^2\text{O}^5$. By boiling the salt for an hour in a reflux apparatus with 50 times its weight of absolute alcohol, it is completely resolved into free phosphoric acid which dissolves in the alcohol, and insoluble CaHPO^4 . The same result was obtained with 30 pts. of absolute alcohol after two hours' boiling. Absolute ether dissolves the pure salt without alteration, and a specimen contaminated with adhering mother-liquor may be completely purified by agitation with ether.

Decomposition by Sodium Carbonate.—According to Frebault a. Destrem (*Bull. Soc. Chim.* [2], xxvii. 499), the reaction between monocalcic phosphate and sodium carbonate consists not, as generally supposed, in the separation of calcium carbonate and formation of sodium phosphate, but in the division of the phosphoric acid between the lime and the soda, and the elimination of the whole of the carbon dioxide as gas, so that it is correctly represented by the following equation proposed by Thénard, Soubeiran, and Lécaneu:

That the calcium phosphate cannot be decomposed by the sodium carbonate in such a manner as to form sodium phosphate and calcium carbonate, is plainly shown by the fact that calcium carbonate is, on the contrary, decomposed by sodium phosphate, with formation of basic calcium phosphate, together with sodium carbonate and free carbon dioxide at high and of sodium bicarbonate at low temperatures. The carbonates of barium, manganese, zinc, and magnesium are decomposed in like manner by sodium phosphate.

Superphosphate. The agricultural value of this mixture of monocalcic phosphate and gypsum, prepared by treating ground bones with sulphuric acid (*iv.* 555), depends on the proportion of soluble phosphate which it contains. Now this amount is found to decrease in course of time, in consequence of the gradual reconversion of the soluble into insoluble phosphate, and the change—known as 'retrogression'—is sometimes attributed to the formation of dicalcic phosphate by the action of the monocalcic salt on undecomposed tricalcic phosphate contained in the mixture. A. Millot, however (*Compt. rend.* lxxviii. 1134; lxxxi. 522; *Ber.* viii. 187), infers, from experiments in which 1 mol. pure tricalcic phosphate was treated with 2 and with 1 mol. sulphuric acid, that the reaction just mentioned takes place only when the quantity of sulphuric acid used is insufficient for the decomposition of the bone-ash,

and consequently the product does not contain any free phosphoric acid. In presence of free phosphoric acid, dry monocalcic phosphate is not resolved by heat into the dicalcic salt and free phosphoric acid. The retrogradation in solubility of the phosphoric acid in superphosphate is especially attributed by Millot to the presence of ferric oxide, alumina, and magnesia. A superphosphate prepared from the coprolites of the Ardennes, in which all the phosphoric acid was originally in the soluble state, was found after two years to contain only 10 per cent. soluble phosphoric acid, the remaining 90 per cent. having become insoluble. On washing this phosphate with hot water till all the gypsum was removed, the residue was found to be free from lime and to consist of the phosphates $\text{Fe}^2\text{O} \cdot 2\text{P}^2\text{O}^5$ and $2\text{Fe}^2\text{O} \cdot 3\text{P}^2\text{O}^5$.

A. Rümpler observes (*Zeitschr. anal. Chem.* vi. 151) that in superphosphates obtained by decomposition of phosphorites containing iron or alumina, a soluble ferric or aluminic phosphate is often formed, having the composition $\text{Fe}^2\text{O} \cdot [\text{PO}(\text{OH})^2]^3$ or $\text{Al}^2\text{O} \cdot [\text{PO}(\text{OH})^2]^3$, and that when this phosphate is treated with a large quantity of water, it is decomposed, with separation of neutral phosphate, $\text{M}^2\text{O} \cdot (\text{PO}^4)^2$, so that the results obtained in estimating the 'soluble' phosphoric acid are too low, and the more so as the quantity of water used in the digestion is greater. From numerous experiments bearing on this matter, Rümpler infers that in analysing superphosphates, the best mode of extracting from them the largest quantity of phosphoric acid is to lixiviate them with the minimum quantity of water, and not, as is the usual practice, to make up a given quantity of superphosphate with water to a litre and take an aliquot part of the liquid for the estimation of the phosphoric acid.

On the Analysis of Superphosphates, see also Joulie (*Compt. rend.* lxxvi. 631; *Chem. Soc. J.* 1873, 766); Erlenmeyer (*Ber.* ix. 1839; *Jahresb. f. Chem.* 1876. 984; *Chem. Soc. J.* xxxi. 759); Albert a. Siegfried (*Zeitschr. anal. Chem.* 1877, 182; *Jahresb. f. Chem.* 1877, 1044).

Action of Heat on Mixtures of Calcium Phosphates and Calcium Carbonate.—Pyro- and orthophosphates of calcium, as well as phosphates of the apatite class, are decomposed by ignition with calcium carbonate, in such a manner that part of the calcium oxide in the latter enters into chemical combination with the phosphate, and is not reconverted into CaCO^3 by the action of ammonium carbonate. The extent of this decomposition varies according to the proportions of the mixture, the intensity and duration of the ignition, and is considerably increased by a high temperature and the presence of organic matter. This mode of decomposition is determined, in the case of calcium pyrophosphate, by the tendency of that salt to pass into normal orthophosphate; in the case of the normal orthophosphates, by their tendency to form basic salts; and in apatites and similar compounds by the interchange between CaCl^2 and CaO . A strongly ignited mixture of 6 pts. pyrophosphate and 1 pt. carbonate yielded, after the CaO had been completely washed out with water, a residue of phosphate which was somewhat difficult to dissolve in nitric acid, and had the composition $7\text{CaO} \cdot 3\text{P}^2\text{O}^5 = \text{Ca}^7\text{P}^6\text{O}^{22}$; its formation may accordingly be represented by the equation :

Experiments with normal orthophosphate led to the formation of a salt having the composition $\text{Ca}^2\text{P}^2\text{O}^5 + \frac{1}{2}\text{CaO}$ or $5\text{Ca}^2\text{P}^2\text{O}^5 + \text{CaO}$. Apatite was decomposed in the manner shown by the equation :

These results indicate the necessity of determining the CO^2 in mineral phosphates before ignition; and as bones comport themselves like a mixture of calcium orthophosphate and carbonate with organic matter, there is no reason to suppose that they contain a substance having the composition $\text{CaO} \cdot 3\text{Ca}^2\text{P}^2\text{O}^5$, as assumed by Aebv (F. Wibel, *Ber.* vii. 220). See BONE (p. 337).

Native Calcium Phosphates.—The following analyses of mineral phosphates and superphosphates used in England for agricultural purposes have been published by W. C. Reid (*Chem. News*, xxxiv. 48, 55).

1-5. Cambridge coprolites from the upper greensand of Cambridgeshire: grey hard nodules, consisting either of true coprolites or of concretions formed round bones. 6, 7, 8. Coprolites from Boulogne. 9-12. Pseudocoprolites from Suffolk: calcareous concretions impregnated with phosphates. 13. Coprolites from Bedfordshire. 14. Lenticular coprolites, a poor variety from Cambridgeshire. 15 and 16. Russian coprolites. 17. South Carolina and Charleston phosphates of high value. They are obtained from chalk-beds, and form irregular nodules enclosing animal remains and imbedded in clay. 18 and 19. Lot or Bordeaux phosphates from the Departments Lot and Lot-et-Garonne, where they occur in veins and thin layers of a limestone. The analyses relate to the best and a poorer quality. 20 and 21. Nassau phosphorites,

ordinarily very rich in iron; not much in request of late. The analyses give the extremes between which the actual values generally fluctuate. 22-25. Spanish and Portuguese phosphorites, usually classed together as Estremadura phosphorite. 26, 27. Norwegian, and 28, Canadian apatite, forming veins in crystalline rocks; exported to England in small quantities only. 29 and 30. Sombrero guano, really a phosphorite; formerly imported in considerable quantity, lately but seldom. The two analyses give extreme values. 31 and 32. Navassa guano, a similar material from the island of Navassa. In this case also the analyses give extreme values.

Composition of Native Calcium Phosphates.

	Ca ² P ² O ⁵	CaCO ³	Fe ² O ³ , Al ² O ³		CaF ²	CaCl ²	Insoluble Silicates

* Probably a misprint for 57.12.

A phosphorite from Rossberg near Rossdörf in Hesse-Darmstadt was found by P. Wagner (*Ber. d. landw. Versuchsst. Darmstadt*, 1874) to contain 38.92 per cent. phosphoric acid; another from Oberamstadt, Hesse-Darmstadt, yielded 23.2 per cent. phosphoric acid, 19.6 silica, and 8.6 alumina. A guano from Australia yielded 60.70 per cent. calcium phosphate containing 2.78 phosphoric acid.

Several samples of phosphorite from Logrosan, Estremadura, very large quantities of which are imported into Germany by way of Hamburg (more than 11000 kg. in 1872), have been analysed by B. Niederstadt (*Ber. vii*, 107). It has the advantage over many others of containing only small quantities of ferric oxide and alumina, so that the retrogression of soluble into insoluble phosphates does not take place in it to any great extent. It contains, however, a large amount of silica:

Ca.P ² O ⁵	Mg.P ² O ⁵	CaCO ³	CaSO ⁴	Fe ² O ³	Al ² O ³	CaF ²	SiO ²	H ² O	
54.691	7.010	8.065	1.200	0.621	0.165	1.520	25.720	0.250	= 99.242
62.352	1.605	13.688	2.440	0.528	0.985	1.204	16.412	0.175	= 99.389
57.369	0.708	7.385	1.599	0.453	0.405	1.322	29.428	0.790	= 99.959
59.594	3.977	13.327	0.858	0.910	0.427	0.983	19.164	0.721	= 99.961

Calcium phosphate from Ciply, in Belgium, containing 20.35 per cent. P²O⁵, has been analysed by Nevoit (*Compt. rend.* lxxix. 256; *Chem. Soc. J.* 1874, 1146).

On Apatite, see p. 116.

Calcio-uranic Phosphate, (CaO.2UO³)P²O⁵ + 8H²O. *Uranite Autunite* (iv. 585). This mineral has lately been examined by Church (*Chem. Soc. J.* 1875, 109) with special reference to its amount of water.

Analyses.—1 and 2. Sulphur-yellow crystals from Cornwall. 3 and 4. Crusts about half an inch thick, composed of irregularly grouped yellow crystals from Autun. 5. Smaller crystals from Autun, having a deeper sulphur-yellow colour:

	1	2	3	4	5
Water lost over Sulphuric acid . . .	not det.	8.24	9.08	8.38	9.48
„ in a vacuum . . .	„	not det.	5.28	not det.	4.95
„ at 100° . . .	13.8	6.90	not det.	7.29	0.75
„ at a red heat . . .	4.85	4.12	5.28	4.02	5.15
Uranic oxide . . .	60.00	not det.	61.34	not det.	60.87
Lime . . .	5.01	—	5.24	—	5.31
Phosphoric anhydride . . .	13.84	—	14.97	13.66	13.40

From the constancy of the loss of water in dry air and in the vacuum, it may be inferred that this water is not merely hygroscopic, but chemically, though loosely combined; and this view is corroborated by the fact that the crystals, in parting with this water, undergo physical alteration, becoming opaque and brittle. The numbers show that uranite in its original state contains 10 mols. H²O, of which .6 mols. are given off under the air-pump.

Cerium Phosphates. Monazite from Arendal, in large dull crystals, free from thorium, has been analysed by Rammelsberg (*Jahrb. f. Min.* 1877, 831). A. Direct result of analysis. B. Corrected for admixtures. C. Values calculated according to the formula (Ce, La, Di)²P²O⁵, in which Ce : (La, Di) = 2 : 3; and Ce = 138; La, Di = 140.

P ² O ⁵	Ce ² O ³	La ² O ³ , Di ² O ³	Fe ² O ³	CaO	SiO ²	
A. 28.78	27.73	39.24	1.30	0.90	1.60	= 99.55
B. 29.92	28.82	40.79	—	—	—	= 99.53
C. 30.28	27.72	42.00	—	—	—	= 100

Sp. gr. = 5.174.

According to these results, monazite free from thorium must be identical with cryptolite (iv. 558).

P. v. Jeremejew (*Zeitschr. Kryst.* i. 398) describes crystals of monazite from the Ilmen mountains, exhibiting combinations of the forms ∞P∞, ∞P∞, ∞P, +P∞, P∞.0P, and twins according to 0P.

An analysis of turnerite by F. Pisani (*Jahrb. f. Min.* 1877, 412), made on a very small quantity of material, gave the approximate values P²O⁵ 28.4, CeO 59.1, LaO 8.9 = 96.4, showing the identity of turnerite with monazite.*

Chromic Phosphate. The violet modification of this salt, Cr²(PO⁴)² + 12H²O, gives off 7H²O at 100°, and is converted into the green modification; with nitric and sulphuric acids it behaves like the violet sulphate (Etard, p. 458).

Glucinum Phosphate, Gl³(PO⁴)³, is precipitated on adding ordinary disodic phosphate to a solution of normal glucinum sulphate (Atterberg, *Bull. Soc. Chim.* [2], xix. 497).

Iron Phosphates. When sodium phosphate and ferrous sulphate are enclosed, together with carbon dioxide and a little water, in a sealed tube, the ferrous phosphate produced by double decomposition of the two salts is coloured blue (even in the dark) by the action of carbon monoxide formed by reduction of the dioxide. About one-sixth of the carbon dioxide is thus reduced in a few days. An ethereal solution of chlorophyll is separated by hydrochloric acid into two layers, the upper of which

* Turnerite was originally regarded as a silicate (v. 919).

contains iron, lime, and phosphoric acid—that is to say, the constituents of vivianite (E. N. Horsford, *Ber.* vi. 1890).

Ferric Phosphates (Millot, *Bull. Soc. Chim.* [2], xxii. 242).—The well-known precipitate obtained on adding ordinary sodium phosphate in excess to a ferric salt has the composition $\text{Fe}^2\text{O}_3 \cdot \text{P}_2\text{O}_5 + 5\text{H}_2\text{O}$ or $\text{Fe}^2(\text{PO}_4)^2 + 5\text{H}_2\text{O}$, and yields on ignition the anhydrous salt $\text{Fe}^2(\text{PO}_4)^2$, which is insoluble in water and is decomposed by alkalis.

The salt $2\text{Fe}^2\text{O}_3 \cdot 3\text{P}_2\text{O}_5 + 10\text{H}_2\text{O}$, first prepared by Rammelsberg, is obtained easily and in any required quantity by treating ferric oxide with excess of phosphoric acid, either at ordinary or at higher temperatures, adding water, filtering, heating the filtrate to the boiling point, and drying the resulting precipitate at 100° . This salt gives off all its water at a red heat, and is then no longer soluble in acids. The salt $\text{Fe}^2\text{O}_3 \cdot 2\text{P}_2\text{O}_5 + 8\text{H}_2\text{O}$ is obtained by heating the last with 2 mols. phosphoric acid.

According to G. W. Waine (*Chem. News*, xxxvi. 132), the ferric phosphate obtained by precipitating ferric chloride with sodium phosphate always has the composition $2\text{FePO}_4 + 5\text{H}_2\text{O}$ or $\text{Fe}^2\text{O}_3 \cdot \text{P}_2\text{O}_5 + 5\text{H}_2\text{O}$, whether it be obtained by adding ferric chloride to excess of sodium phosphate, or sodium phosphate to excess of ferric chloride.

On *Andrewsite*, a native iron phosphate from Cornwall, see p. 84.

Lead Phosphates are decomposed by nitric acid, with formation of lead nitrate and free phosphoric acid, the decomposition being complete if the nitric acid is of such a strength that the lead nitrate will not dissolve in it (Duvillier, *Compt. rend.* lxxxi. 1251). Lead phosphate is easily decomposed by excess of *potassium iodide*, with formation of lead iodide or the double iodide of lead and potassium (Campani, *Gazz. chim. ital.* 1876, 461).

Magnesium Phosphate. A compound of magnesium-hydrogen orthophosphate with nitrogen tetroxide, $4\text{MgHPO}_4 \cdot \text{N}_2\text{O}_4$ is obtained by dissolving magnesium pyrophosphate in nitric acid of sp. gr. 1.25; keeping the solution nearly at the boiling heat for some time to convert the pyrophosphate into orthophosphate; then evaporating to dryness on a sand-bath; reducing the white, gummy, fissured acid residue to coarse powder; and heating it somewhat more strongly—best in a paraffin-bath—till it assumes a rusty-brown colour, and ceases to give off acid fumes. The compound thus prepared is a crystalline powder, whitish-yellow at ordinary, rusty-brown at higher temperatures, and becoming whitish-yellow again on cooling. When strongly heated it gives off water and nitrogen tetroxide, and leaves a residue of magnesium pyrophosphate (E. Luck, *Zeitschr. anal. Chem.* vii. 255).

Manganese Phosphates. These salts have been examined by Erlenmeyer a. Heinrich (*Liebig's Annalen*, cxc. 189).

Monomanganous Phosphate, $\text{MnH}^+(\text{PO}_4)^2 + 2\text{H}_2\text{O}$, previously obtained by Heintz (iv. 571), is prepared by dissolving recently precipitated manganous sulphide in excess of phosphoric acid, leaving the solution to crystallise, and removing the mother-liquor by washing with ether free from water and alcohol. At 100° it gives off water, and is partially decomposed, with separation of phosphoric acid. It remains unaltered in dry air, but deliquesces in moist air, forming an acid liquid from which crystals of the dimanganous salt separate out. The same change takes place when the monomanganous salt is treated with cold water, so that Heintz's statement that this salt is easily soluble in water cannot be regarded as correct.

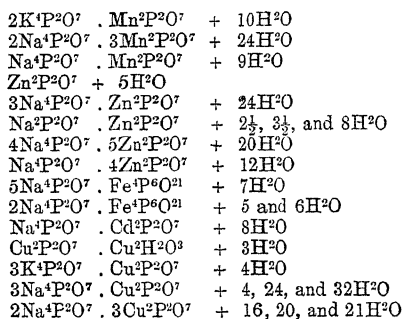

Dimanganous Phosphate, $\text{Mn}^2\text{H}^2(\text{PO}_4)^2 + 6\text{H}_2\text{O}$, or $\text{MnHPO}_4 + 3\text{H}_2\text{O}$, may be obtained by methods already described (iv. 571), or, according to Debray (*Ann. Chim. Phys.* [3], lxi. 433), by treating manganese carbonate with aqueous phosphoric acid, and heating the resulting solution to 70° —or in larger quantity and better crystals by heating the same solution with alcohol till it becomes turbid, and then leaving it to itself for awhile. The crystals thus obtained are, according to Haushofer's measurements, orthorhombic, having the axial ratio, $a : b : c = 0.9445 : 1 : 0.9260$, and mostly exhibiting the combination $\infty\text{P}\infty \cdot \infty\text{P}\infty \cdot 0\text{P} \cdot \text{P} \cdot \frac{1}{2}\text{P} \cdot \frac{1}{2}\text{P}\infty$. An anhydrous dimanganous phosphate, $\text{Mn}^2(\text{PO}_4\text{H})^2$, is obtained by boiling the monomanganous salt with alcohol.

Trimanganous Phosphate, $(\text{Mn})^3(\text{PO}_4)^2 + 7\text{H}_2\text{O}$, is obtained in indistinct crystals by precipitating manganous sulphate with excess of disodic phosphate: it gives off half its water over sulphuric acid. A trimanganous phosphate, differing somewhat from the preceding in the manner in which it gives off its water of crystallisation, is obtained in needle-shaped crystals by treating the dimanganous salt with cold water. It effloresces on exposure to the air, the effloresced product containing from 9 to 11 mols. water according to the degree of moisture of the air. Over sulphuric acid, however, it is likewise converted into the salt with 7 mols. H_2O .

A *pentamanganous phosphate*, $\text{Mn}^5\text{H}^2(\text{PO}^1)^4 + 4\text{H}^2\text{O}$, is obtained by filtering the liquid resulting from the decomposition of the monomanganous salt by water, and keeping it for some time at the boiling heat. It then separates in rose-coloured, rather large and well-defined crystals, which give off their water at 150° , and become opaque, without melting, at a red heat. According to Haushofer's measurements, they are monoclinic. Axial ratio $a : b : c = 1.9927 : 1 : 1.7122$. Angle $ac = 82^\circ 26'$. Combination $\infty \text{P} \cdot \text{OP} \cdot \text{P}\infty$. The prismatic faces are vertically striated. Many crystals likewise exhibit the positive hemidome $\text{P}\infty$ (Erlenmeyer).

When pure manganese dioxide or a permanganate is dissolved at 100° – 110° in syrupy phosphoric acid, a dark amethyst-blue syrup is obtained which is dissolved in all proportions by water, with ruby-red colour (Barreswil's test, *Compt. rend.* xlv. 677); and on heating the solution in the water-bath, it becomes colourless, and deposits a greyish-green muddy precipitate of a peculiar phosphate, which when dried at 106° forms a light greenish-grey powder, appearing under the microscope crystalline and slightly double-refractive. It is insoluble in water, but when boiled with hydrochloric acid, it forms, with evolution of chlorine, a clear light yellow solution containing nothing but manganese and phosphoric acid. From this and the following phosphates, ammonium sulphide throws down the manganese, not as a flesh-coloured hydrated sulphide, but as a blackish-green anhydrous sulphide. At a low red heat, this phosphate gives off a considerable quantity of water, and assumes a brownish ash-grey colour. At 100° – 110° it redissolves in syrupy phosphoric acid, producing the original amethyst-red liquid. On saturating phosphoric acid with this phosphate at the same temperature, and concentrating the solution on the sand-bath, a *second* phosphate is deposited in six-sided plates or tabular rhombohedrons, or rhombic dodecahedrons, $\frac{1}{4}$ mm. in size, strongly lustrous, double-refracting, amethyst-coloured when hot, dark ruby-red at ordinary temperatures. These crystals, which are insoluble in water, are perhaps identical with peach-blossom coloured manganic metaphosphate. By concentrating the amethyst-blue phosphate over a gas-flame at a low red heat, a *third* phosphate is obtained in the form of a honey-yellow transparent glass, soluble in all proportions in water; and on finally driving off the excess of phosphoric acid at a red heat, a *fourth* phosphate is left, in the form of brilliant grey needle-shaped crystals, infusible, and permanent in the fire (W. H. Laspeyres, *J. pr. Chem.* [2], xv. 320).

PYROPHOSPHATES, $\text{M}^1\text{P}^2\text{O}^7 = (\text{M}'\text{O})^2\text{OP} - \text{PO}(\text{OM}')^2$. A number of these salts, principally double salts, have been prepared by C. N. Pahl (*Ber.* vi. 1465), in most cases by dissolving the pyrophosphate of a heavy metal in a solution of an alkaline pyrophosphate. The following have been analysed:

The following table exhibits the specific gravities of several pyrophosphates, as determined by pupils of F. W. Clarke (*Sill. Am. J.* [3], xiv. 281):

Salt	Specific gravity	Determined by
$\text{Na}^1\text{P}^2\text{O}^7$	$\left\{ \begin{array}{l} 2.3851^* \\ \text{and } 2.3613 \end{array} \right\}$ at 17°	C. A. Mohr

For *sodium metaphosphate*, NaPO_3 , C. A. Mohr 2.4756 at 19.5° and 2.4769 at 18° ; for *potassium metaphosphate*, KPO_3 , 2.2639 and 2.2513 at 14.5° ; for *trisodic orthophosphate*, Na_3PO_4 , 2.5111 at 12° and 2.5362 at 17.5° .

Double pyrophosphates of lithium with sodium and potassium have been prepared by Kraut, Nahsen a. Cuno (*Liebig's Annalen*, clxxxii. 165). Mixtures of the aqueous solutions of sodium pyrophosphate and lithium chloride, when left at rest at ordinary temperatures, deposit a double salt only when the lithium pyrophosphate is in excess; when the mixtures are heated, a precipitate of the double salt is also formed more quickly in proportion as the quantity of lithium salt is greater. With an excess of sodium salt, the formation of a crystalline precipitate takes place only after prolonged boiling. The composition of the precipitates differs according to the proportion of the two salts present in the solution. Double pyrophosphates of lithium and potassium are formed in the same way, but less readily.

When *calcium pyrophosphate* is exposed for several hours to a dull red heat, and the fused mass is stirred with an iron spatula, a perfectly transparent glass is obtained which after cooling exactly resembles ordinary glass in appearance, has a density of 2.6, and a refractive power equal to that of crown-glass (1.525). It may be worked like ordinary glass into prisms, lenses, &c., and cut and ground into various forms. It does not dissolve any metallic oxides except those of cobalt and chromium. It resists the action of acids at ordinary temperatures, but is attacked by them when heated; also by potash. On the other hand, it completely withstands the action of hydrofluoric acid, and may therefore be used for making spectacles for workmen who are exposed to the fumes of that acid; it may also be applied to the making of enamel (Sidot, *Compt. rend.* lxxxiv. 1501).

PHOSPHORIC ETHERS. On the action of Ethyl Phosphate on the Chlorides of Phosphorus, see p. 1589.

Phenylphosphoric Acids and Chlorides (Jacobsen, *Ber.* viii. 1519).

Monophenylphosphoric Chloride, $\text{PO}(\text{OC}^6\text{H}^5)\text{Cl}^2$, is formed by adding 1 mol. phenol to 1 mol. POCl_3 , then heating, distilling, and fractionating. It boils at 241° – 243° , and is converted by access of moisture into

Monophenylphosphoric Acid, $\text{PO}(\text{OC}^6\text{H}^5)(\text{OH})^2$.—This acid forms thick deliquescent needles melting at 97° – 98° . During the concentration of its solution it partly decomposes into phenol and phosphoric acid. By distillation it is resolved into phenol and metaphosphoric acid. Its barium salt is very soluble in water, and crystallises in transparent prisms.

Diphenylphosphoric Chloride, $\text{PO}(\text{OC}^6\text{H}^5)_2\text{Cl}$, produced by the action of several molecules of phenol on 1 mol. POCl_3 , boils at 314° – 316° (bar. at 272 mm.), and offers a somewhat considerable resistance to the action of alkalis.

Diphenylphosphoric Acid, $\text{PO}(\text{OC}^6\text{H}^5)_2\text{OH}$, formed from it, is an oily liquid slightly soluble in water and in alcohol. Its sodium salt crystallises in transparent needles.

Triphenyl Phosphate, $\text{PO}(\text{OC}^6\text{H}^5)_3$, formed in the last-mentioned reaction, together with diphenylphosphoric chloride, crystallises in slender needles, melts at 45° , and boils at a very high temperature. It is insoluble in water, but dissolves readily in alcohol (Jacobsen).

Benzyl-phenyl Phosphate, $(\text{C}^1\text{H}^{11})^3\text{PO}^4 = \text{PO}[\text{OC}^6\text{H}^4(\text{C}^7\text{H}^7)]^3$, is obtained by heating benzyl-phenol, $\text{C}^6\text{H}^4(\text{C}^7\text{H}^7)\text{OH}$, on the water-bath with phosphorus pentachloride, and decomposing the product with water. When purified by washing with a small quantity of ether, it forms white crystals, slightly soluble in ether, more readily in alcohol and in chloroform, melting at 93° – 94° (Paternò a. Fileti, *Gazz. chim. ital.* vi. 121).

Triphenyl Monothiophosphate, $\text{PS}(\text{OC}^6\text{H}^5)_3$, is prepared by boiling a mixture of phosphorus thiochloride (1 mol.) and phenol (3 mols.) in a reflux apparatus till the liquid assumes a darker colour, then treating the cooled product with soda-ley, and crystallising it from alcohol:

This ether forms small white needle-shaped crystals which turn red on exposure to light, but lose this colour when kept in the dark. It is insoluble in water, but soluble in ether, chloroform, benzene, and carbon sulphide. It melts at 40°, and boils with decomposition at a temperature above 360°. On mixing its alcoholic solution with a solution of thallous oxide, thallium sulphide is precipitated and triphenyl-phosphate is produced. The thio-ether is not altered by boiling with water. Strong nitric acid does not act upon it, but the red fuming acid oxidises it partially, with separation of a red oil, and completely when heated with it under pressure (P. Schwarze, *J. pr. Chem.* [2], x. 222).

Triphenyl Trithiophosphate, $\text{PO}(\text{SC}^6\text{H}^5)^3$, is formed on boiling phosphorus oxychloride with phenyl-mercaptan, and separates after some time from the cold-saturated alcoholic solution in well-defined prisms, apparently monoclinic. It is insoluble in water, but dissolves in alcohol, ether, benzene, chloroform, and carbon sulphide, melts at 72°, and boils with decomposition at a temperature above 360°. With nitric acid it reacts like the monosulphuretted ether. It is decomposed by gentle heating with water, a mixture of acid phenyl-ethers of thiophosphoric acids passing into solution, while a mixture of neutral ethers remains undissolved (Schwarze).

Triphenyl Tetrathiophosphate, $\text{PS}(\text{SC}^6\text{H}^5)^3$, prepared with phenyl mercaptan and phosphorus thiochloride, forms white needles having a silky lustre, and melting at 86°. It is insoluble in water, but dissolves in alcohol, ether, benzene, chloroform, and carbon sulphide. It does not volatilise without decomposition. With water and with nitric acid, it reacts like the monothiophosphoric ether. Attempts to convert it into triphenylphosphine by the action of metals (bismuth, copper, thallium) were unsuccessful (Schwarze).

PHOSPHORUS SULPHIDES (G. Ramme, *Ber.* xii. 1350). *Phosphorus pentasulphide* is obtained in pale yellow prisms, by heating in sealed tubes at 210° for eight hours a solution of sulphur and common phosphorus in carbon bisulphide. Attempts to prepare the trisulphide P^3S^3 by this method, or by heating a mixture of amorphous phosphorus and sulphur, were unsuccessful, the product in each case consisting of the disulphide PS^2 , or, according to its vapour-density, P^2S^6 . *Phosphorus disulphide* crystallises in pale yellow transparent needles, which melt at 296°–298°.

Heated with water at 150°, it yields phosphorous, phosphoric, and hydrosulphuric acids. The compound P^4S^3 is obtained by heating a mixture of sulphur and red phosphorus in a tube at 260°, or by heating P^2S^6 with common phosphorus in a current of carbonic anhydride at 320°. It dissolves freely in carbon bisulphide, and separates from the solution, on evaporation, in pale yellow prisms melting at 166°.

The substance described by Berzelius as P^2S^{12} (iv. 605) is not a definite compound, but consists of crystals of sulphur mixed with a small quantity of phosphorus. The liquid sulphides of phosphorus mentioned by Berzelius are mixtures of sulphur and phosphorus, which are separated by distillation with water.

PHTHALANILS. Syn. with PHENYL-PHTHALIMIDES (see PHTHALIMIDES).

PHTHALEÏNS and **PHTHALINS** (vii. 977). 1. **Phenol-phthaleïn**, $\text{C}^{20}\text{H}^{14}\text{O}^4$ (A. Baeyer, *Ber.* ix. 1230; xii. 642). This compound is obtained: (1). By the action of phthalic anhydride on phenol in presence of sulphuric acid:

Five parts of phthalic anhydride, 10 pts. phenol, and 4 pts. strong sulphuric acid are heated at 120° for ten hours, the resulting mass is boiled with water, and the residue dissolved in dilute soda-ley. On filtering the liquid, the anhydride of phenol-phthaleïn remains undissolved, and the filtrate mixed with acetic acid and a small quantity of hydrochloric acid, deposits the phthaleïn, which may be purified by solution in alcohol and boiling with animal charcoal. The alcoholic solution mixed with water and heated to the boiling point deposits the phthaleïn in the form of a white or yellowish granulo-crystalline powder. From the aqueous mother-liquors or from a solution in over-heated water, it may be obtained in larger crystals, which, according to Groth, are triclinic.

(2). From Diphenyl-phthalide, $\text{C}^6\text{H}^4 \begin{array}{c} \text{C}(\text{C}^6\text{H}^5)^2 \\ \text{CO} \end{array} \text{O}$, formerly called *Phthalophenone* (p. 1619). When this compound is added at ordinary temperatures to fuming nitric acid, a mixture of isomeric *dinitrodiphenyl-phthalides* is obtained, which, by reduction with tin and hydrochloric acid, yields a mixture of diamido-compounds; and on removing the tin by hydrogen sulphide, precipitating with sodium carbonate, and dissolving the resulting precipitate in hot alcohol, the solution on cooling deposits a *diamidodiphenyl-phthalide*, $\text{C}^{20}\text{H}^{12}(\text{NH}^2)^2\text{O}^2$, in thick plates having an adamantine lustre and melting at 179°–180°, the mother-liquor when concentrated

yielding a small quantity of an isomeric compound in crystalline crusts melting at 205°; and finally, on dissolving the diamido-compound melting at 179°–180° in an acid, and heating the solution with potassium nitrite, the corresponding *dihydroxyl-compound*, $C^{20}H^{12}(OH)^2O^2$, is obtained, which dissolves in alkalis with violet colour, and is identical in every respect with the phenol-phthalein produced from phenol and phthalic anhydride.

Phenol-phthalein is therefore dihydroxy-diphenyl-phthalide, and is closely related in constitution to rosolic acid:

Its formation from phthalic anhydride and phenol is represented by the equation:

and is analogous to the action of aldehydes on phenols in presence of dehydrating agents, *e.g.*

Phenol-phthalein is converted by fusion with *potash* into benzoic acid and dihydroxybenzophenone:

With *phosphorus pentachloride*, it yields dichlorodiphenylphthalide, $C^6H^4 \left\langle \begin{array}{c} C(C^6H^4Cl)^2 \\ \text{CO} \end{array} \right\rangle O$.

Strong *nitric acid* converts phenol-phthalein into a nitro-compound reducible by tin and hydrochloric acid to amidophenol-phthalein, the hydrochloride of which dissolves in soda-ley with blue colour, and when heated to 170° with sulphuric acid, yields a derivative of anthraquinone, probably alizarin.

Tetrabromo-phenolphthalein, $C^{20}H^{10}Br^4O^4$, is formed by the action of bromine in excess on phthalein. It crystallises in short colourless prisms, which melt at 220°–230°, and are sparingly soluble in alcohol and glacial acetic acid. In alkalis it dissolves with violet colour, which disappears with excess of the solvent; but the violet ammoniacal solution is not so decolorised. Heated for six hours at 145°–150° with strong sulphuric acid, it is converted into dibromoxyanthraquinone and dibromophenol:

Phenol-phthalein Hydrate.—Phenol-phthalein, when fused with sodium hydrate, yields phenol-phthalein, which is not decomposed even when strongly heated; but when the phthalein is heated at 100° with three times its weight of potassium hydrate for 24 hours, a substance is formed which crystallises from water in long needles agreeing in composition with the formula $C^{20}H^{14}O^4 + 2H^2O$.

Diacetyl-phenol-phthalein, $C^{20}H^{12}O^4(C^2H^3O)^2$, is readily formed by boiling phthalein with acetic anhydride. It crystallises from wood-spirit in colourless tables melting at 143°.

Phenol-phthalein chloride, $C^{20}H^{12}O^2Cl^2$, is formed by the action of phosphorus pentachloride at 125° on phenol-phthalein. It crystallises from glacial acetic acid and alcohol in beautiful silky laminæ, which melt at 155°–156°, and sublime without decomposition. It is reduced by hydriodic acid.

Phenol-phthalidin, $C^{20}H^{18}O^4 = C^6H^4 \left\langle \begin{array}{c} CH(C^6H^4OH)^2 \\ COOH \end{array} \right\rangle$, or $(C^6H^4OH)^2CH.C^6H^4.COOH$, is formed by the action of zinc-dust on phenol-phthalein dissolved in alcohol. It crystallises in small needles, and forms with potash a colourless solution which is coloured deep red by potassium ferricyanide, phthalein being reproduced. When boiled with acetic anhydride, it yields a *di-acetyl-compound*, which is difficult to purify.

Tetrabromophenol-phthalin may be obtained either by reducing tetrabromophenolphthalein in ammoniacal solution with zinc dust, or by treating phenol-phthalin with excess of bromine in alcohol or glacial acetic acid. It crystallises readily, melts at 140°, and dissolves without colour in alkalis. Its *acetyl-compound* is crystalline, and melts at 165°–166°.

formed by the action of sulphuric acid on phenol-phthalin, and is thrown down by water from the acid solution in the form of an amorphous yellowish precipitate, which dissolves readily in ether to form a yellow solution with greenish fluorescence. It is not crystallisable, and oxidises easily in the air, so that it cannot well be analysed; but the composition of the bromine-derivative described below shows that its formula is $C^{20}H^{14}O^8$, and consequently that it is formed by elimination of water from phenol-phthalin, into which substance it is reconverted by heating it with water at 175° . It dissolves in alkalis without alteration in the absence of air.

Tetrabromophenol-phthalidin, $C^{20}H^{10}Br^4O^8$, is thrown down by water from a solution of the tetrabromophenol-phthalin in strong sulphuric acid, as a yellow precipitate, which crystallises from alcohol in yellow needles. It dissolves sparingly in alcohol and glacial acetic acid, freely in ether and acetone, and forms yellow solutions in alkalis.

metameric with phenol-phthalein and related to phenol-phthalidin in the same manner as triphenyl-carbinol to triphenyl-methane, is produced by oxidation of phenol-phthalidin, the best reagent for the purpose being potassium manganate in alkaline solution. It crystallises from glacial acetic acid in colourless, thin, tabular crystals, and from weak spirit in thin laminae, which melt at 212° . It dissolves in potash-ley, with yellow colour, and is precipitated from the solution in colourless amorphous flocks by acids. It forms a deep violet solution with sulphuric acid, the smallest portion of phthalidein being enough to colour a large quantity of the acid. Its alkaline solution is reduced by zinc-dust to phenol-phthalidin.

Diacetyl-phenol-phthalidein, $C^{20}H^{12}O^4(C^2H^3O)^2$, obtained by boiling phenol-phthalidein with acetic anhydride, crystallises in small prisms melting at 109° .

Phenol-phthalidein chloride, $C^{20}H^{12}O^2Cl^2$, formed by the action of phosphorus pentachloride on phenol-phthalidein at 125° , crystallises from alcohol in silky needles, which melt at 156° .

Tetrabromophenol-phthalidein, $C^{20}H^{10}Br^4O^4$, is formed either by the action of bromine on phenol-phthalidein, or by the oxidation of tetrabromophenol-phthalidin. It crystallises from alcohol in colourless opaque crystals, which melt above 280° ; dissolves in alkalis with yellow, and in strong sulphuric acid with blue colour. When heated to 140° with sulphuric acid, it behaves like tetrabromophenol-phthalein, yielding dibromoxyanthraquinone. The *diacetyl-compound*, $C^{20}H^8(C^2H^3O^2)Br^4O^4$, formed by boiling it with acetic anhydride, melts at 182° – 183° .

Compounds of Phenol-phthalidein with Phenols.—When a phenol is added to the solution of the phthalidein in strong sulphuric acid, the colour of the solution at once changes from violet to blood-red, and on addition of water a red amorphous precipitate is thrown down. The compound with phenol is an amorphous brick-red powder, which dissolves with deep violet colour in alkalis, and is thrown down again by acids as a yellowish-red precipitate. Its alcoholic solution, when treated with bromine, yields a crystalline substitution-product, soluble with blue colour in alkalis. Tetrabromophenol-phthalidein similarly combines with phenol, as does also phenol-phthalidein chloride. The phenol-compound forms with ammonia at 150° – 160° a crystalline substance soluble in alkalis, and with blue colour in strong sulphuric acid.

Phenol-hydroxy-phthalein, $C^{20}H^{14}O^5 = C^6H^3(OH) \left\langle \begin{array}{c} C(C^6H^4OH)^2 \\ CO \end{array} \right\rangle O$, a compound closely resembling phenol-phthalein, is formed by heating hydroxyphthalic anhydride with phenol and sulphuric acid, at 115° . It is somewhat more soluble in water than phenol-phthalein, and its dilute alkaline solution is rose-red. It is reduced by zinc-dust to a colourless hydroxyphthalin, which, by the action of concentrated sulphuric acid, is converted into a greenish-yellow hydroxyphthalidin; the latter, like the phthalidin, is oxidised by sulphuric acid and manganese peroxide in the cold, yielding a colourless hydroxyphthalidein, which dissolves in sulphuric acid, with a blue violet colour (Baeyer, *Ber.* x. 1079).

Diimido-phenol-phthalein, $C^6H^4 \left\langle \begin{array}{c} C(C^6H^4OH)^2 \\ C(NH) \end{array} \right\rangle NH$ (Baeyer a. Burkhardt, *Ber.* xi. 1297).—The ammonium salt of this compound is formed by heating phenol-phthalein for three hours at 160° – 170° with 10 pts. of aqueous ammonia; and on treating this salt with an acid, the free diimido-compound is obtained as a yellowish amorphous precipitate, which may be purified by treating its alcoholic solution with animal charcoal, and recrystallising it from a mixture of alcohol and benzene. It is somewhat soluble in boiling water, dissolves readily in alcohol, acetone, and glacial

acetic acid, sparingly in benzene and in chloroform, and crystallises in small colourless pointed needles melting at 265°–266°. It is dissolved by alkalis without coloration, by strong sulphuric acid, with yellow colour. Heated at 100° with strong hydrochloric acid, it is resolved into phenol-phthalein and ammonia.

Tetrabromodiimidophenol-phthaleïn, $C^6H^4 \begin{smallmatrix} \text{C}(C^6H^2Br^2OH)^2 \\ \text{C}(NH) \end{smallmatrix} \text{NH}$, prepared in like manner by heating tetrabromophenol-phthaleïn with 10 pts. aqueous ammonia for three hours at 160°–180°, melts at 280°, and is converted by acetic anhydride into the *tetracetyl-derivative*,

which melts at 241°. Tetrabromodiimidophenol-phthaleïn is converted by nitrous acid in alcoholic solution into *dibromodinitrodiimidophenol-phthaleïn*:

Resorcinol-phthaleïn, $C^{20}H^{14}O^6 = C^6H^4 \begin{smallmatrix} CO.C^6H^3(OH)^2 \\ CO.C^6H^3(OH)^2 \end{smallmatrix}$ and **Fluoresceïn**, $C^{20}H^{12}O^5 = C^6H^4 \begin{smallmatrix} CO.C^6H^3(OH) \\ CO.C^6H^3(OH) \end{smallmatrix} O$.

Fluoresceïn, the anhydride of resorcinol-phthaleïn, was discovered by Baeyer in 1871 (vii. 524); some of its derivatives were obtained by E. Fischer in 1874 (*Ber.* vii. 1211), and numerous others have more recently been prepared and examined by Baeyer (*Liebigs Annalen*, clxxxiii. 1). It is prepared by heating phthalic anhydride with resorcinol:

5 pts. of phthalic anhydride and 7 pts. of resorcinol are heated at 195°–200° till a solid mass is formed; this mass is boiled with water; and the undissolved portion is washed with alcohol, which dissolves resinous bye-products. The crude fluoresceïn thus obtained is dissolved in dilute soda-ley, precipitated with dilute sulphuric acid and extracted with ether. On adding a little absolute alcohol to this solution and distilling off the ether, fluoresceïn crystallises in grains or crusts. The crude fluoresceïn may also be purified by boiling it with a quantity of dilute soda which is insufficient to dissolve the whole, or by adding calcium chloride to its alkaline solution, filtering off the dark brown precipitate, and adding sodium phosphate, which produces a brown precipitate of calcium phosphate. The liquid is then again filtered and the pure compound precipitated from the filtrate by an acid.

Fluoresceïn is an amorphous, yellow, flocculent precipitate, which, on standing, heating, or drying, becomes crystalline, and consists of $C^{20}H^{12}O^5 + H^2O$. From alcohol it crystallises in dark red anhydrous grains, and from wood-spirit in yellow prisms, which probably contain methyl alcohol. It is almost insoluble in cold water, and dissolves sparingly in hot water with a yellow colour; in presence of acids it is more freely soluble. When freshly precipitated it dissolves readily in alcohol, ether, &c., but in the crystallised state only slowly, and after continued boiling. In hot acetic acid it is readily soluble, but nearly insoluble in benzene, toluene, and chloroform. The ethereal solution is pale yellow, and not fluorescent, whereas the yellowish-red alcoholic solution shows a green fluorescence. It may be heated to 280° without change, and begins to decompose at 290°. It dyes silk and wool yellow, but does not combine with mordants.

Fluoresceïn is a very weak acid, dissolving in strong alkalis with a dark red colour. This solution is not fluorescent, but changes on dilution to yellowish-red and yellow, and then exhibits a splendid yellowish-green fluorescence like that of uranium glass; and even if so much water is added that the liquid appears colourless in transmitted light, it shows in reflected light a green tinge like the colour of some Alpine lakes. The concentrated solution allows only the red and yellow rays to pass, whereas when dilute it gives an absorption-spectrum with a broad dark band in the green.

When alcoholic ammonia is added to a solution of fluoresceïn in ether, a reddish-yellow precipitate is formed, which loses ammonia on boiling or drying. In lime- and baryta-water fluoresceïn dissolves with a reddish-yellow colour; its alkaline solution is not precipitated by magnesium salts, while alum produces a reddish-yellow precipitate, which, on further addition of alum, becomes yellow, and then consists of pure fluoresceïn. The salts of some other heavy metals behave in a similar way; the lead and silver salts are more stable, and form reddish precipitates.

The striking colouring properties of fluoresceïn afford the means of detecting even

traces of resorcinol in presence of other phenols. It is only necessary to heat the substance with an excess of phthalic anhydride to near the boiling point of the latter. If the melt remains colourless, neither resorcinol nor pyrogallol or phloroglucol is present, but if it has a yellowish-red colour, these substances may be present. In the latter case the residue is dissolved in dilute soda, the smallest trace of resorcinol then becoming apparent by the fluorescence of the solution, while pyrogallol yields a blue, and phloroglucol a yellow liquid, which are not fluorescent. If a large proportion of pyrogallol should interfere with the reaction, a solution of potassium permanganate is carefully added, which destroys the gallein at once, but acts only slowly on the fluorescein.

When fluorescein is heated with soda-ley and zinc-dust, the solution becomes colourless. On adding an acid and shaking with ether, *fluorescein* dissolves, and remains on evaporation as a colourless varnish. It forms an alkaline, colourless solution, which absorbs oxygen, while oxidising agents reconvert it quickly into fluorescein.

Fluorescein dissolves in concentrated sulphuric acid, with a dark red colour, a compound of the two bodies being formed, which is obtained pure by heating 2 mols. of resorcin and 1 of phthalic anhydride with an equal weight of sulphuric acid at 100° for five to six hours. The melt is washed with cold water and crystallised from wood-spirit at a low temperature. In this manner yellowish-red prisms are obtained, having the empirical formula $C^{20}H^{12}O^5 + SO^2$, and melting at 140°–150°. They are decomposed by recrystallisation, become turbid in damp air, and are resolved by warm water or alkalis into their components.

When fluorescein is boiled with sulphuric acid for some time, *resorcinol-coerulein* is formed, which is precipitated by water in dark red flakes. It dissolves in alkalis with a greenish blue, and in ether with a reddish-violet colour, and is also soluble in water, the concentrated solution being red, and the dilute splendid reddish violet. It is reduced in an alkaline solution by zinc-dust, and the red liquid thus formed again becomes blue on exposure to the air.

Resorcinol-phthaleïn, $C^{20}H^{14}O^6$, appears to be formed by the action of strong alkalis on fluorescein: for on boiling the latter with an excess of soda, the liquid, when sufficiently concentrated, becomes dark violet, and crystals of the same colour separate out. On adding water, the solution first becomes red, then assumes a dingy colour, and on standing, or more quickly on heating, it assumes the colour of an alkaline solution of fluorescein, which is precipitated on adding an acid. When alcohol is added to the violet solution, it becomes intensely violet, and then gives an absorption-spectrum having a dark band between the blue and green, and another between the green and red. If an acid be added to the violet alkaline solution, a yellow precipitate is formed, dissolving in ether with a yellow colour, and on then adding an alkali the latter becomes again violet. These reactions show that resorcin-phthaleïn is a stable body in presence of acids or strong alkalis, but that in a weak alkaline solution it soon changes again into its anhydride.

Monoresorcinol-phthaleïn, $C^{14}H^{10}O^5 = C^6H^4 \begin{smallmatrix} CO.C^6H^3(OH)^2 \\ COOH \end{smallmatrix}$, is formed by boiling fluorescein with an excess of caustic soda. The violet colour then changes to a brownish yellow, and on dissolving the melt in water, and adding an acid, a milky liquid is formed, from which crystals soon separate. These may be purified by crystallisation from dilute alcohol, and in this manner large yellowish striated crystals are obtained, which have the composition $C^{14}H^{10}O^5 + H^2O$, and give off their water at 100°. They melt at about 200°, but decompose even below this temperature when heated for some time. They dissolve sparingly in hot water, very freely in alcohol and ether, and form with alkalis a yellow solution, giving with silver nitrate a yellowish-white precipitate, which decomposes when heated, with separation of metallic silver. Monoresorcinol-phthaleïn, heated with resorcinol, yields fluorescein, which is also formed by heating it alone, phthalic anhydride subliming at the same time:

When somewhat strongly heated with soda, it is resolved into resorcinol and phthalic acid, which is further decomposed into carbon dioxide and benzoic acid.

Fluorescein-derivatives formed by replacement of Hydrogen in the Hydroxyl-groups.

Diacetyl-fluoresceïn. $C^{20}H^{10}O^5(C^2H^3O)^2$, is formed by heating fluorescein with four or five times its weight of acetic anhydride at 140°, until, on mixing a small quantity with alcohol, yellow crystals separate out, which are insoluble in ammonia. The whole is now treated in the same way, in order to convert the anhydride into the

acetic ether; the crystals are dissolved in acetic acid; and the solution is poured into several volumes of alcohol, whereupon the pure compound crystallises in colourless needles melting at 200° . It dissolves but sparingly in alcohol and wood-spirit, readily in acetic acid and hot acetone, but is insoluble in ether, benzene, and chloroform. It is decomposed into fluorescein and acetic acid by boiling alkalis, and rapidly in alcoholic solution; the same decomposition is produced by concentrated sulphuric acid and hot hydrochloric acid.

Dibenzoyl-fluorescein, $C^{20}H^{10}O^5(C^7H^5O)^2$, is obtained by heating fluorescein with benzoyl chloride for an hour at 140° . The dark brown residue is boiled with water and crystallised from acetone. It forms colourless crystals melting at 215° , dissolves sparingly in alcohol, wood-spirit, and ether, but readily in hot acetone. Alcoholic potash and concentrated sulphuric acid resolve it into its components.

Monethyl-fluorescein, $C^{20}H^{11}O^5(C^2H^5)$.—To prepare this compound, potash-solution is saturated with fluorescein, the liquid evaporated to dryness, and the residue heated for two or three hours at 120° with more than 2 mols. of ethyl bromide and ten times its weight of alcohol. The solution thus obtained is diluted with water and treated with sodium carbonate to remove unaltered fluorescein. The monethyl-compound is then extracted with ether, the solution evaporated, the residue dissolved in alcohol, and the solution concentrated. On heating the syrupy residue with ether, monethyl-fluorescein crystallises in pale yellow needles melting at 155° – 156° . It is readily soluble in alcohol, wood-spirit, chloroform, and benzene, and separates from these solvents as a syrupy mass, miscible with ether, and crystallising therefrom in needles, which are but sparingly soluble in the pure solvent. When water is added to a hot alcoholic solution, it becomes milky on cooling, and deposits turbid, yellow crystals. The compound is insoluble in dilute alkalis, which decompose it on heating. Concentrated sulphuric acid dissolves the ether with a greenish-yellow colour and a light green fluorescence, which disappears on adding water; on neutralising this solution, the unaltered compound is precipitated.

Diethyl-fluorescein, $C^{20}H^{12}O^5(C^2H^5)^2$, is not formed by the action of ethyl bromide on the potassium-compound, and only sparingly when the silver compound is heated with ethyl bromide and ten times its quantity of alcohol. The reddish-brown solution thus formed is concentrated and precipitated with water; the precipitate is treated with sodium carbonate to dissolve unaltered fluorescein; and the insoluble portion dissolved in ether, which is then evaporated, and the residue crystallised from alcohol, from which it separates in pale yellow plates. The compound is sparingly soluble in ether and alcohol; the alcoholic solution shows a vivid yellow fluorescence. It is not changed by dilute alkalis, but concentrated alkalis and sulphuric acid decompose it into alcohol and fluorescein.

Fluorescein chloride, $C^{20}H^{10}O^5Cl^2$, is easily obtained by heating 1 mol. fluorescein with 2 mols. phosphorus pentachloride for an hour or two to 100° . The product is successively treated with boiling water, a warm solution of sodium carbonate, and boiling alcohol. On dissolving the residue in hot toluene, and adding alcohol, the chloride crystallises out, and may be purified by repeating this operation. It forms colourless prisms melting at 252° , and dissolving readily in hot benzene, toluene, and chloroform, sparingly in alcohol, ether, acetic acid and chloroform. It is not changed by aqueous or alcoholic potash, while on fusing it with potash it is completely destroyed; but on heating it with slaked lime and a little water to 230° for some hours, it is again converted into fluorescein. Cold concentrated sulphuric acid dissolves it without alteration, but on boiling the solution, decomposition takes place, and on adding water, dark red flakes are precipitated, which dissolve in ether with a wine-red colour.

When the chloride is heated with an excess of fuming hydriodic acid to 150° for 5 or 6 hours, the iodide $C^{20}H^{12}O^5I^2$ is formed, crystallising from alcohol, ether, and acetic acid in small, rhombohedral plates, melting at 229° – 230° . It dissolves in dilute, but not in concentrated, alkalis.

Fluorescein-derivatives formed by replacement of Hydrogen in the Benzene-nuclei.

Dinitro-fluorescein, $C^{20}H^{10}(NO^2)^2O^5$, is obtained, but not quite pure, by dissolving fluorescein in 20 pts. of sulphuric acid and adding to the solution at 0° 2 pts. of fuming nitric acid. It is an amorphous yellow powder, dissolving in potash with a brown colour, which on heating changes to red and blue. On heating it with acetic anhydride, the compound $C^{20}H^8(NO^2)^2O^5(OCOCH^3)^2$ is formed, crystallising from alcohol in pale yellow needles. The same compound is formed by acting with nitric acid on a solution of acetylfluorescein in sulphuric acid, but not by dissolving it in cold nitric acid, while, on heating, tetranitrofluorescein is formed.

When dinitrofluoresceïn, or, better, its acetyl-compound, is boiled for five minutes with twenty times its weight of a ley containing 15 per cent. of alkali, the liquid changes to red and then blue. Acids produce a yellow precipitate, crystallising from ether-alcohol in glistening red crystals, consisting of $C^{10}H^{12}(NO^2)^2O^4$. This compound dissolves in alkalis with a blue colour, which on dilution first changes into violet and then again into blue. In its absorption-spectrum the yellow is completely cut off, and it shows a faint band between the blue and the green. The potassium salt of this *dinitro-fluoresceïn hydrate* appears to be formed by acting with alcoholic potash on dinitro-fluoresceïn, a blue crystalline body separating out, which is soluble in water.

Hydrochloric acid and tin reduce dinitro-fluoresceïn in alcoholic solution, diamido-fluoresceïn being probably formed. Its hydrochloride crystallises in greenish-grey needles, and dissolves in alkalis with a cherry-red colour. With nitrous acid it yields a body crystallising in yellow needles, and dissolving in alkalis with a light reddish-brown colour, and a strong dark green fluorescence.

Tetranitro-fluoresceïn, $C^{10}H^2(NO^2)^4O^8$, is formed by adding an excess of fuming nitric acid to about 5 grams of fluoresceïn; a violent reaction soon sets in, and as soon as the whole is dissolved, the compound may be precipitated with water, washed with water and a little alcohol, and dissolved in 50 pts. of boiling glacial acetic acid. On cooling, it separates in colourless, warty crystals. It is sparingly soluble in alcohol, with a yellowish-red colour and a faint yellowish-green fluorescence. The addition of a little mineral acid changes the colour into a pale reddish-violet, while on adding more, the liquid becomes colourless. In alkalis it dissolves with a yellowish-red colour, and in boiling water with a red colour. It dyes on wool an intense and fast orange. Dilute boiling alkalis do not change it, but concentrated alkalis change the colour to brown, and then to a pale yellow.

Tin and hydrochloric acid reduce tetranitrofluoresceïn to an amido-compound, dissolving in alkalis with a splendid bluish-violet colour. In ammonium sulphide it dissolves with a brownish-red colour, which changes to violet on heating. Acids produce a brown precipitate, crystallising from ether in brown needles, and dyeing on silk a dingy violet.

Monobromofluoresceïn is formed by suspending fluoresceïn in 4 pts. of glacial acetic acid, and adding the required quantity of bromine mixed with 4 pts. of acetic acid. The compound is a yellowish-red amorphous body, which could not be obtained in crystals, and is changed by boiling acetic anhydride into a sticky mass. The alkaline solution has a reddish colour and faint green fluorescence.

Dibromofluoresceïn is formed by using 2 mols. of bromine. It forms compact reddish-brown needles with a deep green reflex, melts at 260° - 270° , and dissolves sparingly in acetic acid, alcohol, and acetic ether. Its alkaline solution is reddish-yellow, and shows a faint yellowish-green fluorescence. On boiling, the liquid changes into violet and blue, and the fluorescence into a dark green. On boiling it with acetic anhydride, the diacetyl-compound is formed, crystallising in colourless needles, which become red at 180° , and melt at 208° - 210° .

Dibromodinitrofluoresceïn, $C^{10}H^6Br^2(NO^2)^2O^8$, is formed by the action of nitric acid on dibromofluoresceïn or by that of bromine on dinitrofluoresceïn; also by dissolving 1 mol. of the tetranitro-compound in boiling acetic acid and adding 2 mols. bromine. It crystallises in compact yellow needles, which are very slightly soluble in alcohol and acetic acid, and dissolve in alkalis with a yellowish colour, changing to pale pink on addition of water. It is not fluorescent, but gives an absorption-spectrum resembling that of eosin. Its acetyl-derivative forms colourless needles which become violet at 210° and melts at 250° .

Tetrabromofluoresceïn, or *Eosin*, $C^{10}H^2Br^4O^8$.—This beautiful body, which is now manufactured on the large scale, and has been introduced into commerce by H. Caro as a dye-stuff, is formed by mixing fluoresceïn with 4 pts. of acetic acid, and adding the required quantity of bromine, which is diluted with four times its weight of acetic acid. It is also formed by adding bromine to a mixture of fluoresceïn and alcohol. It is purified by converting it into the pure potassium salt, and decomposing it by a mineral acid. An amorphous reddish-yellow precipitate is thus obtained, which is dried and dissolved in twenty times its weight of absolute alcohol, which is then distilled off until crystals begin to separate; or the potassium salt is decomposed by dilute sulphuric acid, and the liquid shaken with ether. The amorphous eosin is much more freely soluble than the crystals; the alcoholic solution is reddish-yellow and not fluorescent; it is but sparingly soluble in acetic acid, and almost insoluble in water, chloroform, and benzene. The crystals obtained from alcohol consist of $C^{10}H^2Br^4O^8 + C^2H^4O$, the alcohol being given off at 100° . If to a boiling alcoholic solution water is added until it becomes turbid, and then a little hydrochloric acid, the

liquid on boiling becomes clear again, and dull flesh-coloured crystals separate out, consisting of the pure compound.

Eosin is a bibasic acid; its salts are decomposed by mineral acids, but only imperfectly by acetic acid.

The *potassium salt*, $C^{20}H^6Br^4O^3K^2 + 6H^2O$, occurs in commerce as 'soluble eosin,' and forms brown, indistinct, prismatic crystals, with a blue and yellowish-green reflection. To obtain it in well-defined crystals, 100 pts. are dissolved in 50 pts. of water, and after addition of 100 pts. of alcohol and filtering, the solution deposits on standing splendid large plates, which in transmitted light appear red, and show the above reflection. They form a red powder, and belong to the triclinic system, being combinations of ∞P , $\infty \bar{P}\infty$, $\infty \bar{P}\infty$. They contain 5 mols. of water. On dissolving them in dilute alcohol, small reddish-brown crystals with a greenish-yellow reflex crystallise on cooling; they appear to contain 1 mol. alcohol. When the aqueous solution is quickly dried, the salt separates as a varnish having a yellowish-green metallic lustre. It dissolves in 2 pts. of water. The concentrated solution is dark yellowish-red, and in a thin layer pale pink. A dilute solution is yellowish-red, and exhibits a strong greenish-yellow fluorescence, which is also seen when the solution is very weak. Its absorption-spectrum has a broad dark band in the green. Its alcoholic solution exhibits similar colours, but a stronger fluorescence. The absorption-spectrum is destroyed by mineral acids, but not by acetic acid. A dilute aqueous solution containing 1 pt. in 150 gives the following reactions:

It is not changed by magnesium sulphate. Calcium and barium chloride give crystals on quickly boiling down the liquid, while cadmium sulphate deposits crystals in twelve hours, and nickel sulphate after weeks. Mercuric chloride gives at once a crystalline precipitate, and on standing a mixture of red and yellow crystals. Red amorphous precipitates are formed by salts of silver and lead, and reddish-brown by copper salts, while alum, zinc sulphate, stannous chloride, cobalt, nitrate, ferric and ferrous chloride, manganese sulphate, and bismuth nitrate, give amorphous reddish-yellow precipitates.

The *ammonium salt*, $C^{20}H^6Br^4O^3(NH^4)^2$, is obtained in small red needles, when a solution of tetrabromofluorescein in alcoholic ammonia is concentrated; they give off some ammonia on drying.

The *barium salt*, $C^{20}H^6Br^4O^3Ba + 2H^2O$, is prepared by mixing a solution of 2 pts. of the potassium salt with a solution of 1 pt. of barium chloride in such proportion that 60 pts. of water are present. On boiling, crystals separate out, of which more are obtained on evaporating the mother-liquor after cooling; they form small rhombic plates with a green reflex; the aqueous solution is yellowish-red, and shows a green fluorescence.

The *cupric salt*, $C^{20}H^6Br^4O^3Ca + \frac{1}{2}H^2O$, forms small yellowish-red needles, with a faint green lustre; it is more freely soluble than the barium salt.

The *cadmium salt* is deposited from a dilute solution in very glistening, small six-sided plates, having a brilliant greenish-yellow lustre; at 100° it loses water and becomes green.

The *silver salt*, $C^{20}H^6Br^4O^3Ag^2$, is a dark red precipitate, which is insoluble in salt-solutions, but dissolves in pure water and alcohol, and on heating it with the latter to 150° and leaving the solution to cool, it crystallises in microscopic, indistinct prisms, which are almost black. The precipitated salt becomes green when dried in a vacuum.

The *lead salt*, $C^{20}H^6Br^4O^3(PbOH)^2$, is obtained as a red precipitate, when the potassium salt is mixed with lead acetate, while the nitrate produces a similar precipitate which is not quite pure, $C^{20}H^6Br^4O^3Pb$.

Red Monethyl-tetrabromofluorescein or *Erythrin*, $C^{20}H^6Br^4O^3 \begin{Bmatrix} OC^2H^5 \\ OH \end{Bmatrix}$, is formed when the potassium salt of eosin is heated at 140° – 150° for four or five hours with 15 pts. of alcohol and a quantity of potassium ethyl-sulphate, which would be sufficient to form the neutral ether. On cooling, the tubes are found to contain a gelatinous mass mixed with large crystals, which, on adding water, remain undissolved, while the unchanged potassium salt of eosin dissolves. The crystals, which consist of the potassium-compound of erythrin, are dissolved in alcohol of 50 per cent., and the solution mixed with acetic acid. If it be concentrated, erythrin separates as an amorphous precipitate, but from a dilute solution, it crystallises on evaporation in red needles with a beetle-green lustre. Erythrin is also formed, but not so readily, by the action of ethyl bromide on the potassium salt of eosin.

Erythrin dissolves slowly but freely in alcohol, with a reddish-yellow colour, and more readily in chloroform and acetic acid. From the first two solvents it separates in warty crystals, but when its solution in a mixture of acetic acid and alcohol is

diluted with water, distinct crystals are obtained. Erythrin heated with sulphuric acid to 150° is converted into eosin.

The *potassium salt*, $C^{20}H^4Br^4O^5(C^2H^3)K + H^2O$, is very sparingly soluble in water and absolute alcohol, but readily in hot, dilute alcohol of 50 per cent. The concentrated solution is yellowish-red, the dilute solution, pale pink, with a yellowish-green fluorescence; its absorption-spectrum is almost the same as that of eosin. The salt, called in commerce 'insoluble eosin,' dyes silk and wool like eosin, but the shades are more inclined to violet. The crystals appear to be rhombohedrons. They have a strong beetle-green lustre, and yield a pink powder. Silver nitrate precipitates the solution; the precipitate is amorphous, red in reflected light, and beautiful violet in transmitted light; it becomes crystalline on heating or standing, has a beetle-green lustre in the dry state, and appears deep blue in transmitted light. The lead salt is a similar precipitate.

Colourless Monethyl-tetrabromofluorescein.—This isomeride of erythrin is formed, together with the diethyl-compound, when the silver salt of eosin is heated with an excess of ethyl iodide or bromide, and twenty times its weight of alcohol at 100° for three to four hours. To separate the two ethers, the product is repeatedly exhausted with boiling alcohol, in which the monethyl-ether is more readily soluble and crystallises on cooling in yellow needles. As soon as the red crystals of the diethyl-ether appear, the treatment with alcohol is stopped, and the yellow crystals are boiled with a solution of potash in alcohol of 50 per cent., which dissolves chiefly the monethyl-compound. The solution is then mixed with more dilute alcohol and acetic acid, and the ether which separates out is again treated in the same way, and is thus obtained in colourless needles. It is sparingly soluble in boiling alcohol, and a little more freely in glacial acetic acid; its very pale solution is coloured light yellow by alkalis, and gives yellowish-white precipitates with silver nitrate and lead acetate. It dissolves but sparingly in carbonates and dilute alkalis. The existence of two isomeric monethyl-compounds shows that the two hydroxyls occupy different positions.

Diethyl-tetrabromofluorescein, $C^{20}H^6Br^4O^5(C^2H^5)^2$, is obtained not only as described above, but also by heating the silver salt of the red monethyl-ether with ethyl iodide. To isolate it from the residue from the preparation of the white monethyl ether, this residue is exhausted with chloroform, and the crystals, after boiling with dilute alcoholic potash, are recrystallised from chloroform. It forms small but well-defined crystals, which appear to be rhombohedrons, and dissolve very sparingly in alcohol and ether, with a yellowish colour, and freely in chloroform and glacial acetic acid, with a reddish-yellow colour. Aqueous alkalis do not decompose it on boiling, but alcoholic potash, as well as hot sulphuric acid, converts it into eosin.

Monomethyl-tetrabromofluorescein, or *Methylerythrin*, $C^{20}H^5Br^4O^5(CH^3)$, is sparingly soluble in alcohol, more freely in chloroform, and crystallises in red needles, having a beetle-green lustre.

Acetyl-tetrabromofluorescein is formed by heating eosin with three times its weight of acetic anhydride to 140° . It forms colourless needles dissolving sparingly in alcohol, acetone, wood-spirit, and acetic ether, and more freely in hot benzene and chloroform. On heating, it becomes red at 180° , but melts only at 278° .

Tetrabromofluorescein chloride, $C^{20}H^4Br^4O^5Cl$, is obtained by heating tetrabromofluorescein with phosphorus pentachloride for an hour at 100° . The product, after being well boiled with water and a dilute alkali, is dissolved in seventy times its weight of concentrated sulphuric acid at 150° , filtered through asbestos, and then mixed with 3 vols. of alcohol. The liquid is then heated to the boiling point, and water added, until crystals begin to separate out. It forms colourless needles, which melt and sublime without decomposition; its only solvent is concentrated sulphuric acid, which decomposes it only at the boiling point.

When tetrabromofluorescein is heated with concentrated potash on a water-bath, the liquid soon assumes a blue colour, and shows, when diluted, a very strong, dark-green fluorescence. The dilute solution turns red in contact with the air, but the concentrated solution remains blue. Mineral acids produce a pale reddish-yellow precipitate of the hydrate $C^{20}H^5Br^4O^5 + H^2O$, which has undoubtedly a constitution analogous to that of the dinitro-compound. When the solution is heated on a water-bath, the blue colour changes to dark yellow, more quickly if the potassium salt is heated with twenty times its weight of soda of 50 per cent. Mineral acids precipitate the solution.

Dibromomonoresorcinol-phthalein, $C^8H^4 \begin{Bmatrix} CO.C^6HBr^2(OH)^2 \\ CO.H \end{Bmatrix}$, crystallises in small, colourless, rhombic plates, which melt at 218° – 220° . It is almost insoluble in

water, and dissolves in alkalis and alcohol with a yellow colour. On fusing it with resorcinol, dibromofluoresceïn seems to be formed, and when it is heated with phenol and sulphuric acid at 120°, a body is formed, dissolving in alkalis with a red colour.

The acid liquid from which the preceding compound has been precipitated contains *dibromoresorcinol*, $C^6H^2Br^2(OH)^2$, which is shaken out with ether. It crystallises from warm water in colourless needles, melting at 92°–93°; the aqueous solution gives, with ferric chloride, first a violet colour, which soon changes into an indistinct dirty green.

Water and sodium-amalgam, or zinc-dust and soda, reduce tetrabromofluoresceïn to fluoresceïn, and when the tetrabromo-compound is boiled for five minutes with twenty times its weight of concentrated sulphuric acid, *heptabromocœrulin*, $C^{10}H^{13}Br^7O^{10}$, is formed, which, by adding water, is precipitated as a dark violet mass, and during washing, begins to dissolve with a blue colour. On dissolving it in dilute potash, and adding alcoholic potash, a dark-blue precipitate of the potassium-salt is obtained, which yields, with acids, the pure cœrulin, readily soluble in acetone, from which it crystallises in steel-blue needles. The absorption-spectrum of the dilute solution shows a faint broad band in the green, and the dilute alkaline solution, which has a greenish-blue colour, gives an absorption-band in the red.

Quinol-phthaleïn, $C^{20}H^{12}O^5$. *Hydroquinone-phthaleïn*.—This compound, isomeric with fluoresceïn, and therefore, properly speaking, the anhydride of quinol-phthaleïn, $C^{20}H^{14}O^5$, was discovered by Grimm (*Ber.* vi. 596), who obtained it, together with quinzarin, by heating a mixture of quinol and phthalic anhydride with strong sulphuric acid. According to Ekstrand, however (*ibid.* xi. 713), it is better to use zinc-chloride as the dehydrating agent, the yield of the phthaleïn being then 70 per cent. of the quinol used, whereas with sulphuric acid it is only 25 per cent. The best proportions are 2 mols. quinol, 1 mol. phthalic anhydride, and a quantity of zinc chloride equal to thirteen times the weight of the mixture, the whole being heated at 120°–130° for twelve to fourteen hours:

The product is boiled with water to remove the stannic chloride, unaltered quinol, and phthalic anhydride; it is at first viscid, but ultimately becomes crystalline. To purify it, the crystalline residue is dissolved in alcohol, and boiled for a long time with animal charcoal, the filtrate, which is cloudy at first, gradually solidifying to a felted mass of needles. Pure quinol-phthaleïn is colourless, and melts at 226°–227° (uncorr.) (Ekstrand); at 233°–234° (Grimm). It dissolves but slightly in hot water, and separates on cooling in small tabular crystals; easily in wood-spirit, alcohol, acetic acid, and acetone; also in ether, from which it separates in long needles on evaporation. It is but sparingly soluble in chloroform or benzene even when hot, and not at all in light petroleum. The needles which separate from the alcoholic solution contain 1 mol. alcohol; if, however, the alcoholic solution is diluted with much water, needles are precipitated, which on boiling are converted into thin plates containing 1 mol. of water instead of alcohol. From the ease with which the alcohol and water replace one another, it is probable that the latter is present as water of crystallisation, and does not go to the formation of hydroxyl-groups so as to produce a tetrahydroxyl-compound; and that this is confirmed by the fact that this water is easily driven off below 160°, and that the hydrated and dehydrated products are perfectly similar in their properties; moreover, it has not been found possible to obtain a triacetyl-derivative of this body. A solution of quinol-phthaleïn mixed with an alkali acquires a deep violet colour, which becomes brown and muddy on standing. In sulphuric or hydrochloric acid, quinol-phthaleïn dissolves to a red liquid, and the latter acid gives a crystalline compound, corresponding probably with the hydrochloride of orcin-phthaleïn, but it has not yet been investigated.

Diacetyl-quinol-phthaleïn, $C^{20}H^{10}(C^2H^3O)^2O^5$, obtained by heating the phthaleïn with acetic anhydride for two or three hours, forms colourless crystals melting at 210°.

Bromo-compounds.—When a solution of the phthaleïn in alcohol or acetic acid is acted on by bromine, the mixture left at rest, and then diluted with water, a yellow flocculent precipitate is obtained, soluble in dilute alcohol, but it has not yet been obtained in crystalline form.

Pentabromo-quinol-phthaleïn, $C^{20}H^7Br^5O^5$, is obtained as a yellow crystalline precipitate when an excess of bromine is added to an acetic acid solution of the phthaleïn, and the mixture boiled for a long time. The pure compound is a colourless crystalline powder (m. p. over 300°), insoluble in acetic acid, but easily soluble in nitrobenzene, from which it separates in small tables. It gives a colourless solution with alkalis.

Quinol-phthalin, $C^{20}H^{14}O^5$, is obtained when the phthalein is heated for four hours with zinc-dust and soda-solution. It crystallises from benzene in large colourless tables (m. p. 202° uncorr.), containing 1 mol. benzene; dissolves to a colourless solution in alkalis, and to a red liquid in sulphuric acid, the solution when diluted with water giving an olive-green flocculent precipitate of quinol-phthalidin, which dissolves in ether with a green fluorescence; the ethereal solution, however, soon oxidises, with production of a dark violet powder. Quinol-phthalin does not combine with hydrochloric acid.

Diacetyl-quinol-phthalin, $C^{20}H^{12}(C^2H^3O)^2O^5$, is obtained by boiling the phthalin for two hours with an excess of acetic anhydride. It crystallises in colourless prisms (m. p. 190° uncorr.), and dissolves in wood-spirit much more easily than diacetyl-phthalein. At first it is not acted on by alkalis, but gives a violet coloration on gentle warming.

Orcinol-phthalein, or rather its **Anhydride**,

(E. Fischer, *Ber.* vii. 1214; *Liebig's Annalen*, clxxxiii. 63). This compound is prepared by heating 3 pts. phthalic anhydride, 5 pts. distilled orcinol, and 5 pts. strong sulphuric acid at 135° for about two hours. At this temperature, the reaction goes on smoothly and without evolution of sulphur dioxide, whereas at lower temperatures that gas is given off in considerable quantity. By dissolving the melt in dilute potash-ley, boiling the solution, precipitating with acetic acid, and recrystallising the precipitate from acetone, the compound is obtained in colourless needles mostly united in forked groups. It is insoluble in water, ether, benzene, and toluene, but dissolves readily in alcohol, wood-spirit, acetone, and hot glacial acetic acid, and is precipitated from the last-mentioned solution by water in white flocks. Alkalis dissolve it with dark red colour. It is decomposed by heat. On boiling it with strong sulphuric acid and mixing the resulting solution with water, dark brown flocks are thrown down, consisting of a body which dissolves in ammonia with dark brown colour, and is precipitated by baryta in the form of a black lake.

Monacetyl-orcinol-phthalein is obtained by prolonged boiling of the phthalein with glacial acetic acid. The *diacetyl-derivative*, $C^{22}H^{14}(C^2H^3O)^2O^5$, formed by treating the phthalein with 3 or 4 pts. of acetic anhydride, crystallises from alcohol in white slender needles, melting at 219° – 220° , insoluble in water, ether, and benzene, sparingly soluble in alcohol and wood-spirit, more freely in acetone; easily resolved into its constituents by alkalis and concentrated acids.

Orcinol-phthalein unites with *mineral acids*, forming dark-red unstable compounds, among which the *hydrochloride*, $C^{22}H^{16}O^5.HCl$, is most readily obtained pure, and separates from an alcoholic solution of the phthalein mixed with strong hydrochloric acid in dark red flocks, which give off their hydrochloric acid on exposure to the air, even at ordinary temperatures, and more quickly when heated or boiled with water.

When bromine is added to a solution of the phthalein in boiling acetic acid, the *tetrabromo-compound* is formed, while in a cold alcoholic solution the *pentabromo-compound* is produced. Both these compounds are pale yellow powders, nearly insoluble in all solvents.

Orcinol-phthalin, $C^{22}H^{20}O^5$, is formed by the action of zinc-dust on a solution of the phthalein in dilute soda-ley, the red liquid becoming colourless and yielding, on addition of sulphuric acid, white flakes of the phthalin, which when heated in the air are reoxidised to the phthalein. Its *diacetyl-compound*, $C^{22}H^{18}(C^2H^3O)^2O^5$, formed by heating it with acetic anhydride, is much more stable, and crystallises from benzene in cubes melting at 211° .

PHTHALEIN DYES. F. Reverdin (*Monit. scient.* [3], vii. 860) has obtained a yellow dye-stuff, called *chrysolin*, by the action of sulphuric acid on a mixture of phthalic acid and benzyl-resoreinol (formed by the action of benzyl chloride on resoreinol, *q. v.*), or by first heating 460 grams of sulphuric acid and 1 kilo. of phthalic acid in a retort placed in an oil-bath at 130° – 140° , whereby phthalic anhydride is produced, then adding 1 kilo. of resorcinol, 460 grams of sulphuric acid, and 1 kilo. of benzyl chloride, and heating the whole gently over a water-bath. When no more hydrochloric acid is evolved, the reaction is completed by heating for twelve hours in the oil-bath at 135° – 145° . The whole is then left to cool, and the solid mass is broken up and dissolved in dilute caustic soda at the boiling point. When the residue no longer diminishes, the solution is filtered, and the acid colouring matter is precipitated by means of hydrochloric acid, washed with cold water, dissolved in a quantity of sodium carbonate sufficient to saturate the acid, and evaporated to dryness. The sodium salt of benzylated fluorescein constitutes *chrysolin*. This substance forms a

mass with green metallic reflex, and yields a red-brown powder. It is soluble in water and alkalis, the solutions being precipitated by acids in yellow flocks. It yields bromated, iodated, and nitro-derivatives, which are all fine colouring matters. It may be fixed directly upon silk and wool. The latter takes the dye better when mordanted with lead acetate and alum. Cotton is mordanted with sulphate of alumina and dyed at a hand-heat. The shade of chrysolin approaches that of turmeric; it resists the action of light well. Similar colouring matters are produced by the action of the chlorides of fatty hydrocarbons on resorcinol. Methyl-resorcinol prepared by heating sodium resorcinate in alcoholic solution with methyl chloride under pressure likewise yields a yellow dye-stuff when treated as above.

Bouchardt a. Girard (*Monit. scient.* [3], vii. 985) have also obtained colouring matters by the introduction of alcohol-residues into resorcinol and the phthaleins. For this purpose, phenols and diphenols are heated to 120°–150° with diatomic acids, e.g. oxalic, lactic, camphoric, phthalic acids, &c.; the products are subjected to the action of solutions of alkaline hypochlorites or hypobromites; and the resulting colouring matters are precipitated from the alkaline solutions by acids. Thus when fluorescein, produced by heating a mixture of 1.4 kg. resorcinol with 1 kg. phthalic anhydride to 200°, is dissolved in a small quantity of soda-ley, and gradually mixed with 56 litres (per 1 kg. fluorescein) of a solution of sodium hypochlorite (sp. gr. 1.4), a colouring matter, called 'Aureosin,' is obtained, which, when separated by an acid, exhibits a greenish-yellow dichroism in reflected light and a red colour in transmitted light. Silk dyed with it fluoresces like the solution. This aureosin, treated at boiling heat with nitric acid diluted with 2 vols. water, is converted into another dye-stuff, called 'Rubeosin,' which dissolves in alkaline liquids with deep red colour, and dyes silk scarlet. If alkaline hypobromites are used instead of hypochlorites, the resulting colouring matters exhibit a somewhat more yellowish tint. Similar dye-stuffs are obtained by the action of sodium or potassium acetate in presence of acetic acid upon eosin, the reaction being completed, at 200°–250°, within three or four hours. The product analogous to aureosin is converted by oxidation into a body analogous to rubeosin. Phthalins may also be oxidised by hypochlorites or hypobromites in presence of cobalt-salts, and the process stopped at any required point. The bodies obtained by the action of alcoholic bromides and iodides on aureosin and rubeosin are likewise dye-stuffs. Lastly, products resembling aureosin are formed by oxidising fluorescein with mixtures of bromates or chlorates with hydrochloric or hydrobromic acid respectively.

PHTHALIC ACIDS, $C^8H^6O^4 = C^6H^4(CO^2H)^2$. (1). ORTHOPHTHALIC, or simply PHTHALIC ACID [1 : 2], is formed by oxidation of orthotoluic acid with potassium permanganate (Weith, *Ber.* vii. 1057):

Synthetically it may be formed by combination of carbon monoxide with salicylic acid and with resorcinol. From *salicylic acid* it is produced by heating that substance with a mixture of sulphuric acid and potassium ferrocyanide, and when the reaction is ended, treating the resulting mass with ether, which extracts the phthalic acid, or by heating a mixture of sulphuric acid and formic acid with salicylic acid until gas is no longer disengaged. The mass is exhausted with ether, which on evaporation yields perfectly pure phthalic acid. *Resorcinol* combines readily with carbon monoxide to form phthalic acid, but as an excess of resorcinol is always present, the phthalic acid unites with it and forms fluorescein. When salicylic acid or resorcinol is heated with oxalic acid and sulphuric acid, that is to say, with a mixture yielding carbon dioxide and monoxide simultaneously, neither phthalic acid nor fluorescein is formed; but when salicylic acid or resorcinol is heated with a mixture of oxalic acid and glycerol, that is, with a mixture yielding carbon dioxide in the first phase of the operation and carbon monoxide in the second, carbon dioxide is disengaged freely, and phthalic acid or fluorescein appears as soon as the mixture yields carbon monoxide (A. Guyard, *Bull. Soc. Chim.* [2], xxix. 247).

Preparation from Naphthalene.—The following modification of Depouilly's process for obtaining phthalic acid by the action of potassium chlorate and hydrochloric acid on naphthalene (*Compt. rend.* lvi. 82; *Jahresb. f. Chem.* 1866, 399) is recommended by C. Häussermann (*Dingl. pol. J.* cccxiii. 310). A mixture of 1 pt. naphthalene and 2 pts. potassium chlorate is added by successive small portions to a five-fold quantity of ordinary hydrochloric acid; the product is well washed with lukewarm water, then dried, and digested at a gentle heat with petroleum-benzin; and the resulting mass, consisting chiefly of naphthalene tetrachloride, is heated with five or six times the quantity of nitric acid of specific gravity not exceeding 1.35, till the liquid is perfectly homogeneous. On expelling the excess of acid, and leaving the liquid to cool, phthalic acid crystallises out in quantity equivalent to 30 per cent. of phthalic anhydride.

Phthalic acid is also formed from *nitronaphthol* (m. p. 128°) by repeated treatment with nitric acid and evaporation (Liebermann, *Ber.* viii. 689).

Phenyl Phthalate, $C^6H^4(COOC^6H^5)^2$, is prepared by heating phthalic chloride with the calculated quantity of phenol as long as hydrochloric acid continues to be evolved, and crystallising the product from hot alcohol. It forms groups of small colourless prisms, melts at 60°, and distils without alteration. Nitric acid attacks it violently, forming dinitrophenol and nitrophthalic acid. A hot alcoholic solution of the ether treated with potassium hydrosulphide yields the potassium salt of thio-phthalic acid together with phenol:

(J. Schreder, *Ber.* vii. 704).

Phthalic Anhydride, $C^6H^4O^3 = C^6H^4 \begin{smallmatrix} \text{CO} \\ \diagup \quad \diagdown \\ \text{CO} \end{smallmatrix} O$, is produced by the action of acetic anhydride or acetyl chloride on phthalic acid:

It melts at 127°. The anhydrides of succinic, diphenic, and other bibasic acids may be prepared by similar reactions (Anschütz, *Ber.* x. 1881).

Phthalic anhydride heated with *phenols* in presence of dehydrating agents (sulphuric acid, zinc chloride, &c.), produces phthaleins (pp. 1603-1613). On gently heating it with ordinary phenol and sulphuric acid, the liquid assumes a yellowish-red colour, and phenol-phthalein, $C^{20}H^{14}O^4$, is formed, which, on further addition of sulphuric acid, is converted, without change of colour, into phenol-phthalein-sulphonic acid. On increasing the heat, the yellow-red colour changes to dark red and ultimately to brown-yellow, and the liquid, on addition of water, deposits flocks of monoxyanthraquinone, $C^{14}H^8O^3$ (p. 99). The formation of this latter body is not essentially dependent on the previous formation of phenol-phthalein, but may take place directly from phenol. A similar result is obtained when the phenol is replaced by phenolsulphonic acid, phenoldisulphonic acid, oxysulphobenzide, anisole, anisic acid, or salicylic acid:

(Baeyer a. Caro, *Ber.* vii. 968).

Phthalic anhydride, heated with *acetic* and *propionic anhydrides* in presence of the sodium salts of the respective acids, yields phthalyl-acetic and phthalyl-propionic acids respectively (pp. 1621, 1622). Heated with *phenylacetic* (*α-toluidic*) acid, it yields benzylidene-diphthalyl (p. 1621):

When phthalic anhydride is heated with *succinic acid* and sodium acetate, the mixture being kept in a state of fusion as long as it continues to give off carbon dioxide, a residue is obtained which, after crystallisation from nitrobenzene, consists of ethineorthophenylene-diketone or ethine-diphthalyl:

This compound crystallises in yellow needles, melting above 350°. When boiled with dilute potash-ley, it dissolves slowly, and the solution yields with hydrochloric acid a precipitate of phenylene-ethylene-ketone carboxylic acid (p. 1561):

formed from ethine-diphthalyl by assumption of 2 mols. water.

When ethine-diphthalyl dissolved in acetic acid is heated with *bromine* at 100° in a sealed tube, two atoms of hydrogen are replaced by bromine and a molecule of water is taken up, producing the compound

which is decomposed by heating with alkalis (Gabriel a. Michael, *Ber.* x. 1559).

(2). **META- or ISOPHTHALIC ACID**, $[\text{CO}^2 : \text{CO}^2\text{H} = 1 : 3]$, is produced: *a.* Together with metabromobenzoic acid, by the action of ethyl-chlorocarbonate and sodium-amalgam on metadibromobenzene (Wurster, p. 163). *β.* By fusing potassium benzoate with potassium formate (Meyer, p. 259). *γ.* By heating the nitril of disulphobenzoic acid, $\text{C}^6\text{H}_4\text{CO}^2\text{H}\cdot\text{SO}^3\text{H}\cdot\text{H}\cdot\text{SO}^3\text{H}\cdot\text{H}^2$, or that of benzenedisulphonic acid $[1 : 3]$ with alcoholic potash (p. 251). *δ.* By oxidation of meta-toluic acid (Weith a. Landolt, *Ber.* viii. 715). *ε.* By prolonged boiling with nitric acid of the products obtained by the action of hydrochloric acid on resorcinol (Barth a. Weidel, *Ber.* x. 1464). *ζ.* By oxidation of colophony with nitric acid (Schreder, *Lieb. Ann.* clxxii. 93).

Phenyl Isophthalate crystallises in long slender needles melting at 120° (Schreder, *Ber.* vii. 704).

(3). **PARAPHTHALIC or TEREPHTHALIC ACID** $[1 : 4]$ is formed: *a.* By heating sodium parasulphobenzoate with sodium formate, and, together with isophthalic acid, by heating sodium benzoate to the point of carbonisation (p. 260). *β.* By heating the nitril of benzeneparadisulphonic acid with alcoholic potash (p. 250). *γ.* Together with terebic acid, by oxidation of turpentine-oil with nitric acid of sp. gr. 1.4, diluted with 2 vols. water (Schreder, *Ber.* vii. 794). This is the process by which terephthalic acid was first obtained (v. 725). W. C. Williams, however (*Ber.* vi. 1094), by oxidising turpentine-oil with nitric acid of sp. gr. 1.25, obtained only terebic acid without a trace of terephthalic acid. *δ.* Together with paratoluic acid, by the action of nitric acid on the portion of Eucalyptus oil boiling between 172° and 175° (Homeyer, *Arch. Pharm.* [3], v. 326). *ε.* By oxidation of curcumin with chromic acid mixture (Gajevsky, *Ber.* vi. 196).

Ethers. *Propyl Terephthalate*, $\text{C}^6\text{H}_4(\text{CO}^2\text{C}^3\text{H}_7)^2$, obtained by heating silver terephthalate mixed with two or three times its weight of sand, with propyl iodide, crystallises in white needles an inch long, dissolves easily in hot alcohol and in ether, and melts at 31° . *Pseudopropyl terephthalate*, prepared in like manner, crystallises in shining white laminae, melting at 55° – 56° , and exhibiting the same relations of solubility as the normal propyl-ether. *Isobutyl terephthalate*, $\text{C}^6\text{H}_4(\text{CO}^2\text{C}^3\text{H}_7)^2$, is best prepared from terephthalyl chloride and isobutyl alcohol, and crystallises in dazzling white needles having a fatty lustre, melting at 52.5° , easily soluble in ether. The normal butyl ether has not been obtained in crystalline form (J. Berger, *Ber.* x. 1742). *Phenyl terephthalate*, prepared by heating terephthalyl chloride with phenol, forms long slender needles melting at 120° (Schreder, *ibid.* vii. 704).

Homoterephthalic acid, $\text{C}^6\text{H}^3\text{O}^4 = \text{C}^6\text{H}^4 \begin{smallmatrix} \text{CH}_2\text{COOH} \\ \text{COOH} \end{smallmatrix}$, is formed, together with propyl-benzoic acid, by oxidation of propyl-benzene (*q.v.*) with dilute nitric acid. It is a faintly yellowish powder, which sublimes without fusing, is nearly insoluble in all solvents, and forms a silver salt, $\text{C}^6\text{H}^3\text{O}^4\text{Ag}^2$, and a barium salt, $\text{C}^6\text{H}^3\text{O}^4\text{Ba} + 3\frac{1}{2}\text{H}_2\text{O}$ (Paternò a. Spica, *Gazz. chim. ital.* 1877, 361).

Hydroxyphthalic Acids, $\text{C}^6\text{H}^3(\text{OH})(\text{COOH})^2$, syn. with PHENOL-DICARBOXYLIC ACIDS (pp. 1531–1534).

Nitrophthalic Acids, $\text{C}^6\text{H}^3(\text{NO}^2)(\text{COOH})^2$. The prismatic nitrophthalic acid, melting at 212° , which Faust obtained by digesting *o*-phthalic acid with a mixture of nitric and sulphuric acids (vii. 978), is also formed, together with the corresponding aldehyde (m. p. 135°), by oxidising nitronaphthalene in acetic acid solution with chromic acid. It is decomposed by hydrobromic acid, with formation of carbon dioxide and di- and tri-bromobenzoic acids. Hydriodic acid converts it into metamidobenzoic acid (Beilstein a. Kurbatow, *Ber.* xii. 688).

According to Faust, this acid is reduced by tin and hydrochloric acid to metamidobenzoic acid, with evolution of carbon dioxide. According to O. Miller, on the other hand (*Ber.* xi. 1191), the reduction is not attended with evolution of carbon dioxide, but yields a tin-salt, $\text{C}^6\text{H}^3(\text{NH}^2)(\text{COOH})^2\cdot\text{HCl}\cdot\text{SnCl}^2 + 2\text{H}_2\text{O}$, which separates in nearly colourless needles, crystallises from aqueous solution in light brown rhombic plates and needles, but from dilute hydrochloric acid in crystals of the original form and colour. The formation of the hydrochloride of metamidobenzoic acid takes place only when the solution, after being freed from tin by hydrogen sulphide, is concentrated by evaporation.

Amidophthalic acid.—The ethylic ether of this acid is prepared by mixing a solution of ethyl nitrophthalate (obtained by the action of hydrochloric acid on a hot solution of the nitronaphthalic acid above described) in 2 vols. of alcohol, with 10 vols. of hydrochloric acid, of sp. gr. 1.09; the mixture being kept cool by means of ice, and zinc-dust added gradually, till the oily drops disappear and a distinct evolution of gas takes place. The liquid is then diluted with water and nearly neutralised with sodium carbonate, and sodium acetate is added, whereupon ethyl amidophthalate

crystallises out. This product crystallises from ether in large, colourless, monoclinic prisms, agreeing in composition with the formula $C^6H^3(NH^2)(COOC^2H^3)^2$. It dissolves in hydrochloric acid without alteration, and is precipitated from the solution by alkalis or by sodium acetate (W. Königs, *Ber.* x. 124).

Isonitrophthalic acid (m. p. 160°) (O. Miller, *Ber.* xi. 393, 992, 1191).—This acid is formed, together with the preceding nitro-acid, by heating phthalic acid on the water-bath with a mixture of nitric and sulphuric acids. The two nitro-acids are produced in nearly equal quantities, and after they have been precipitated by water, the filtered liquid is found to contain picric and acetic acids, with a very small quantity of formic acid. The ordinary prismatic nitro-acid is easily separated by repeatedly crystallising the crude nitro-product from water; but the isonitrophthalic acid, which is more soluble, crystallises in needles, and forms a compound with picric acid, is more difficult to separate. The separation may, however, be effected by picking out the needle-shaped crystals, converting them into the sparingly soluble barium salt, and decomposing this salt with hydrochloric acid. The isonitro-acid thus obtained forms pale yellow slender needles very easily soluble in water, alcohol, and ether, insoluble in benzene; it melts at 160° , and is resolved at 165° into water and the anhydride.

The barium salt, $C^6H^3(NO^2)(CO^2)^2Ba + 2H^2O$, is a light yellow precipitate made up of microscopic laminae. The silver salt, $C^6H^3(NO^2)(CO^2Ag)^2$, is thrown down by silver nitrate from a solution of the acid neutralised with ammonia, as a whitish precipitate, sparingly soluble in pure water, but very soluble in ammoniacal water, and separating from this solution in long colourless needles.

Normal Ethyl Isonitrophthalate, $C^6H^3(NO^2)(CO^2C^2H^5)^2$, is formed, together with very small quantities of the acid ether, on saturating the alcoholic solution of the acid with hydrochloric acid. It is liquid at first, but afterwards solidifies to a crystalline mass which melts at 32° . By reduction, it yields *ethyl isoamidophthalate*, $C^6H^3(NH^2)(CO^2C^2H^5)^2$, which crystallises from alcohol in short prisms of considerable size.

When isonitrophthalic acid is reduced by tin and hydrochloric acid, the resulting tin-salt does not separate out like that which is obtained from the prismatic nitro-acid; ultimately, however, metamidobenzoic acid is formed in this as in the former case.

Thiophthalic Acid, $C^6H^4 \begin{smallmatrix} \text{COSH} \\ \text{COOH} \end{smallmatrix}$ [1 : 2] (Schreder, *Ber.* vii. 704). The potassium salt of this acid is obtained by dissolving potassium sulphhydrate (2 mols.) in a hot alcoholic solution of 1 mol. phenyl phthalate (p. 1614), whereupon the liquid turns red. After the reaction has continued for a quarter of an hour, ether is added, which precipitates part of the resulting potassium thiophthalate in the form of a red oil. The greater part of the colourless liquid decanted therefrom is distilled off; and the remainder is diluted with water—whereby phenol is precipitated—and after removal of the latter, acidulated with hydrochloric acid. The thiophthalic acid thereby separated in slender needles is purified by distillation, whereby a colourless oil is obtained which immediately solidifies; the last traces of free sulphur, however, can be removed from it only by fusion with finely divided silver or with mercury. The substance thus purified crystallises from alcohol in long brittle needles having the composition of thiophthalic anhydride, $C^6H^4 \begin{smallmatrix} \text{CO} \\ \text{CO} \end{smallmatrix}$. Its formation is represented by the following equations:

Thio-isophthalic acid, [1 : 3].—The potassium salt of this acid is formed in like manner by the action of KHS on phenyl isophthalate, and is thrown down from the resulting solution by ether in yellow needles, which when decomposed by hydrochloric acid yield thio-isophthalic acid in the form of an oil (Schreder).

Thioterephthalic acid, [1 : 4].—The potassium salt, prepared in like manner, separates on addition of ether in the form of a red mud. The acid separated therefrom forms after purification a white amorphous powder not volatile without decomposition (Schreder).

PHTHALIC ALCOHOL, $C^6H^{10}O^2 = C^6H^4(CH^2OH)^2$ (Hessert, *Ber.* xii. 646). This alcohol, produced by the action of sodium-amalgam on phthalic chloride, is a crystalline body, soluble in water, alcohol, and ether, melting gradually at 56° – 62° . It is oxidised by potassium permanganate to phthalic acid, by nitric acid to phthalide, and is distinguished from the latter compound, which it otherwise resembles, by the

action of sulphuric acid, this reagent dissolving it with a red colour, and rapidly converting it into resinous products. On reduction by boiling it with hydriodic acid and phosphorus, it yields orthoxylene. It acts readily on acetic and benzoic chlorides. The *acetate*, $C^6H^4(CH^2 \cdot OC^2H^3O)^2$, is a crystalline body (m. p. 37°) which may be distilled without decomposition, and is converted by the action of hydrochloric acid gas into the chloride $C^6H^4(CH^2Cl)^2$, which when heated with lead nitrate and water yields phthalide (p. 1618).

PHTHALIC ALDEHYDES, $C^6H^6O^2 = C^6H^4(COH)^2$. The compound hitherto regarded as orthophthalic aldehyde (vi. 943) appears from recent investigations by Hessert to have the constitution of an anhydride, $C^6H^4 \begin{smallmatrix} CH^2 \\ \diagup \quad \diagdown \\ CO \end{smallmatrix} O$. See PHTHALIDE (p. 1618).

Terephthalic Aldehyde, $C^6H^4(COH)^2$ [1 : 4], is prepared by boiling tolylene chloride, $C^6H^3Cl^2$, with 20 pts. water and 1 pt. lead nitrate till nitrous acid is no longer given off, and distilling the mixture, the aldehyde then passing over, though not readily, with the vapour of water. When purified by crystallisation from boiling water, it forms white slender needles which melt at 114° – 115° , dissolve with moderate facility in ether, very easily in alcohol, very slightly in cold water, and in about 60 pts. of boiling water; it dissolves also at 40° – 50° in 20–25 pts. of a saturated solution of acid sodium sulphite, but the resulting compound has not been obtained in the solid state. By oxidation with potassium dichromate and sulphuric acid, it yields terephthalic acid. By mixing its alcoholic solution with an alcoholic solution of potassium cyanide, it is converted into an amorphous yellowish substance which melts at 170° – 174° , is insoluble in water and in ether, somewhat soluble in boiling alcohol, soluble in alkalis but not in alkaline carbonates, and appears to be a polymeride of terephthalic aldehyde (Grimaux, *Compt. rend.* lxxxiii. 825).

The tolylene chloride obtained from coal-tar xylene is accompanied by a liquid chloride, which, when treated as above, yields needles melting at 88° , and probably consisting of *isophthalic aldehyde* (Grimaux).

PHTHALIC CHLORIDES, $C^6H^4(COCl)^2$. *Orthophthalic chloride* acts upon dimethylaniline, producing dimethylaniline-phthalein (p. 1310), and in like manner on other tertiary bases, e.g. on methyldiphenylamine (O. Fischer, *Ber.* ix. 1753).

Isophthalic chloride is obtained by heating isophthalic acid with phosphorus pentachloride. The mixture liquefies, and on distilling it after the evolution of hydrochloric acid has ceased, the chloride is obtained as an oil which boils at 276° , and quickly solidifies. After rectification it is nearly inodorous and melts at 41° .

Terephthalic chloride has a pungent, cinnamon-like odour, melts at 78° , and boils at a temperature too high to be exactly determined (Schreder, *Ber.* vii. 704).

PHTHALIDE, $C^6H^6O^2 = C^6H^4 \begin{smallmatrix} CH^2 \\ \diagup \quad \diagdown \\ CO \end{smallmatrix} O$ (Baeyer u. Hessert, *Ber.* x. 123; Hessert, *ibid.* x. 1445; xi. 637). This compound, hitherto regarded as orthophthalic aldehyde, $C^6H^4(COH)^2$, is formed by the action of nascent hydrogen on phthalic chloride:

According to Hessert, it is best prepared by a modification of Kolbe a. Wischin's process (vi. 943), namely by the action of zinc and hydrochloric acid on an *etheral solution* of phthalic chloride. Metallic zinc is covered with a solution of phthalic chloride (8 to 10 grams) in ether (400 c.c.), and dilute hydrochloric acid is gradually added, the liquid being kept cool at the beginning; afterwards, however, the action goes on more slowly, and stronger hydrochloric acid may be used. The solution of zinc chloride which forms must be removed from time to time, so that the zinc may always project into the ethereal liquid. After about twelve hours, the ethereal solution is distilled off; the phthalide which remains is digested with water to remove undecomposed chloride; ammonium carbonate added in excess; and the product again extracted with ether. On subsequently distilling off the ether, the phthalide remains as a mass which solidifies in the crystalline state, and may be purified by recrystallisation from water.

Pure phthalide melts at 73° . When heated at 180° – 200° with *hydriodic acid* (b. p. 127°) and *red phosphorus*, it is completely resolved into a mixture of hydrocarbons boiling between 112° and 120° , and intermediate in composition between toluene and xylene. By *potassium permanganate* in alkaline solution it is easily oxidised to phthalic acid. When its warm aqueous solution is mixed with a concentrated solution of *acid sodium sulphite*, the liquid solidifies after some time to a mass of long silky needles, which were supposed by Kolbe a. Wischin (vi. 493) to consist

of a compound of phthalic aldehyde with the acid sodium sulphite. Hessert, however, finds that they do not contain a trace of this salt, but consist of the pure compound $C^6H^4O^2$, which therefore appears to be incapable of uniting with acid sulphites of alkali-metal, and accordingly cannot be regarded as an aldehyde. On this account, and in accordance with the reactions about to be described, Hessert assigns to it the constitutional formula above given.

Alkalis and alkaline carbonates, at the boiling heat, convert phthalide into an acid, $C^6H^4O^2 = C^6H^4 \begin{smallmatrix} \text{CH}^2\text{OH} \\ \text{COOH} \end{smallmatrix}$, called benzene-ortho-alcoholic acid (originally called *phthaldehydeic acid*), metameric with hydroxytoluic acid, $C^6H^3(CH^3)(OH)CO^2H$, which separates from the cooled solution on acidulation as a white powder. This acid is much less soluble in cold water than phthalide, but dissolves readily in alcohol and ether. It melts at 118° , giving off 1 mol. H^2O and being reconverted into phthalide. The same change takes place on boiling it with water. It is a well-characterised monobasic acid, reddens litmus strongly, and dissolves with effervescence in alkaline carbonates. Its salts are all soluble in water; those of the alkaline earths dissolve in the smallest quantities of water and alcohol, without however being deliquescent. The *silver salt*, prepared with recently precipitated silver oxide, crystallises from the aqueous solution in small octohedrons; its solution decomposes when heated. The *lead salt* is decomposed by water. Aqueous ammonia gradually dissolves phthalide, producing *ammonium benzene-o-alcoholate*; alcoholic and ethereal solutions of ammonia do not act upon phthalide, even at 220° . At 240° , however, the ethereal solution of ammonia gives rise to a new body which is nearly insoluble in water, alcohol, ether, and carbon sulphide, but dissolves in glacial acetic acid at boiling heat, and crystallises therefrom in slender needles which do not melt at 260° .

Aniline acts on phthalide at a temperature above its boiling point, converting it into the compound $C^6H^4 \begin{smallmatrix} \text{CH}^2 \\ \text{CO} \end{smallmatrix} N.C^6H^5$. The two substances are heated together in a sealed tube at 200° – 220° for some hours; and the product is precipitated by dilute hydrochloric acid, washed with water, and crystallised from hot alcohol, from which it separates in silvery laminae melting at 160° . It is very sparingly soluble in boiling water, somewhat more freely in ether, easily in chloroform. It is decomposed by boiling with concentrated alkalis or acids. By oxidation it is converted into phthalidanil, $C^6H^4 \begin{smallmatrix} \text{CO} \\ \text{CO} \end{smallmatrix} N.C^6H^5$, or phthalanilic acid.

Sodium-amalgam converts phthalide in aqueous or alcoholic solution chiefly into hydrophthalide, $C^6H^4 \begin{smallmatrix} \text{CH}^2 \\ \text{CHOH} \end{smallmatrix} O$, which is obtained as a viscid mass, very easily soluble in all solvents except water, gradually becoming solid when dried over sulphuric acid, and horny at a gentle heat. Potassium permanganate oxidises it to phthalic acid. Together with the hydrophthalide there is also formed a small quantity (about 10 per cent.) of a body having the composition $C^{16}H^{18}O^4$, which crystallises from alcohol in fine white needles melting at 197° , soluble in water and alcohol, sparingly in ether, insoluble in chloroform. By oxidation with potassium permanganate it yields phthalic acid and diphtalic acid, $C^{18}H^{10}O^6$ (vii. 980), whence it appears to consist of phthalylpinacene, $C^6H^4 \begin{smallmatrix} \text{CH}^2\text{OH} & \text{HOH}^2\text{C} \\ \text{CHOH} & \text{—HOHC} \end{smallmatrix} C^6H^4$ (Hessert).

Diphenyl-phthalide, $C^{20}H^{14}O^2 = C^6H^4 \begin{smallmatrix} \text{C}(C^6H^5)^2 \\ \text{CO} \end{smallmatrix} O$. This compound, formerly called *phthalophenone*, was discovered by Friedel a. Krafft (*Revue scientifique*, 2 Mars, 1878), who obtained it by heating phthalic chloride with benzene in presence of aluminium chloride, and represented its formation by the equation

analogous to that which expresses the formation of diphenyl ketone (benzophenone) from benzoyl chloride and benzene. But according to Baeyer (*Ber.* xii. 642), the aluminium chloride acts, not upon the chlorine, but on the oxygen-atom of one of the groups $COCl$, giving rise to its replacement by $2C^6H^5$, the reaction taking place by two stages as follows:

On the conversion of this compound into phenol-phthalein, see PHTHALEINS (p. 1603).

Benzyl-phthalide, $C^{14}H^{12}O^2 = C^6H^4 \left\langle \begin{smallmatrix} CH.CH^2.C^6H^5 \\ CO \end{smallmatrix} \right\rangle O$, is formed by the action of sodium-amalgam on deoxybenzoin-carboxylic acid (p. 1620). It crystallises in long colourless needles, melts at 56° – 57° , dissolves in alcohol, ether, and hot alkalis, but is insoluble in water (Michael a. Gabriel, *Ber.* xi. 1020).

PHTHALIDEIN (PHENOL), $C^{20}H^{14}O^4$, and **PHTHALIDIN**, $C^{20}H^{14}O^3$. See PHTHALEINS (pp. 1604, 1605).

PHTHALIMIDE, $C^8H^5NO^2 = C^6H^4 \left\langle \begin{smallmatrix} CO \\ CO \end{smallmatrix} \right\rangle NH$. This compound, originally obtained by heating phthalate or phthalamate of ammonium (iv. 632), is also produced, together with carbon dioxide and ammonia, by fusing phthalic anhydride with urea, and, with evolution of phosgene gas, by the action of phthalic chloride on urea. It melts at 228° – 229° (R. Biedermann, *Ber.* x. 1166).

Ethyl-phthalimide, $C^{10}H^9NO^2 = C^6H^4(CO)^2N(C^2H^5)$, obtained by distilling phthalic anhydride with aqueous ethylamine, forms white needles melting at 78° – 79° . *Tribromethyl-phthalimide*, obtained, together with the dibromo-derivative, by the action of bromine on ethyl-phthalimide, crystallises in truncated prisms, which melt with decomposition at 186° – 188° . It is insoluble in water, slightly soluble in hot alcohol, decomposed by hot aqueous potash into hydrogen bromide and a basic compound (A. Michael, *Ber.* x. 1644).

Phenyl-phthalimide, or *Phthalanil*, $C^{14}H^9NO^2 = C^6H^4(CO)^2N(C^6H^5)$.—This body, obtained by melting phthalic acid with aniline, has been already described (iv. 632). It is also formed by limited oxidation of the compound $C^6H^4 \left\langle \begin{smallmatrix} CH^2 \\ CO \end{smallmatrix} \right\rangle N(C^6H^5)$, produced by the action of aniline on phthalide (p. 1619), and is

converted by further oxidation into phthalanilic acid, $C^6H^4 \left\langle \begin{smallmatrix} CO.NH.C^6H^5 \\ COOH \end{smallmatrix} \right\rangle$ (iv. 628).

Substituted Phthalanils are obtained by melting phthalic anhydride in excess with substituted anilines, as long as water continues to be given off, boiling the pulverised melt with water to remove the excess of phthalic acid, and recrystallising the product from an appropriate solvent.

p-Chlorophenyl-phthalimide, $C^6H^4(CO)^2N.C^6H^4Cl$, prepared from *p*-chloraniline and phthalic anhydride, crystallises from boiling alcohol in long slender silky needles, melting at 194° – 195° , easily soluble in hot alcohol, benzene, and glacial acetic acid, less soluble in ether.

p-Bromophenylphthalimide, $C^6H^4(CO)^2N.C^6H^4Br$, from bromaniline (m. p. 65°). crystallises from an alcoholic solution in scales or needles, which melt at 203° .

p-Iodophenylphthalimide, prepared from *p*-iodaniline (m. p. 60°), forms needle-shaped crystals melting at 227° , soluble in benzene and in glacial acetic acid.

m-Nitrophenylphthalimide, $C^6H^4(CO)^2N.C^6H^4(NO^2)$, obtained from *m*-nitraniline (m. p. 110°) is deposited from boiling acetic acid in colourless needles melting at 242° (S. Gabriel, *Ber.* xi. 2260).

m-Diphtalimidodibromodiphenyl, $[C^6H^4(CO)^2N]^2C^{12}H^4Br^2$, obtained in like manner from phthalic anhydride and dibromobenzidine, separates from boiling glacial acetic acid in groups of slender crystals, is nearly insoluble in alcohol, ether, and benzene, and melts at 300° – 301° .

Diphtalimidodiphenyl, similarly prepared from benzidine, crystallises in yellow scales, very sparingly soluble, and melting at a very high temperature (Gabriel).

Paratolylphthalimide, $C^{15}H^{11}NO^2 = C^6H^4(CO)^2N(C^6H^4.CH^3)$, is obtained by fusing together phthalic acid and paratoluidine in molecular proportions, and distilling the product. It crystallises from alcohol in needles, melts at 200° , is nearly insoluble in boiling water and in cold alcohol, but soluble in hot alcohol, and can be sublimed. On account of its sparing solubility it is but very slowly oxidised by potassium permanganate, the product consisting of *hydroxyphthalyl-paramidobenzoic acid*, $C^6H^4 \left\langle \begin{smallmatrix} CO.NH.C^6H^4.COOH \\ COOH \end{smallmatrix} \right\rangle$, which is also nearly insoluble in water, melts with decomposition at 275° – 277° , and is converted by heating with hydrochloric acid into paramidobenzoic acid (Michael, *Ber.* x. 576).

PHTHALIMIDOBENZOIC ACID, $C^{15}H^9(CO)^2N.C^6H^4.COOH$. The *ortho*-compound is obtained by fusing phthalic anhydride with anthranilic acid, and separates on cooling from the solution of the product in boiling water, in broad yellowish prisms melting at 217° , easily soluble in ether, benzene, and glacial acetic acid. Its

silver salt is a white pulverulent precipitate. The *meta-acid*, prepared in like manner, forms spherical groups of crystals or capillary needles melting at 275.5°-276°, soluble in hot glacial acetic acid, less soluble in benzene and in ether. Its *silver salt*, $C^6H^4(CO)_2N.C^6H^4.CO_2Ag$, separates from a hot solution in radio-fibrous groups of needle-shaped crystals (Gabriel, *loc. cit.*)

PHTHALOPHENONE, $C^{20}H^{14}O^2$. Syn. with Diphenyl-phthalide (p. 1619).

PHTHALYL (DI-), $C^6H^4 \begin{smallmatrix} \diagup CO \diagdown \\ \diagdown CO \diagup \end{smallmatrix} C^6H^4$. This compound, formed by the action of finely-divided silver on phthalic chloride, has been already described (vii. 979).

Ethine-diphthalyl, or *Ethine-orthophenylene-diketone*, $C^{18}H^{10}O^4 = C^6H^4 \begin{smallmatrix} \diagup CO \diagdown \\ \diagdown CO \diagup \end{smallmatrix} CH-CH \begin{smallmatrix} \diagup CO \diagdown \\ \diagdown CO \diagup \end{smallmatrix} C^6H^4$, obtained by heating phthalic anhydride with succinic acid in presence of sodium acetate, is described under PHENYLENE KETONES (p. 1561 of this volume).

Benzylidene-diphthalyl, $C^{15}H^{10}O^2 = C^6H^4 \begin{smallmatrix} \diagup CO \diagdown \\ \diagdown CO \diagup \end{smallmatrix} CH.C^6H^5$, is formed, with evolution of CO_2 , by heating phthalic anhydride with phenylacetic (*α*-toluic) acid and sodium acetate:

It is insoluble in hot water and in dilute ammonia, but dissolves in boiling alcohol, and in hot aqueous ammonia or potash solution. On the addition of an acid to its solution in caustic alkali, *orthodeoxybenzoincaroxylic acid*, $COOH.C^6H^4.CO.CH^2.C^6H^5$, separates in the liquid state, but solidifies when left at rest for several hours. This acid when pure is soluble in alcohol, and is deposited from a boiling aqueous solution in long shining prisms (m. p. 74°-75°) containing 1 mol. of water of crystallisation, which is expelled at 50°. The silver salt, $C^{16}H^{12}AgO^4$, is indistinctly crystalline. The acid heated to 190° with hydriodic acid is converted into *ortho-dibenzylcarboxylic acid*, $COOH.C^6H^4.CH^2.CH^2.C^6H^5$, which is deposited from its solution in alcohol in large tabular crystals, insoluble in water, but readily soluble in alkalis. The aqueous solution of ammonium ortho-dibenzylcarboxylate forms a white precipitate with lead and silver salts, pale blue with copper salts. The silver salt when gently heated yields dibenzyl, $C^6H^5.CH^2.CH^2.C^6H^5$.

Orthodeoxybenzoincaroxylic acid is converted by sodium-amalgam into benzyl-phthalide, $C^6H^4 \begin{smallmatrix} \diagup CH-CH^2-C^6H^5 \\ \diagdown CO \diagup \end{smallmatrix} O$ (Michael a. Gabriel, *Ber.* xi. 1018).

Imido-deoxybenzoincaroxylic Anhydride, $C^{15}H^{11}NO = C^6H^4 \begin{smallmatrix} \diagup CH^2.C^6H^5 \\ \diagdown CO \diagup N \end{smallmatrix}$, is

formed by the action of ammonia at 100° on deoxybenzoincaroxylic acid, and separates, on recrystallising the resinous residue thereby produced from alcohol, in yellow scales melting at 182°-183°, insoluble in hot water, not affected either by alkaline or by acid solutions. Its formation appears to take place by two stages, thus:

(Gabriel a. Michael, *Ber.* xi. 1679).

PHTHALYLACETIC ACID, $C^{10}H^8O^4 = C^6H^4 \begin{smallmatrix} \diagup CO \diagdown \\ \diagdown CO \diagup \end{smallmatrix} CH-COOH$ (Michael a. Gabriel, *Ber.* x. 391, 1551, 2199). This acid is prepared by boiling a mixture of 1 pt. phthalic anhydride, 2 pts. acetic anhydride, and 0.2 pt. dry sodium acetate:

After the boiling has been continued for two hours, two-thirds of the quantity of acetic anhydride added is to be distilled off, and the residue mixed with four or five times its volume of glacial acetic acid, whereupon the pthallylacetic acid separates out, and may be obtained in colourless needles by crystallisation from glacial acetic acid or nitrobenzene. When the process is thus conducted, the yield amounts to 14 per cent. of the phthalic anhydride used; but if the boiling be continued for more

than two hours, large quantities of resin are formed, and the yield of phthalylacetic acid is greatly diminished.

Reactions.—1. A neutral solution of phthalylacetic acid in *potash* yields, on addition of hydrochloric acid, a precipitate of the unaltered acid; a solution containing excess of potash, on the other hand, gives no immediate precipitate with hydrochloric acid, but the acidulated liquid, if left at rest, gradually deposits a new acid, $C^{10}H^{10}O^6$, containing the elements of 1 mol. phthalylacetic acid and 2 mols. water. This acid is bibasic, and has the constitution of benzacet-ortho-carboxylic acid $C^6H^4 \begin{smallmatrix} \text{CO.CH}^2\text{COOH} \\ \text{COOH} \end{smallmatrix} + H^2O$. When boiled in aqueous or alkaline solution, or when fused, it gives off water and carbon dioxide, and is converted into acetophenone-*o*-carboxylic acid, $C^6H^4 \begin{smallmatrix} \text{CO.CH}^3 \\ \text{COOH} \end{smallmatrix}$. This last acid, which may also be produced directly by heating phthalylacetic acid with water to 200° , forms crystals having a vitreous lustre, a sweet taste, and melting at 114° – 115° . Its salts are difficult to crystallise.

2. The action of *bromine* on phthalylacetic acid dissolved in acetic acid gives rise to tribromacetophenone-*o*-carboxylic acid, $Br^3C.CO.C^6H^4.COOH$, which melts at 159.5° – 160° , and is resolved by alkalis into bromoform and phthalic acid. When, on the other hand, bromine acts upon dry phthalylacetic acid in presence of chloroform, the mixture being heated for two hours at 100° in a sealed tube, phthalylmonobromacetic acid, $C^6H^4(CO)^2CBr.COOH$, is formed, which melts at 232° – 235° , and is easily decomposed by alkalis and water at 180° . 3. *Chlorine* acts on phthalylacetic acid suspended in glacial acetic acid in the same manner as bromine, converting it into trichloracetophenone-*o*-carboxylic acid, which melts at 144° . 4. *Ammonia* converts it into phthalylacetamide.

5. Phthalylacetic acid, heated on the water-bath with strong *sulphuric acid*, is converted, with separation of carbon dioxide and water, into a yellow body, C^6H^4O , which is also formed in small quantity in the preparation of phthalylacetic acid. This compound, when fused with potash, is converted into an acid body having the empirical formula $C^6H^4O^2 = C^6H^4O + H^2O$, which crystallises in colourless prisms, dissolves easily in alcohol, ether, glacial acetic acid, and alkalis, but only sparingly in benzene and carbon disulphide. Heated to low redness with lime, it yields triphenylbenzene, $C^6H^5(C^6H^5)^2$. This reaction shows that the acid in question must be a polymeride of $C^6H^4O^2$, and that it is in fact *phenenyl-tribenzoic acid*, $C^6H^3(C^6H^4.COOH)^3$. On this view, the formation of triphenylbenzene from it will be represented by the equation

(Michael a. Gabriel, *Ber.* xi. 1007).

6. *Sodium-amalgam* converts phthalylacetic acid in alkaline solution into a monobasic acid, $C^{10}H^8O^4$ (m. p. 150°), which may be regarded as the anhydride of benzhydrylacetocarboxylic acid, $C^{10}H^{10}O^5$:

Benzhydrylacetocarboxylic acid is not known in the free state, but some of its salts have been prepared. The *barium salt*

gives off $\frac{1}{2}$ mol. water at 100° . When heated to 220° – 240° , it gives off, in addition to its water of crystallisation, a second molecule of water, and its solution, acidulated with hydrochloric acid, then yields a pulverulent precipitate of a bibasic acid, isomeric with the anhydride $C^{10}H^8O^4$. The group $CH(OH)CH^2.COOH$ is thereby converted into $CH=CH-COOH + H^2O$, and the new acid is *cinnamocarboxylic acid*, $C^6H^4 \begin{smallmatrix} \text{CH=CH} \\ \diagdown \\ \text{COOH} \end{smallmatrix}$, which takes up 2 at. bromine, forming the dibromide,

$C^6H^4 \begin{smallmatrix} \text{CHBr.CHBr} \\ \diagdown \\ \text{COOH} \end{smallmatrix}$, and unites with nascent hydrogen, forming hydro-

cinnamocarboxylic acid, $C^6H^4 \begin{smallmatrix} \text{CH}^2\text{CH}^2\text{COOH} \\ \diagdown \\ \text{COOH} \end{smallmatrix}$.

PHTHALYLPROPIONIC ACID, $C^{11}H^8O^4 = C^6H^4 \begin{smallmatrix} \text{CO} \\ \diagdown \quad \diagup \\ & \text{CO} \end{smallmatrix} CH.CH^2.COOH$

(Gabriel a. Michael, *Ber.* xi. 1017, 1679). This acid is prepared by heating a mixture of phthalic and propionic anhydrides with sodium propionate, dissolving the product in boiling acetic acid, and filtering the liquid while hot. On cooling, the acid separates in slender needles melting at 245°-248°.

Phthalyl-propionamide, $C^6H^4(CO)^2.CH.CH^2.CONH^2$, separates in iridescent scales melting at 193°-195°, on adding an acid to a hot solution of phthalylpropionic acid in ammonia.

Propiophenone-carboxylic acid, $C^6H^4 \begin{smallmatrix} \diagup CO.C^2H^5 \\ \diagdown COOH \end{smallmatrix}$, is formed when phthalylpropionic acid is boiled with excess of potash-solution: $C^{11}H^8O^4 + H^2O = C^{10}H^{10}O^3 + CO^2$, and crystallises from its alcoholic solution in slender colourless needles, which melt at 91°-92°. The silver salt, $C^{10}H^9AgO^3$, also forms long needle-shaped crystals.

Phthalylpropionic acid is converted, by the action of *phosphorus* and *strong hydriodic acid*, into propylbenzoic acid, $COGH.C^6H^4.CH^2.CH^2.CH^3$; thus: $C^{11}H^8O^4 + H^4 = C^{10}H^{12}O^2 + CO^2$. This compound, which is easily soluble in the usual solvents, forms crystalline scales melting at 53°.

The action of strong *sulphuric acid* on phthalylpropionic acid at the heat of the water-bath is similar to that which it exerts on phthalylacetic acid (p. 1621), giving rise to the compound $C^{20}H^{14}O^3$, which crystallises from alcohol in silky needles, melts at 235°-237°, is insoluble in acids and aqueous alkalis, and appears to yield an acid by fusion with potash. Its formation may be represented by the equation:

and the reaction may resolve itself into two stages, the first consisting in the formation of the diketone, phthalylethylidene, thus:

two molecules of which then unite together under the influence of the sulphuric acid, with elimination of a molecule of water

the change being similar to that which takes place in the conversion of acetone, C^3H^6O , into mesityl oxide, $C^{10}H^{10}O$.

Phthalylpropionic acid, dissolved in dilute *soda-ley*, is converted by assumption of water into benzoylpropiocarboxylic acid, $C^{11}H^{10}O^3 = C^6H^4 \begin{smallmatrix} \diagup CO.C^2H^4.CO^2H \\ \diagdown CO^2H \end{smallmatrix}$.

This acid has not been isolated, but its formation may be inferred from the action of sodium-amalgam on the alkaline solution just mentioned, whereby a body is formed which crystallises from dilute alcohol in shining colourless needles having the composition $C^{11}H^{10}O^4$. This last compound is slightly soluble in cold, moderately soluble in hot water, and dissolves readily in the other ordinary solvents; it softens at 135°, melts at 140°, dissolves in aqueous alkalis, decomposes carbonates, and is converted by boiling with baryta-water into a barium salt having the composition $C^{11}H^{10}BaO^5$. From these properties, and from the analogy of the reaction to that which takes place with phthalyl-acetic acid, the body $C^{11}H^{10}O^4$ may be regarded as

$C^6H^4 \begin{smallmatrix} \diagup CH-C^2H^4.COOH \\ \diagdown CO \end{smallmatrix} O$, that is, as an *anhydride of benzhydrylpropiocarboxylic acid*, $C^6H^4 \begin{smallmatrix} \diagup CH(OH).C^2H^4.COOH \\ \diagdown COOH \end{smallmatrix}$. The constitution of the barium salt may be represented by the formula:

PHYCOCYANOGEN and **PHYCOERYTHRIN**. See PLANT-COLOURS.

PHYLLIC ACID. A substance obtained by C. Bougarel (*Bull. Soc. Chim.* [2], xxviii. 148) from the leaves of several trees, *e.g.* the cherry-laurel, quince, apple, peach, almond, mulberry, and elder. It is found in the alcoholic extract of the leaves, and, after purification, forms colourless crystalline granules, soluble in alcohol, ether, chloroform, and carbon bisulphide, insoluble in water. Sp. gr. about 1.014. It melts at 170°, and solidifies on cooling in flat prisms terminated by pyramids of about 120°. When heated above 180° it decomposes, giving off white fumes of balsamic odour, which condense in oily drops. Dilute acids have no effect upon it. In contact with cold potash, it does not apparently dissolve, but combines slowly, forming a body which crystallises in prismatic needles with square base. These needles, which are

the potassium salt of phyllic acid, are slightly soluble in cold water, soluble in hot slightly alkaline solutions; insoluble in strong alkalis; soluble in alcohol, ether, and chloroform. The analysis of the acid led to the formula $C^{72}H^{64}O^{16}$, which, however, requires confirmation. Both the acid and its salts are optically dextrogyrate.

PHYLLITE- or SERICITE-GNEISS. A rock occurring in the Casanna Pass, in the Engadine, Switzerland, examined by C. W. Gumbel (*Jahrb. f. Min.* 1878, 383; *Chem. Soc. J.* xxxii. 207).

PHYLLOCYANIC ACID, PHYLLOCHROMOGEN, PHYLLOX-ANTHEIN. See CHLOROPHYLL (p. 452).

PHYSOSTIGMINE. According to Hesse (*Jahresb. f. Chem.* 1877, 177), this base, the active principle of the Calabar bean (iv. 635), is amorphous. The bean, however, yields also a substance (m. p. 133° – 134°) very much like cholesterolin and isocholesterolin, and this is probably the substance which was mistaken by Vee (*J. Pharm.* [4], i. 70) for a crystalline alkaloid (the so-called 'eserine') of the Calabar bean. The base described by Petit (vii. 472) under the name of *esérine* was doubtless identical with physostigmine.

PHYTOSTERIN, $C^{26}H^{44}O$ (Hesse, *Liebig's Annalen*, cxcii. 175). A neutral substance, identical or homologous with cholesterolin, obtained from Calabar beans by extraction with petroleum-ether. The resulting solution leaves on evaporation an oily residue, which after some time solidifies to a butyaceous mass of crystals; and on pressing this mass between bibulous paper to remove the oil, dissolving the residue in hot alcohol, and recrystallising from ether and alcohol successively, brilliant colourless tabular crystals are obtained which melt at 132° – 133° , and give on analysis numbers agreeing with the formula $C^{26}H^{44}O.H^{2}O$. By recrystallisation from petroleum ether, this substance is obtained in anhydrous needles.

A solution of phytosterin in chloroform shows left-handed polarisation, $(\alpha)_D = -34.2^{\circ}$ at 15° . Phytosterin seems to be identical with Kolbe's 'cholesterin obtained from peas.'

Cholesterolin, obtained from gall-stones, crystallises from alcohol and from chloroform in forms the same as those assumed by phytosterin, but the crystals obtained from an ethereal solution consist for the most part of tables. Cholesterolin melts at 145° – 146° . Dehydrated cholesterolin in chloroform solution gave a left-handed polarisation, $(\alpha)_D = -(36.61 + 0.249 \rho)$.

Cholesterolin, according to all chemists who have hitherto examined it, has the same composition as that which Hesse assigns to anhydrous phytosterin, viz. $C^{26}H^{44}O$ (i. 924; vi. 446; vii. 328; viii. 454). Hesse, however, is inclined to regard it as the next lower homologue of phytosterin, viz. $C^{25}H^{42}O$; he thinks it probable, also, that the two substances occur together in the animal organism.

PICOLINE, C^6H^7N . See PYRIDINE-BASES.

PICOTITE. This black chromiferous spinel, originally found as a constituent of Lherzolite (iv. 640), occurs also in the basalt nodules of Kasakov. Two analyses by F. Farsky (*Verh. geol. Reichsanst.* 1876, 207) gave the following results:

SiO ²	Al ² O ³	Cr ² O ³	MgO	FeO
3.77	50.34	5.75	17.87	22.27 = 100
1.25	52.47	7.01	18.23	21.42 = 100.38

PICRACONITINE. A base isomeric with aconitine, sometimes occurring, together with the latter, in the root of *Aconitum Napellus*. It is amorphous, and exhibits but little physiological activity (C. R. A. Wright, *Chem. Soc. J.* xxxi. 243).

PICRAMIDE, or *Trinitraniline*, $C^6H^2(NO^2)^3NH^2 = C^6.NH^2.NO^2.H.NO^2.H.NO^2$ (p. 210). This compound, heated with alcoholic ammonium sulphide at 130° , is converted into a dinitrodiphenylene-diamine, melting at 210° – 211° (p. 1558).

Picramide unites with aromatic hydrocarbons and amines, forming crystalline compounds. The *benzene-compound*, $C^6H^2(NO^2)^3NH^2.C^6H^6$, separates from a solution of picramide in benzene, on slow evaporation, in pale yellow transparent prisms which fall to pieces on exposure to the air. A similar compound, crystallising in brown transparent needles, is formed with *toluene*.

The compounds of picramide with *aromatic bases* separate in crystalline form when warm concentrated alcoholic solutions of the bases are added to excess of picramide; they give off the base at 100° . The *aniline-compound*, $C^6H^2(NO^2)^3NH^2.C^6H^7N$, forms black shining needles or prisms; the *paratoluidine* and *dimethylaniline-compounds* also form black shining crystals (Mertens, *Ber.* xi. 843). Hepp (*Bull. Soc. Chim.* [2], xxx. 4) also describes compounds of picramide with aniline, which differ from those obtained by Mertens, in giving off the whole of the aniline on exposure to the air.

PICRIC ACID, $C^6H^2(NO^2)_3OH$. Syn. with Trinitrophenol. See PHENOL (p. 1528).

PICRO-ALUNOGEN. A magnesio-aluminic sulphate occurring in stalactites in the iron-mine of Vigneria, Elba. An analysis by G. Roster (*Jahrb. f. Min.* 1877, 531) gave:

SO ²	Al ² O ³	MgO	K ² O	CoO	H ² O
36.387	9.160	8.189	0.368	trace	45.690 = 99.794

agreeing nearly with the formula $2MgSO^4, Al^2S^3O^{12} + 28H^2O$, which requires 36.80 per cent. SO², 9.48 Al²O³, 7.36 MgO, and 46.36 H²O, and showing that the mineral is nearly allied to pickeringite, $MgSO^4, Al^2S^3O^{12} + 22H^2O$ (v. 583).

PICROPHARMACOLITE. A native calcium arsenate allied to pharmacolite (p. 1513).

PICROROCCCELLIN. A bitter substance obtained from *Roccella fuciformis* (q.v.)

PICROSCLEROTINE. A bitter and highly poisonous alkaloid obtained from ergot of rye (Dragendorff, *Russ. Zeitschr. Pharm.* xvi. 609; *Chem. Centr.* 1878, 125, 141; *Chem. Soc. J.* xxxiv. 518; Blumberg, *Pharm. J. Trans.* [3], ix. 23, 66, 147; *Chem. Soc. J.* xxxvi. 270).

PICROTEPHROÏTE. A light red mineral from Laangban in Norway, which may be regarded as tephroïte (Mn^2SiO^4 , v. 254), in which the manganese has been partly replaced by magnesium. An analysis by Pajkull (*Jahresb. f. Min.* 1878, 209) gave:

SiO ²	MnO	CaO	MgO	Loss on ignition
33.70	51.19	0.95	12.17	0.44 = 98.45

PICROTOXIN (Paternò a. Ogliaro, *Gazz. chim. ital.* 1876, 531; 1877, 193). The composition of this substance has hitherto been represented by the formula $C^{12}H^{14}O^5$, deduced by Barth from the analysis of a dibromo-derivative, $C^{12}H^{12}Br^2O^5$, and a mononitro-derivative, $C^{12}H^{13}(NO^2)O^5$, which he prepared and analysed, and from older analyses of the substance itself (iv. 643). Paternò a. Ogliaro, however, having prepared a specimen of picrotoxin, the purity of which was guaranteed by the fact of its melting point remaining constant at 199°–200°, even after repeated fractional crystallisation, found that it gave, as the mean of five closely agreeing analyses, 59.27 p.c. C. and 5.52 H., whence they deduce the formula $C^9H^{10}O^4$, which requires 59.34 per cent. C. and 5.49 H., whereas $C^{12}H^{14}O^5$ requires 60.50 C. and 5.88 H. By the action of bromine on picrotoxin, a crystalline mass was obtained containing only 21.39 per cent. bromine, whereas Barth's formula of the dibromo-compound requires 40 per cent. The hot alcoholic solution of this brominated compound deposited, on cooling, crystals which were free from bromine, sparingly soluble in alcohol, became coloured at 240°, and decomposed completely at 253°, and therefore did not consist of picrotoxin.

By saturating an ethereal solution of picrotoxin with hydrochloric acid, Paternò a. Ogliaro obtained a crystalline compound, $C^{27}H^{28}O^{11} = 3C^9H^{10}O^4 - H^2O$, insoluble in all ordinary solvents, and melting at a temperature above 310°. This compound, which they call *picrotoxide*, is also formed by the action of acetyl chloride and other dehydrating agents on picrotoxin. Subsequently, however, by the action of bromine on picrotoxin suspended in ether, they obtained a brominated compound, $C^{15}H^{15}BrO^6$, and a body having the composition $C^{15}H^{15}O^7$ or $C^{15}H^{16}O^6 + H^2O$. This substance they regard as a *hydrate of picrotoxide*, assigning to picrotoxin the formula $C^{15}H^{16}O^6$, which gives nearly the same percentage composition (61.65 C., 5.48 H., and 32.87 O.) as the formula $C^{27}H^{28}O^{11}$ (61.36 C., 5.31 H., and 33.33 O.) A *diacetyl-derivative*, $C^{15}H^{16}(C^2H^3O)^2O^7$, is formed by the action of acetyl chloride on the hydrate of picrotoxin. The whole subject seems to require further investigation.

PICRYLAMINES and **PICRYL-NITRANILINES**. Bases produced by the action of picryl chloride on the nitraniines. See BENZENE, NITRAMIDO- (p. 199).

PIGMENTS. On the *black* pigment of Hair and Feathers, see FEATHERS (p. 461).

A *green* pigment, prepared by decomposing barium chromate with sulphuric acid, and heating the chromium trioxide thereby liberated to bright redness, is described by T. Douglas (*Chem. News*, xl. 59; *Chem. Soc. J.* xxxvi. 987).

A fine *white* pigment, possessing great covering power when mixed with oil, is obtained by precipitating zinc chloride or sulphate with an alkaline sulphide, calcining the dried precipitate in a furnace, and levigating it by raking it out, while quite hot, into vats of cold water (Phipson, *Chem. News*, xxxviii. 105; *Chem. Soc. J.* xxxiv. 1017).

PILINITE. A mineral, hitherto regarded as a zeolite, occurring in felted needles, together with quartz, epidote, and desmin, in cavities of the granite of Strigau in Silesia. From microscopic measurements it is inferred to belong to the orthorhombic system, and in the flexibility of the needles it resembles the silicates of the asbestos-group. Sp. gr. 2.263 at 15°. Analysis gave:

SiO ²	Al ² O ³ , Fe ² O ³	CaO	Li ² O	H ² O
55.70	18.64	19.51	1.18 *	4.97 = 100

with traces of magnesia, soda, and potash. These numbers may be represented by the formula $\text{Ca}^2\text{Al}^3\text{Si}^2\text{O}^{15} + aq = 2\text{CaO}, \text{Al}^2\text{O}^3, 5\text{SiO}^2, \text{H}^2\text{O}$ (A. v. Lasaulx, *Jahrb. f. Min.* 1876, 358).

PILOCARPENE and PILOCARPINE. See JABORANDI (p. 1141).

PIMARIC ACID, $\text{C}^{30}\text{H}^{50}\text{O}^2$. This acid resin, which Laurent obtained from galipot, the hardened turpentine of *Pinus maritima* (iv. 645), has been further examined by A. Caillot (*Bull. Soc. Chim.* [2], xxi. 387). When fresh galipot, after washing with cold alcohol, is dissolved in twice its weight of 85 per cent. alcohol at 60°, and the solution is quickly cooled, pimaric acid separates in small crystals exhibiting the characters described by Laurent, including the melting point, 125°. Under the microscope, these crystals present the appearance of elliptic laminae, gradually changing into octagons. The alcoholic solution is strongly lævogyrate, and the more so as it is more dilute. The rotation of a 5.8 p. c. solution for the line D is -92.7; that of a 24.8 p. c. solution, -78.6.

The properties of pimaric acid are not altered by repeated crystallisation from a rapidly cooled solution in warm alcohol; but if it be dissolved to saturation in boiling alcohol and the solution left to cool very slowly, it separates in hard crusts which redissolve but slowly. At each repetition of this treatment, the melting point of the acid rises, and its rotatory power becomes less. When an alcoholic solution of the acid is heated in a sealed tube, it gradually loses the whole of its lævorotatory power, and ultimately becomes dextrorotatory. The acid thus altered by boiling with alcohol consists of three portions, viz.: (1). *Dextropimaric acid* (rotatory power + 56°), slightly soluble in cold alcohol, crystallising in rectangular plates, and melting at a temperature above 200°. (2). Laurent's *pyromaric acid* having a lævorotatory power of -66°, more soluble than the preceding, melting at 145°, and separating from warm alcohol in hemi-ellipses, which change into triangular laminae, and sometimes into crystals resembling galena. (3). A feebly lævorotatory acid, which hitherto has not been completely separated from the accompanying residues of the other two. The same alteration, though less complete, is produced in pimaric acid by simple dissolution in ethyl acetate, chloroform, benzene, turpentine-oil, and especially in carbon bisulphide. The acid contained in the latter solution had a rotatory power of only -11.5, which is increased to -37 on expelling the carbon sulphide and dissolving the residue in alcohol. A hot solution of pimaric acid in aqueous sodium carbonate yields crystals, not of sodium pimarate, as stated by Duvernoy, but of dextropimarate and pyromarate, while the sodium salt of the third acid above mentioned remains in solution (Caillot).

The sodium or calcium salt of pimaric acid yields by dry distillation propylene, amylene, propione, and a terebene (Bruylants, *Instist.* 1876, 238).

PIMELIC ACID, $\text{C}^8\text{H}^{12}\text{O}^4 = \text{C}^8\text{H}^{10}(\text{COOH})^2$. An acid having this composition was found by Laurent among the products of the oxidation of oleic acid by nitric acid; and similar products were obtained by Bromois, Gerhardt, Sacc, and Arppe, by the action of nitric acid on wax, spermaceti, and other fatty bodies (iv. 646). All these, however, appear to have been impure products, and, according to Arppe, were for the most part nothing but mixtures of adipic and succinic acids (*Jahresb. f. Chem.* 1864, 377). Two definite modifications of the acid $\text{C}^8\text{H}^{12}\text{O}^4$ are, however, known, one called *pimelic acid*, obtained by the action of melting potash on camphoric acid (Hlasiwetz a. Grabowski, vi. 389), and by saponification of amylene dicyanide, $\text{C}^8\text{H}^{10}(\text{CN})^2$ (Bauer a. Schuler, *Ber. x.* 2031); the other, called *α -pimelic acid*, by the action of nitric acid on suberone (Dale a. Schorlemmer, *Chem. Soc. J.* xxvii. 935), and by the reducing action of hydriodic acid and red phosphorus on furonic acid (Baeyer, p. 834).

Pimelic acid.—To obtain this acid by saponification of amylene dicyanide, the preparation of which in the pure state appears to be difficult, Bauer a. Schuler allow an alcoholic solution of potash to flow in a slow stream into a heated mixture of amylene dibromide and potassium cyanide; distil off the alcohol, together with monobromamylene, after the heat has been continued for some time; mix the residue with sulphuric acid; and extract the pimelic acid, thus set free, with ether. The calcium

* Determined by difference.

salt of the acid thus obtained exhibited the characteristic properties of that of the pimelic acid prepared by Kachler from camphoric acid. The process above described yielded also, together with a small quantity of formic acid, another acid isomeric with pimelic acid, which, however, was not obtained pure (Bauer a. Schuler).

Pimelic acid prepared from camphoric acid is usually obtained, after purification, in transparent crystalline crusts, sometimes, however, in distinct crystals which, according to measurements by v. Zepharovich (*Wien. Akad. Ber.* lxxiii. [1 Abth.] 7) of crystals prepared by Wreden (*Liebig's Annalen*, clxiii. 323), belong to the triclinic system. $a : b : c = 0.4971 : 1 : 0.5992$. In the first octant (upper, front, right), $\alpha = 81^\circ 50'$; $\beta = 100^\circ 2'$; $\gamma = 85^\circ 6'$. Observed forms $\infty \bar{P} \infty$, $\infty \bar{P} \infty$, $0P$, $\bar{P}' \infty$, $\bar{P} \infty$, $2\bar{P} \infty$, $\bar{P} \infty$. Angle $0P : \infty \bar{P} \infty = 99^\circ 12'$; $0P : \infty \bar{P} \infty = 79^\circ 7'$; $\infty \bar{P} \infty : \infty \bar{P} \infty = 96^\circ 29'$; $0P : \bar{P}' \infty = 32^\circ 51'$. Cleavage perfect parallel to $\infty \bar{P} \infty$ and $\bar{P} \infty$. The trace of the plane of the optic axes forms on $\infty \bar{P} \infty$ with the obtuse edge a an angle of $59^\circ 5'$. Angle of optic axes in oil = 70° ; the first (positive) median line falls in the right upper octant.

Pimelic acid melts at 114° , is very soluble in water, alcohol, or ether, and has a taste like that of tartaric acid. The ammonium salt forms very soluble, hygroscopic leaflets containing $C^7H^{10}(NH_4)^2O^4$. The sodium salt is very soluble, and contains $C^7H^{10}Na^2O^4$. The barium salt is exceedingly soluble, and its solution evaporated under the air-pump first deposits plates and then dries up to a porous mass, which, when dried at 200° , contains $C^7H^{10}BaO^4$. The magnesium salt dries up to an amorphous mass, containing $C^7H^{10}MgO^4$. The copper salt was obtained as a green precipitate, which, when dried at 160° , contained $C^7H^{10}CuO^4$. A solution of the ammonium salt is not precipitated by the salts of manganese, ferrous, zinc, cobalt, nickel, chromium, cadmium, or mercurous, but it is precipitated by the salts of ferric, aluminium, lead, or bismuth. The ethylic ether, $C^7H^{10}(C^2H_5)^2O^4$, prepared by passing hydrochloric acid into an alcoholic solution of pimelic acid, is a heavy oil having a fruity odour, and boiling at 236° – 240° .

Pimelic anhydride, $C^7H^{10}O^3$, produced by distillation of the acid, is a colourless liquid boiling at 245° – 250° , and reconverted into the acid by hot dilute alkalis.

Pimelic chloride, $C^7H^{10}Cl^2O^2$, obtained by treating the acid with phosphoric chloride and heating the product at 120° , distils, with partial decomposition, at 210° .

When pimelic acid is treated either with bromine or with bromine and water, amorphous products are obtained, and in the former case butyric acid is also formed. This acid is likewise produced when pimelic acid is fused with potash: hence it is highly probable that the higher fatty acids which accompany pimelic acid in its production from camphoric acid result from the decomposition of butyric acid. Assuming this, the reaction which takes place in the preparation of pimelic acid from camphoric acid, $C^{10}H^{16}O^4$, may be represented by the equation:

(Kachler, *Liebig's Annalen*, clxix. 168).

α -Pimelic acid is produced: 1. By oxidation of suberone with nitric acid, $C^7H^{12}O + O^3 = C^7H^{10}O^4$. 2. By heating furonic acid with 5 pts. of hydriodic acid (b. p. 127°) and $\frac{1}{2}$ pt. red phosphorus at 200° : $C^7H^8O^3 + 3H^2 = C^7H^{12}O^4 + H^2O$ (Baeyer, *Ber.* x. 1358).

α -Pimelic acid is distinguished from pimelic acid by its melting point, 103° (D. a. S.), 100° (Baeyer); its crystalline form, which is very much like that of meconic acid (p. 1269); and the property exhibited by its calcium salt, $C^7H^{10}CaO^4$, of dissolving in cold more freely than in hot water. The barium salt, $C^7H^{10}BaO^4 + H^2O$, forms transparent, tabular, very soluble crystals; the silver salt, $C^7H^{10}Ag^2O^4$, is a heavy, white precipitate, not altered by light, slightly soluble in boiling water (Dale a. Schorlemmer).

Constitution of the isomeric Pimelic acids.—Both these acids are amylene-dicarboxylic acids. Supposing, then, that the amylene cyanide from which Bauer a. Schuler obtained pimelic acid contained ordinary amylene, i.e. trimethyl-ethylene (p. 80), it follows that pimelic acid must be represented by the formula

and if suberic acid be regarded as a normal compound, its ketone (suberone), and the α -pimelic acid formed therefrom will be represented by the following formulæ:

PINACOLIN, $C^6H^{12}O$. This compound, which Fittig obtained by dehydration of pinacone, or hexylene-glycol, $C^6H^{14}O^2$ (iv. 617), is regarded by Friedel a. Silva (*Compt. rend.* lxxvi. 226) as an anhydride of pinacone; and pinacolyl-alcohol, $C^6H^{14}O$, produced by the action of sodium or sodium-amalgam on pinacolin (vii. 982), is regarded by the same chemists as a tertiary hexyl-alcohol, viz. *dimethyl-isopropyl-carbinol*, the relations between the three bodies being represented by the following formulæ:

But the true dimethyl-isopropyl carbinol produced by treating isobutyryl chloride with zinc-methyl, and decomposing the product with water (p. 1035), differs considerably in physical properties from pinacolyl alcohol, and the formation of the latter by hydrogenation of pinacolin, and its reconversion into that body by oxidation, show that it is a secondary alcohol, viz., *methyl-katabutyl carbinol*, of which pinacolin is the ketone:

This view of the constitution of pinacolin is confirmed by its formation from trimethyl-acetyl chloride and zinc-methyl, as observed by Butlerow (p. 1148):

A further confirmation of the same view is afforded by the formation of trimethyl-acetic (pivalic) acid (p. 1501), by oxidation of pinacolin, observed by Friedel a. Silva:

The formation of pinacolin from pinacone (tetramethyl-glycol) may be represented by the equation

(Butlerow, *Ber.* vi. 1254).

On the homologues of pinacolin obtained by the action of trimethyl-acetyl chloride on zinc-ethyl, and of ethyl-dimethyl-acetyl chloride on zinc-methyl and zinc-ethyl respectively, see **KETONES** (p. 1148).

Phenyl-methyl Pinacolins.—Phenyl-methyl ketone (acetophenone) might be expected to yield three pinacolins, represented by the following formulæ:

but, although several products are formed by the long-continued action of zinc and strong hydrochloric acid on an alcoholic solution of acetophenone, only one of the resulting pinacolins has been isolated viz., no. III. The oily liquid boiling between 300° and 330° , which remains after distilling the crude product in a current of steam, to remove unaltered acetophenone, deposits crystals of this acetophenonepinacolin; and the mother-liquor yields, on fractional distillation, pinacolin, acetophenonepinacone, a substance of unknown composition, melting at 107° , and an oil boiling below 300° , which does not solidify, and may perhaps contain small quantities of the pinacolins I. and II. *Pinacolin* III. crystallises in rhombic prisms, which are soluble in benzene, chloroform, ether, glacial acetic acid, and hot alcohol. It melts at 41° , boils at 310° , and is decomposed by soda-lime into acetic acid and diphenylmethylethane, $(C^6H^5)^2CH.CH^3$. This hydrocarbon boils at 264° , yields benzophenone on oxidation, and is identical in its properties with the hydrocarbon described by Goldschmidt and by Radziszewski as diphenylethane (p. 673). By the action of hydriodic acid and red phosphorus, the pinacolin is reduced to diphenylethylmethylethane, $(C^6H^5)^2C(C^6H^5)(C^6H^5)$, which crystallises in transparent plates or prisms melting at 127.5° , and is perhaps identical with the diphenyldimethylethane obtained by Engler a. Bethge from phenylmethyl-carbinyl bromide (p. 668) and by Radziszewski (*Ber.* vii. 142) by the action of zinc-dust on a mixture of ethyl-benzene and bromethylbenzene (Thörner a. Zincke, *Ber.* xi. 1988).

On *Benzpinacolins* and *Tolyl-phenyl Pinacolins*, $C^{18}H^{24}O$, see **KETONES** (p. 1155).

PINACOLYL ALCOHOL, $C^6H^{14}O = CH^3.CHOH.C(CH^3)^2$. See **HEXYL ALCOHOLS** (p. 1035).

PINACONES. The six-carbon pinacone, $C^6H^{14}O^2$, is formed by treating tetramethylethylene bromide, $(CH^3)^2C=C(CH^3)^2$, with silver acetate, and saponifying the resulting tetramethyl-ethylene acetate with baryta. A crystalline hydrate of pinacone, $C^6H^{12}O^2.6H^2O$, is thus obtained, melting at 46.3° , and identical in every respect with that which is produced by the action of sodium-amalgam on aqueous acetone (iv. 648): hence it follows that pinacone is tetramethylethylene glycol, $(CH^3)^2(OH)C-C(OH)(CH^3)^2$ (Pawlow, *Liebigs Annalen*, xcvi. 122).

The following method of preparing pinacone in considerable quantity is given by Friedel a. Silva (*Bull. Soc. Chim.* [2], xix. 289). A solution of potassium carbonate (of such strength as not to dissolve any perceptible quantity of acetone, but to be easily decomposed by sodium) is introduced into a row of 14 to 16 flasks; 600–700 grams of acetone are distributed between the same vessels, and 200 to 250 grams of sodium, in pieces about the size of a pea, are thrown in. The sodium sinks in the layer of acetone, and comes in contact with the watery layer, where it liberates hydrogen, which is almost completely fixed by the acetone. After the whole of the sodium has been introduced, the upper layer of the liquid is fractionally distilled, and in this manner from 250 to 300 grams of pseudopropyl alcohol are obtained, together with 60 to 65 grams of anhydrous pinacone, which may be dissolved in water, and crystallises out as the pure hydrate.

Pinacolyl-pinacone, $C^{12}H^{22}O^2$, is formed in the preparation of pinacolyl alcohol from pinacolin (vii. 982), and remains, on distilling off the alcohol, in the form of a crystalline mass which melts at 69° (Friedel a. Silva).

Benzpinacone, $C^8H^{20}O^2$. This compound, which Linnemann obtained (iv. 648) by the action of zinc and dilute sulphuric acid on diphenyl ketone (benzone or benzophenone), is usually regarded as tetraphenyl glycol, $(C^6H^5)^2(OH)C-C(OH)(C^6H^5)^2$, that is to say, as related to diphenyl-ketone in the same manner as ordinary pinacone to acetone. If this were its true composition, it might be expected to form secondary as well as primary ethers by substitution of alcohol-radicles for the hydrogen of the two hydroxyl-groups. Thörner a. Zincke, however (*Ber.* x. 1473), after repeated efforts, have found it impossible to effect this substitution, so that the constitution of the pinacone must for the present remain undecided.

Benzpinacone, heated for six to eight hours with hydriodic acid and red phosphorus, is converted into tetraphenylethane, $C^2H^2(C^6H^5)^4$, which is easily separated from a small quantity of the unaltered pinacone by extraction with ether, and crystallises in large prisms melting at 206° (Graebe, *Ber.* viii. 1054).

According to Thörner a. Zincke, benzpinacone, when fused or distilled, is not converted into a physical isomeride, as stated by Linnemann, but is resolved into benzophenone and benzhydrol, $C^8H^{22}O^2 = C^{12}H^{10}O + C^{12}H^{12}O$, the decomposition being complete even at the melting point of the pinacone.

Benzpinacolins, $C^8H^{20}O$. Thörner a. Zincke (*Ber.* x. 1473; xi. 68, 1396). Two bodies of this composition, distinguished as α - and β -pinacolins, are produced by the action of acids and acid chlorides on benzpinacone, also by heating diphenyl ketone in alcoholic solution with zinc and hydrochloric acid. At the same time there is formed a large quantity of benzpinacone, whence it would appear that pinacones are intermediate products of the conversion of ketones into pinacolins.

α -Benzpinacolin may be obtained pure by treating an alcoholic solution of diphenyl ketone with zinc and dilute sulphuric acid, and heating the product, which is a mixture of the pinacolin and pinacone, to 190° – 200° , whereby the pinacone is resolved into benzophenone and benzhydrol, which may be removed by ligroin, leaving the α -pinacolin to be further purified by crystallisation from alcohol. Thus prepared, it crystallises in tufts of needles which melt at 204° – 204.5° ; it dissolves sparingly in cold alcohol and glacial acetic acid, more easily when heated. Benzene, chloroform, &c., dissolve it easily; ether, however, only slightly. When α -benzpinacolin is heated with acetyl chloride, aqueous hydrochloric acid, or alcohol and sulphuric acid, it passes into the β -modification; oxidised by a solution of chromic anhydride in acetic acid, it is resolved into benzophenone and benzoic acid.

α -Benzpinacolin is identical with the tetraphenyl-ethylene oxide which Behr obtained by oxidation of tetraphenyl-ethylene (vii. 1150). This mode of formation, however, is not conclusive as to the constitution of the pinacolin, and does not determine whether it is an inder anhydride or an ether of benzophenone; neither are the products obtained on heating α -benzpinacolin with soda-lime more conclusive as to its constitution. The chief product is a hydrocarbon mixed with benzophenone and benzoic acid. This hydrocarbon has the empirical formula C^8H^{10} , and crystallises

from hot alcohol or glacial acetic acid in well-formed colourless crystals, which melt at 243° – 244° , and at the same time turn yellow. Benzene, toluene, carbon bisulphide, and chloroform dissolve it easily, whilst it is less easily soluble in ether, ligroin, cold alcohol, or glacial acetic acid. Its solutions show a beautiful blue fluorescence, which is destroyed by picric acid. The properties of this hydrocarbon show plainly that it is not identical with tetraphenyl-ethylene, of which however it may be a polymeride. The determination of its molecular formula would throw great light on the constitution of α -benzpinacolin.

The resolution of benzpinacone into benzophenone and benzhydrol, which takes place in the preparation of the α -pinacolin, is accompanied by formation of water and of a body isomeric with the pinacolin:

This body forms beautiful colourless crystals, melts at 107° – 108° , and is identical with that which Linnemann obtained by the action of heat on benzhydrol. Linnemann represented it by the formula $(\text{C}^6\text{H}_5)^2\text{CH}.\text{O}.\text{CH}(\text{C}^6\text{H}_5)^2$, regarding it as ether of benzhydrol. Thörner a. Zincke, however, observe that it is formed by the action of heat on benzpinacone more easily than benzhydrol, which is in the first instance resolved into diphenylmethane and benzophenone: $2\text{C}^{18}\text{H}^{12}\text{O} = \text{C}^{18}\text{H}^{12} + \text{C}^{18}\text{H}^{10}\text{O} + \text{H}_2\text{O}$. Hence it appears most probable that this body is not an ether of benzhydrol, but that it is more nearly related to the α -pinacolin.

β -Benzpinacolin, $(\text{C}^6\text{H}_5)^3\text{C}.\text{CO}.\text{C}^6\text{H}_5$, melts at 178° – 179° . It yields by oxidation benzoic acid and triphenylcarbinol, $(\text{C}^6\text{H}_5)^3\text{C}.\text{OH}$, but no triphenylacetic acid, and therefore differs in its behaviour from the pinacolins of the fatty series. When heated to 300° , with soda-lime, it yields benzoic acid and triphenylmethane:

By reduction with hydriodic acid and phosphorus, it yields a hydrocarbon, $\text{C}^{26}\text{H}^{20}$, presumably tetraphenylethane or triphenylbenzylmethane, $(\text{C}^6\text{H}_5)^3\text{C}-\text{CH}_2-\text{C}^6\text{H}_5$. This hydrocarbon is soluble in benzene, chloroform, carbon bisulphide, hot alcohol, and acetic acid, sparingly in ether, and crystallises from benzene in brilliant rhombic tables, which speedily turn opaque and fall to powder in the air. It crystallises from alcohol in beautiful long white prisms, which melt at 205° – 206° , and sublime in small needles at a higher temperature (Thörner a. Zincke).

Tolylphenyl pinacone, $\text{C}^{28}\text{H}^{26}\text{O}^2$, is formed from tolylphenyl ketone (p. 1154) in the same manner as benzpinacone from diphenyl ketone; it exhibits the same relations to solvents as the latter, but frequently does not separate from the alcoholic solution till after great concentration, and then crystallises in indistinct microscopic needles melting at 164° – 165° . Like benzpinacone, it is resolved by heating and by the action of alcoholic potash into tolylphenyl ketone and tolylphenyl hydrol, the latter of which has been obtained only in the liquid state: $\text{C}^{28}\text{H}^{26}\text{O}^2 = \text{C}^{14}\text{H}^{12}\text{O} + \text{C}^{14}\text{H}^{14}\text{O}$. By oxidation the pinacone is converted into tolylphenyl ketone.

Tolylphenyl pinacone, like benzpinacone, is converted by all etherifying agents—including zinc-chloride—into tolylphenyl pinacolins, and for the most part into the β -modification, which is the more stable of the two. The α -pinacolin is most easily obtained by mixing the alcoholic solution of the pinacone with a small quantity of hydrochloric acid, and leaving the mixture to itself for awhile at ordinary temperatures (Thörner a. Zincke, *Ber.* x. 1474). See further, p. 1155.

PINE. Experiments by Fliche a. Grandean (*Ann. Chim. Phys.* [4], xxix. 383; *Chem. Soc. J.* xxvii. 382) on the growth of the cluster pine (*Pinus Pinaster*) on different soils, show that this tree does not flourish on calcareous soils containing but a small proportion of potash. The ash of a twig of the plant with bark and leaves grown on such soil was found to be very poor in potash.

Experiments by the same chemists (*Ann. Chim. Phys.* [5], xi. 224) on the leaves of *Pinus laricio austriaca* yielded the following results: (1). From the opening of the bud to the fall of the leaf, the leaves of coniferous plants become continually richer in dry substance. (2). During the same time they lose part of their nitrogen, which is reabsorbed, while the proportion of ash increases. (3). The proportion of phosphoric acid, sulphuric acid, and potash in the ash diminishes. (4). The proportion of lime, iron, and silica increases. (5). For the proportion of magnesia and soda, no rule can be laid down. (6). Assimilation in coniferous leaves is very rapid in the first year, slackens at the beginning of the second, and afterwards ceases almost entirely. (7). The composition of the soil has a decided influence on the quality and quantity of coniferous leaves, this influence being, however, comparatively less when external conditions are favourable to growth. (8). Coniferous leaves have approximately the same composition as those of leafy trees, but they are always somewhat richer

in total amount of dry substance, poorer in nitrogen, and considerably poorer in ash, which, moreover, differs in composition from that of leafy trees. The removal of fallen leaves is injurious to the growth of coniferous forests. (9). For forest cultivation on poor soils, conifers are to be preferred to other trees; and for planting on a calcareous soil in a climate where only conifers will grow, *Pinus austriaca* is the best of all.

PINEY TALLOW. This tallow, obtained by boiling the fruits of *Vateria indica* (from Malabar) with water, forms a yellow-green mass having a density of 0.91, melting at 30°, and consisting of a mixture of 75 per cent. palmitic acid and 25 per cent. oleic acid. It may be bleached by boiling with a solution of nitre mixed with sulphuric acid, or by exposure to air and light. Candles made of it burn better than common tallow candles, and do not give off any odour when blown out (G. Dalsie, *Gazz. chim. ital.* viii. 107).

PINK. The ash of the garden pink, *Dianthus Caryophyllus*, has been analysed by R. Andreasch (*J. pr. Chem.* [2], xviii. 204) with the following results:

	Roots	Stalks	Leaves	Flowers
K ² O	23.33	23.00	35.51	49.41

PINOLITE. See MAGNESITE (p. 1244: further *Min. Mitth.* 1874, 281; *Jahresb. f. Chem.* 1874, 1314).

PIPERIC ACID, C¹²H¹⁰O⁴. The constitution of this acid has been studied by Fittig a. Mielk (*Liebig's Annalen*, clxxii. 134). Piperonylic acid, C⁸H⁶O⁴, the product of oxidation of piperic acid, having been shown by former experiments (vii. 983) to have the constitution represented by the formula CH² < O > C⁶H³.COOH, it appeared

probable that piperic acid might be represented by CH² < O > C⁶H³.C⁵H³O², the group C⁵H³O² being the residue of an acid belonging to the sorbic acid series, and resolvable into —CH=CH—CH=CH—COOH; and these suppositions have been verified by the more exact investigation of the products obtained by the action of bromine on piperic and hydropiperic acids.

Action of Bromine on Piperic acid.—When 1 mol. finely divided piperic acid is suspended in anhydrous carbon sulphide cooled by ice, and 2 mols. bromine are gradually added, a crystallogranular powder is formed, consisting of the *tetrabromide of piperic acid*, or *tetrabromopiperkydronic acid*, C¹²H¹⁰O⁴Br⁴, or

This acid, when heated to 160°–165°, decomposes with somewhat violent evolution of gas, and melts to a brown viscid liquid. It dissolves readily in cold ether or alcohol, but cannot be recrystallised from the resulting solutions, as it is at the same time partly converted into an amorphous viscid mass, probably an ether or a decomposition-product of the tetrabrominated acid. On treating this acid with cold dilute soda-ley, or boiling it with sodium carbonate, the whole of the bromine is removed as sodium bromide, and piperonal, C⁹H⁴O³, is formed, which may be obtained in considerable quantity by warming or agitating the product with ether. When, on the other hand, the tetrabromo-compound is boiled with water, it is converted into an oil which solidifies on cooling, and on repeated crystallisation from dilute alcohol, yields colourless shining prisms slightly soluble in cold alcohol and melting at 136°. This compound, which Fittig a. Mielk formerly obtained by the successive action of bromine and

sodium carbonate (vi. 946), is likewise produced by treating the tetrabrominated acid with a cold solution of sodium carbonate. Its composition is represented by the formula $C^{12}H^8Br^2O^4$, which might be that of a dibromopiperic acid. Nevertheless, the compound in question is not an acid, since it is quite insoluble in aqueous sodium carbonate, and is not immediately altered by potash-ley, even when somewhat concentrated. It is rather to be regarded as an anhydride analogous to lactide, and represented by the formula :

and may be designated as dibromopiperide. When heated with soda-ley or boiled for some time with sodium carbonate, it is completely resolved into piperonal and hydrobromic acid, but when subjected to the regulated action of sodium carbonate, it yields an intermediate product, bromhydroxypiperide,

which, after filtration from a small quantity of the unaltered dibromo-compound, and removal, by agitation with ether, of the piperonal—which is always formed at the same time by complete decomposition of another portion of the latter—remains dissolved in the alkaline liquid. This liquid, when acidulated, deposits at first a small quantity of a brown amorphous precipitate which must be quickly separated by filtration, and the filtrate gradually deposits the bromhydroxypiperide in small crystals; it may also be dissolved out of the alkaline solution by agitation with ether. It is contained in the alkaline liquid in the form of a sodium salt :

the acid of which, however, when set free by sulphuric acid, immediately changes into the corresponding anhydride, viz. bromhydroxypiperide. This compound is but sparingly soluble in hot and nearly insoluble in cold water, very easily soluble in hot alcohol, less easily in cold alcohol and in ether, requiring 100 pts. of the latter at 10° to dissolve it. The crystals, according to measurements by Reusch, belong to the monoclinic system, and exhibit the combination $\infty P. \infty P \infty. 0P. R \infty. -\frac{1}{2}P$, with tabular development in the direction of the clinopinacoid. Axial ratio $a : b : c = 0.8005 : 1 : 1.1954$. Angle $ac = 119^\circ 16'$. The plane of the optic axes coincides with the plane of symmetry. In its chemical relations, bromhydroxypiperide agrees almost exactly with dibromopiperide; it has no acid properties, but is gradually decomposed by alkalis, with reddening and formation of piperonal.

When piperic acid is treated with an ethereal solution of bromine, and the product is shaken up with aqueous sodium carbonate, small colourless nacreous laminae separate, which were formerly supposed to have the composition $C^{12}H^8Br^2O^6$ (vi. 936), but have been shown by later experiments to consist of the sodium salt, $C^{12}H^8Br^2NaO^3 + 1\frac{1}{2}H^2O$, of an acid, $C^{12}H^{10}Br^2O^5$, which may be regarded as a derivative of the saturated compound, $C^{12}H^{14}O^5$ (piperhydronic acid), and named *tetrabromhydroxypiperhydronic acid*. This acid, separated from the solution of the sodium salt by hydrochloric acid, is almost insoluble in water, crystallises from dilute alcohol in small transparent crystals, begins to decompose at a temperature above 100° , and melts with violent decomposition at 155° . When drenched with aqueous sodium carbonate, it is instantly converted into the sparingly soluble sodium salt, but turns yellow after prolonged contact, and decomposes on boiling, with formation of monobromopiperonal. The *calcium salt*, $(C^{12}H^8Br^2O^5)^2Ca + 2H^2O$, separates on adding calcium chloride to a dilute solution of the sodium salt, in small white shining sparingly soluble laminae. The *barium salt*, $(C^{12}H^8Br^2O^5)^2Ba + 3H^2O$, resembles the sodium salt, but is still less soluble. Both these salts become anhydrous at 90° .

By subjecting tetrabromhydroxypiperonic acid to the regulated action of sodium carbonate (as in the preparation of bromhydroxypiperide from dibromopiperide, p. 1631), it is possible to obtain a compound intermediate between that acid and its

ultimate product of decomposition, monobromopiperonal. This compound, *dibromohydroxypiperide*, $C^{12}H^8Br^2O^3$, separates from the ethereal solution on spontaneous evaporation, in large well-defined prisms; it is but slightly soluble in water, more soluble in alcohol and ether. It is not an acid, and is not attacked by solution of sodium carbonate at ordinary temperatures, but is converted thereby on heating into monobromopiperonal.

Tetrabromhydroxypiperhydronic acid may be derived from the tetrabromide of a bromopiperic acid, $CH^2\langle O \rangle C^6H^2Br.C^4H^4Br^4.COOH$, and its constitution may be represented either by the formula

or by

and that of dibromhydroxypiperide by either of the corresponding formulæ

or

Monobromopiperonal, heated with potassium permanganate, is converted into monobromopiperonylic acid, $C^6H^5BrO^4$, which crystallises well, melts at 204° – 205° , and sublimes without decomposition.

Action of Bromine on Hydropiperic acid, $C^{12}H^{12}O^4$.—This acid, treated with bromine in the manner described for the preparation of tetrabromopiperhydronic acid from piperic acid (p. 1631), is converted into dibromopiperhydronic acid, $C^{12}H^{12}Br^2O^4$, which is insoluble in water, sparingly soluble in carbon sulphide, easily in ether, and separates therefrom in small colourless crystals, melting at 135° – 136° . It decomposes at about 150° , and suffers partial decomposition on solution in warm alcohol; dissolves easily and without decomposition in cold aqueous sodium carbonate, but is decomposed on boiling therewith, without, however, yielding piperonal. When heated with caustic soda-solution, it does not yield either piperonal or any other volatile body, but the solution when evaporated deposits sodium piperate. From this reaction of the dibrominated acid—which is analogous to that of the corresponding brominated acids of the acrylic series—it follows that hydropiperic acid has the constitution represented by the formula $CH^2\langle O \rangle C^6H^3.CH^2.CH^2.CH=CH.COOH$, the second possible formula being excluded by the non-production of piperonal by the action of alkalis on this acid—which is inconsistent with the attachment of bromine to the CH -group directly connected with the benzene-nucleus. This formula is, moreover, in accordance with the action of melting potash on hydropiperic acid, whereby protocatechuic and acetic acids are produced, but no butyric acid. In this reaction, a dihydroxyphenylpropionic acid, $C^6H^3(OH)^2.CH^2.CH^2.COOH$, is perhaps first formed, and afterwards resolved, like similar acids under the influence of potash, into the two acids above mentioned.

PIPERIDINE, C^5H^9N . This base is formed, together with pyrethric acid, by the action of alcoholic potash on pyrethrin, a crystalline substance obtained from *Radix Pyrethri* (R. Buchheim, *N. Rep. Pharm.* xxv. 335).

Piperidine is not decomposed by fuming hydrochloric acid at 300° . Its hydrochloride combines directly with bromine to form a crystalline addition-product, which rapidly decomposes even at the ordinary temperature. On heating this bromine-compound, or a mixture of bromine and piperidine hydrochloride, in sealed tubes at 200° , hydrobromic acid and a small quantity of bromoform are produced, and on the addition of water to the contents of the tubes, a substance having the composition $C^5H^8Br^2NO$ separates out in crystalline plates. The crystals are almost insoluble in cold water and ether; they dissolve in ammonia or soda-solution, but are reprecipitated by dilute acids. They are decomposed by heat without melting. When platonic chloride is added to a solution of this substance in strong hydrochloric acid, the *platinochloride*, $2(C^5H^8Br^2NO.HCl).PtCl^4$, is deposited in long needles, which are decomposed by water. The *silver salt*, $C^5H^8AgBr^2NO$, is a sparingly soluble crystalline powder; the *methylic ether*, $C^5H^7(CH^3)Br^2NO$, crystallises in white needles, which melt at 192° .

The existence of these compounds seems to indicate the presence of a hydroxyl-
VOL. VIII. 5 N

group in the piperidine derivatives, e.g. $C^6H^2Br^2(OH)N$; $C^6H^2Br^2(OAg)N$ (A. W. Hofmann, *Ber.* xii. 984).

PIPERIDYL- α -ALANINE or **PIPERIDYL- α -PROPIONIC ACID**, $C^8H^{13}NO^2 = CH^3 - CH = N - C^6H^{10} - COOH$, is prepared by digesting ethyl α -chloro-propionate for twenty-four hours at 100° in a sealed tube with excess of anhydrous piperidine. The product, consisting of piperidyl- α -alanine and piperidine hydrochloride, is boiled with barium hydrate to remove the piperidine, the barium is precipitated by sulphuric acid, and this acid by lead hydrate. The filtrate, when evaporated, leaves piperidyl- α -alanine, which crystallises from water and alcohol in prisms, and is precipitated from its alcoholic solution by ether, as a white syrupy mass convertible by trituration into a granular powder. It is tasteless and scentless, has a neutral reaction, and forms crystallisable salts both with bases and with acids. It does not form a stable compound with platonic chloride, but on mixing its aqueous solution with *auric chloride*, evaporating, dissolving the residue in alcohol, and evaporating the solvent, after filtration from separated gold, an *aurochloride* is obtained in stellate groups of needles, very soluble in water, less soluble in ether, insoluble in chloroform. By the influence of light and heat, it is partially decomposed, with separation of gold (J. Brühl, *Ber.* ix. 34).

PIPERINE, $C^{17}H^{19}NO^2$. For the extraction of this alkaloïd from pepper, and its estimation, the following method is recommended by L. Cazeneuve a. Caillot (*Bull. Soc. Chim.* [2], xxvii. 290). Ground pepper is treated with twice its weight of slaked lime and a sufficient quantity of water, the whole being heated to boiling for a quarter of an hour. The solution is then evaporated to dryness on the water-bath, and the powder exhausted with commercial ether, from which the piperine can be obtained nearly pure on evaporation in large crystals of a faint straw-yellow colour. To obtain it perfectly pure, it must be dissolved in alcohol and recrystallised. The crystals obtained from the ether are, however, quite pure enough for determining the amount of alkaloïd in the pepper. For this purpose, it is best to operate on 10 grams of pepper, and dry the piperine obtained from the ether solution at 100° :

Sumatra pepper	gave 8.1 per cent piperine (mean)
Black Singapore do. . . .	7.15 " " "
White do. do. . . .	9.15 " " "
Penang do. do. . . .	5.24 " " "

The superior richness of the white Singapore pepper in piperine is due to the absence of the inactive pericarp.

On the estimation of Piperine, see also PLANT-BASES.

PIPERONAL. On the formation of this aldehyde from tetrabrompiperhydronic acid, see PIPERIC ACID (p. 1631).

The vapour-density of piperonal has been found by W. Knecht (*Ber.* x. 1274) to be 5.181, agreeing nearly with the formula $C^8H^6O^2$, which requires 5.20.

PIPERONYLIC ACID, $C^8H^6O^4 = CH^2 \begin{smallmatrix} O \\ \diagup \quad \diagdown \\ O \end{smallmatrix} C^6H^3 - COOH$. *Methylene-protocatechuic acid* (p. 291).—This acid is a constituent of Coto-bark (p. 573). To obtain it therefrom, the bark, previously extracted with ether, is digested with milk of lime; the alkaline solution is acidified with hydrochloric acid, and agitated with ether; and the residue obtained on evaporating the ethereal solution is dissolved in hot alcohol, which on cooling deposits the piperonylic acid as a white crystalline powder, melting at 229° , and beginning to sublime at 210° . Piperonylic acid dissolves in cold concentrated sulphuric acid, forming a yellow solution, which rapidly turns brown, and finally black, no gas being evolved during the process. Water produces in the yellow solution a yellow, and in the black solution a black precipitate, the filtrate in each case containing protocatechuic acid.

Mielch a. Pittig, by oxidising piperonylic acid with nitric acid, obtained oxalic and carbonic acids; but when concentrated nitric acid is allowed to act on the acid for a few minutes only, a mixture of nitropiperonylic acid and methylene-mononitro-catechol is formed. When piperonylic acid is added in small quantities to fuming nitric acid cooled to 0° , carbon dioxide is given off, and methylenedinitrocatechol is produced. In each case the nitro-products are precipitated from the acid mixture by the addition of caustic soda.

Nitropiperonylic or *Methylene-nitroprotocatechuic acid*, $C^8H^5(NO^2)O^4$, crystallises in yellow scales (m. p. 172°), which dissolve easily in water, and on the addition of caustic soda or potash to the aqueous solution, a yellow coloration is produced which turns blood-red on boiling. With ferric chloride no change is produced. This acid is monobasic; it forms well-crystallised salts, which burn vigorously when ignited (Jobst a. Hesse, *Ber.* xi. 1031).

PITTACAL. See PYROGALLOL.

PIVALIC ACID, $C^5H^{10}O^2 = C(CH^3)^3.COOH$. See PENTOIC ACIDS (p. 1501).

PLAGIOCLASE. *Triclinic Felspar*. See FELSPEAR (pp. 770-775). The granular plagioclase, occurring in the limestone strata of Geppersdorf near Strehlen, in Silesia, has been described and analysed by E. Schumacher (*Jahrb. f. Min.* 1878, 814; *Chem. Soc. J.* xxxvi. 903).

PLANT-BASES. The following method for the estimation and separation of plant-bases or vegeto-alkaloids, differing in several points from the well-known Stas-Otto method (i. 125), is given by Dragendorff (*Pharm. J. Trans.* [3], vii. 24). 1. The substances under examination are exhausted with water, and a small quantity of sulphuric acid (instead of tartaric acid and alcohol); the resulting solution is partly neutralised with magnesia and evaporated; and the syrupy residue is treated with alcohol mixed with dilute sulphuric acid. The alcoholic filtrate is freed from alcohol by distillation, and the aqueous residue is filtered, with addition of water if necessary, and shaken up at 40° with petroleum-ether, which takes up *piperine*, to be recognised by its reaction with strong sulphuric acid (blood-red coloration disappearing on addition of water, iv. 658).

2. The remaining aqueous solution is nearly neutralised with magnesia or ammonia and agitated with benzene, which takes up *caffeine*, *delphinine*, *colchicine*, *cubebene*, *digitalin* [which is not an alkaloid], and traces of *veratrine*, *physostigmine*, and *berberine*. Among these bodies, *caffeine* may be recognised by its reaction with chlorine-water and ammonia (or hydrochloric acid and potassium chlorate), giving the colour of murexid; *digitalin* by the red colour of its solution in strong sulphuric acid, changing to yellow or greenish on dilution with water (ii. 329; vi. 546); *veratrine* by the yellow colour which it gives with sulphuric acid, changing to crimson and ultimately to violet (v. 996). Solutions of *colchicine* and *berberine* leave on evaporation yellow residues, the former dissolving in strong sulphuric acid with dark yellow, the latter with olive-green colour, disappearing on evaporation, and leaving the liquid colourless. *Colchicine* and *berberine* may also be distinguished by their reaction with iodine, *colchicine* yielding with tincture of iodine a kermes-brown precipitate (i. 1081), while an alcoholic solution of a *berberine* salt, mixed with a dilute solution of iodine in potassium iodide, avoiding excess of iodine, deposits green spangles of a polarising salt resembling sulphate of iodoquinine (vi. 340). *Delphinine* is coloured light brown by sulphuric acid. *Physostigmine* is not coloured by sulphuric acid but may be recognised by the contraction of the pupil which it produces.

3. The slightly acid liquid is then shaken up with amyl alcohol, which takes up *theobromine*, as well as traces of *narcotine*, *aconitine*, and *atropine* [*theobromine* may be recognised by its property of gradually dissolving in water with yellowish colour, changing to blue on addition of ammonia; also by dissolving without colour in strong sulphuric acid]; and the residual aqueous liquid is treated with chloroform, which takes up from it *papaverine* and *thebaine*, together with small quantities of *narceine*, *brucine*, *physostigmine*, *berberine*, *veratrine*, and *narcotine*. *Papaverine* is recognised by the blue-violet colour which it gives with strong sulphuric acid; *thebaine* by the red colour which it gives with the same reagent.

4. The liquid separated from the chloroform extracts, instead of being made alkaline with soda-ley to separate morphine (as in the Stas-Otto method), is treated for that purpose with ammonia, which is added to it under a layer of petroleum-ether at 40°, the vessel being shaken immediately after the liquid has become alkaline. The petroleum-ether then dissolves *strychnine*, *brucine*, *quinine*, *emetine*, *veratrine*, *conine*, *nicotine*, and *papaverine*. *Nicotine* and *conine* may be dissolved out by water, and from the aqueous solution, after neutralisation with sulphuric acid, *nicotine* is precipitated by potassio-cadmic iodide in small crystals, *conine* in the amorphous state; the other bases, freed from petroleum ether and dried, are treated with ether, which takes up *quinine*, *emetine*, *papaverine*, and *veratrine*. From this mixture, the *veratrine* may be separated by dissolving the whole in the smallest possible quantity of dilute sulphuric acid, and precipitating with sodium carbonate, whereby only *quinine*, *emetine*, and *papaverine* are reprecipitated. *Strychnine* and *brucine* may be separated by means of alcohol, in which *strychnine* is nearly insoluble. *Emetine* is recognised by its action on the organism, the other alkaloids by known reactions.

5. The alkaline aqueous solution is next treated at 40°-50° with benzene, whereby *quinine*, *cinchonine*, *atropine*, *hyoscyamine*, *aconitine*, *physostigmine*, and *codeine* are removed. *Cinchonine* remains behind on evaporating the solution of these bodies to dryness, and exhausting the residue with ether; on evaporating the ethereal extract, dissolving the residue in very dilute sulphuric acid, and mixing the solution with a slight excess of ammonia, *quinine* and *aconitine* are precipitated, whilst *atropine*,

hyoscyamine, and codeine remain in solution. Aconitine and quinine are separated by dissolving them in a very small quantity of hydrochloric acid, and adding platinum chloride, which throws down the quinine; and from the remaining solution, after removal of the platinum by hydrogen sulphide, the aconitine may be dissolved out by chloroform. Atropine may be distinguished from hyoscyamine, which it resembles in its action on the pupil, by the odour which it emits when heated with potassium dichromate and sulphuric acid.

6. The bases which may still be present in the alkaline aqueous residue are *morphine*, *solanine*, *curarine*, and a small quantity of *narceine*, together with traces of *berberine*. From this mixture, *morphine* and *solanine*, together with a small quantity of *narceine*, may be separated by acidulating with sulphuric acid, heating to 50° – 60° , covering the surface of the liquid with a layer of amyl alcohol, then adding excess of ammonia and agitating. The *morphine* then crystallises out from the amyl-alcoholic solution, and the *solanine* gelatinises as the liquid cools. *Curarine*, with traces of *berberine* and the remainder of the *narceine*, is separated from the last aqueous liquid by evaporating to dryness with pounded glass, digesting with alcohol, and evaporating, this treatment being repeated if necessary. *Curarine* is characterised by being for the most part an amorphous mass, and by giving with sulphuric acid alone a fine blue colour (ii. 186), and with sulphuric acid and potassium dichromate a violet colour like that produced by strychnine (v. 440).

On the distinguishing reactions of Plant-bases, see also Selmi (p. 55 of this volume).

PLANT-COLOURS. The following observations by H. C. Sorby (*Proc. Roy. Soc.* xxi. 442) relate to those vegetable colouring matters, soluble in carbon sulphide and in non-volatile oils, which appear to be of the greatest importance to the life of plants. They are divided into seven groups, according to their origin, mode of occurrence, and spectroscopic appearances. Of these, the most important and most widely diffused is: (1). The chlorophyll-group, consisting of three substances, soluble in carbon sulphide, insoluble in water, exhibiting absorption at both ends of the spectrum, and distinct absorption-bands in the red, the strongest of which is related to the red fluorescence: decomposed more or less easily by acids into new products, the spectra of which are analogous to, but quite distinct from, those of the respective substances in their natural state; very quickly decomposed by direct sunlight in contact with the air. These three substances are: a. *Blue chlorophyll*, the most widely diffused of all plant-colours: it has a blue-green colour and three strong absorption-bands in the red, the least refrangible being the strongest of the three. The absorption at the blue end consists essentially of a broad black band between the blue and the violet, which can be seen only in a moderately pure solution, with very clear daylight. b. *Yellow chlorophyll*, which cannot be isolated, but is easily recognisable in association with the preceding. Its solution in benzene exhibits in the red an absorption-band somewhat farther from the red end than the principal band of blue chlorophyll, and a second much fainter in the orange; there is also a broad and strong band in the middle of the blue, the whole of the blue being absorbed. With alcohol as a solvent, the absorption-bands of all these three bodies are shifted towards the more refrangible end of the spectrum, and the first band of yellow chlorophyll becomes broader, so that in mixtures it becomes confounded with that of the blue chlorophyll. c. *Chlorofucin*, occurring in fresh-water Algae, may be obtained in the pure state and of a yellow-green colour. Its spectrum shows two dark absorption-bands, one between the red and orange, another between the orange and yellow. The whole of the green is transmitted, but the whole of the blue is cut off, and when the solution is dilute, a broad and somewhat obscure band may be seen by very clear daylight in the centre of the blue. The fluorescence-spectra of these three substances are distinguished from one another still more clearly than the absorption-spectra, by a greater difference in the positions of the narrow bright red bands. The three members of the chlorophyll-group are decomposed with greater or less facility by acids, each giving rise to a different product, so that, though they have many generic properties in common, they must be regarded as well-marked species, and not in any way as mere accidental modifications of the same substance.

2. The Xanthophyll-group comprises a large number of substances, the following six of which are commonly met with in leaves or fronds or in fungi. They all exhibit two conspicuous absorption-bands in the green or blue, beyond which the spectrum becomes very faint; with alcohol as a solvent, these bands are shifted further towards the violet. The bands are not immediately altered by weak acids or alkalis; hydrochloric acid slowly decolorises the alcoholic solution. Light decomposes it more readily in proportion as the absorption-bands are more shifted towards the red end. The substances *a* to *e* are so arranged that the two absorption-bands in each one are shifted towards the violet end more than those in the one immediately preceding; in the first they are situated in the green; in the fifth at the green end

of the blue. a. *Phycoxanthin*: the solution in carbon sulphide has a fine crimson colour, the alcoholic solution is yellow. b. *Pezizaxanthin*: orange-yellow, obtained from *Peziza aurantia*. c. *Orange Xanthophyll*: a very widely diffused colouring matter; the solution in carbon sulphide has a faint reddish orange colour. d. *True Xanthophyll*: faint orange-yellow. e. *Yellow Xanthophyll*: obtained especially from yellow flowers; the solution in carbon sulphide is lemon-yellow. f. *Fucoaxanthin*: the chief colouring matter of the olive-coloured *Algæ*; its solution in carbon sulphide has an amber colour; the spectrum is intermediate between those of c and d; alcohol produces much less increase of refrangibility in the bands; the substance is also less easily decomposed by light.

3. *Lichnoxanthin*-group: spectra without bands, but with more less extended absorption of the blue end; much less affected by light and by acids than the two preceding groups: a. *Orange Lichnoxanthin*: the absorption extends over the blue and green, and shades off as far as the yellow. b. *True Lichnoxanthin*: orange-yellow; the absorption ends suddenly in the middle of the green. c. *Yellow Lichnoxanthin*: the absorption does not extend quite so far into the green.

4. *Phycocyanogen*-group: Soluble in water. a. *True Phycocyanogen*, with a distinct absorption-band in the orange, and a narrow one in the red, imparting to the solution a very intense red fluorescence. b. *Crimson Phycocyanogen*: the chief absorption-band lies between the yellow and green; a second broad band exciting fluorescence in the orange.

5. *Phycerythrin*-group: soluble in water and non-fluorescent; a. *Crimson Phycerythrin* has an absorption-band at the yellow end of the green. b. *Red Phycerythrin* has an absorption-band at the blue end of the green.

6. *Erythrophyll*-group: soluble in water, insoluble in carbon sulphide; these bodies appear to be not essential constituents of leaves, but merely occasional products. Their number is considerable, but the conditions of their existence are as yet but little known; they are but slightly affected by light.

7. *Chrysotannin*-group: pale yellow aqueous solutions, slowly altered by light; their oxidation-products yield the autumnal yellow of leaves.

Crystallised Chlorophyll.—A. Gautier (in 1877) obtained pure crystallised chlorophyll by the following process. The green leaves of spinach and cresses are bruised in a mortar, with addition of sodium carbonate, so as to neutralise the acidity of the juice, and then pressed; the solid residue is suspended in alcohol of 55°, again pressed, and the process is repeated with alcohol of 83°, whereby chlorophyll, wax, fats, and pigments are dissolved. The liquid is then filtered, and shaken with pure animal charcoal, the green colouring matter being thereby absorbed after several days; the charcoal is washed with alcohol of 65°, which removes a yellow crystallisable substance, and then washed with dry ether, or light petroleum, whereupon the chlorophyll dissolves, and is deposited in dark-green crystals by slow evaporation.

Chlorophyll thus prepared forms needles about half a centimeter long, of soft consistence, and turning yellowish- or greenish-brown on keeping. Some of the smaller crystals transmit green light, and some lilac. The crystalline form appears to be an oblique rhomboidal prism, the rhombohedral angle being about 45°. Chlorophyll presents a striking analogy to bilirubin; it is soluble in the same solvents; it is removed from its solutions by animal charcoal, and may be recovered by treatment with ether or petroleum; it forms salts with bases; is easily oxidised in presence of light; undergoes numerous changes accompanied by alteration of colour; and combines directly with nascent hydrogen. When digested with hydrochloric acid, it splits up into phylloxanthin, a brown substance, crystallising from ether or hot alcohol, and Frémy's phyllocyanic acid, an olive-green substance, soluble in alcohol and ether, and forming salts with bases. Chlorophyll prepared as above is perfectly free from iron (Gautier, *Compt. rend.* lxxix. 861).

A crystallised substance, called 'chlorophyllane,' apparently identical with Gautier's crystallised chlorophyll, has lately been obtained, together with erythrophyll, by Hoppe-Seyler (*Ber.* xii. 1555) by treating grass-leaves previously freed from wax by digestion in ether, with hot alcohol. The analyses of the two substances by Gautier and Hoppe-Seyler give the following results:

	C	H	N	O	P	Mg	Ash	
Cryst. chlorophyll	73.97	9.80	4.15	10.33	—	—	1.75	Gautier
Chlorophyllane	73.4	9.7	5.62	9.57	1.37	0.34	—	Hoppe

Decoloration of Green Leaves in Bright Sunshine.—Experiments by J. Boehm (*Landw. Vers.-St.* xxi. 463) show that the green leaves of the scarlet runner, when exposed to bright sunshine, are first bleached, then become brown, and acquire a metallic lustre, and finally perish: further, that the underside of the leaf is much more sensitive to light than the upper.

On the Change of Colour of Leaves in Autumn, see Kraus (*N. Rep. Pharm.* xxii. 273; *Jahresb. f. Chem.* 1873, 842).

Alteration of the Colours of Flowers.—D. S. Martin (*Amer. Chem.* vii. 300) observes that the changes in the colours of the petals of certain flowers are in some way dependent upon atmospheric moisture. The petals of the dark blue variety of *Ipomœa purpurea* turned red in damp air, and when they were exposed to rain, sharply defined spots were formed upon them, red at first, but afterwards turning white. These changes are attributed by Martin, on the ground of special experiments, to an acid substance present in the air.

Diffusion of Plant-colours.—These colouring matters exhibit considerable diversity in their modes of diffusion when the organs containing them are immersed in a saturated solution of borax. The dissolved colouring matters diffuse rapidly, a red flower of *Antirrhinum majus* becoming in a few days transparent and colourless, like glass, whereas solid colouring matters, or those which are deposited in granular form, diffuse in a borax solution either very slowly or not at all; the common marigold (*Calendula officinalis*) retains the yellow colour of its flowers and the green of its leaves even when immersed in borax-solution for a year. When dissolved and granularly deposited colouring matters occur together in a plant, they may be separated by diffusion; thus the violet colour of *Iberis amara* diffuses quickly, giving place to a previously invisible greenish-yellow colour. The petals of *Pelargonium roseum* quickly lose their red colour by diffusion, and acquire a violet tint due to a granular colouring matter. The red leaves of a variety of *Atriplex hortensis*, which, according to Saussure's observations, give off oxygen like green leaves, also contain chlorophyll, the presence of which may be demonstrated by a diffusion experiment. The *Floridææ* likewise contain chlorophyll in addition to a red colouring matter which diffuses easily in borax-solution. The one-called *algæ*, whether green or red, contain only granular colouring matters; the *Diatomaceæ* contain an easily diffusible yellow colouring matter, *phylloranthin*, together with chlorophyll. The roots of a fresh plant of *Lemna* dipped into the juice of *Phytolacca decandra* did not take up any of the colouring matter of that plant, but the colouring matter of a drop of fresh blood was readily absorbed by a leaf of *Drosera rotundifolia* (J. B. Schnetzler, *N. Arch. ph. nat.* lx. 388).

PLANT-MUCILAGE. The mucilage of quince-pips, linseed and fleabane seed, has been examined by Kirchner a. Tollens (*Liebig's Annalen*, clxxv. 205). To obtain it, the material was digested with water for four hours; the viscid mucilage thereby obtained was passed through a hair-sieve, then boiled, filtered through linen, concentrated by evaporation, acidulated, and precipitated with strong alcohol; and the precipitated mass was successively treated with acidulated and with pure alcohol, then repeatedly with ether, and finally dried over sulphuric acid.

Quince-mucilage thus prepared is greyish-white and swells up, when soaked in water, to a gelatinous mass, forming a mucilaginous solution only on the addition of a small quantity of potassium hydrate. It still contains 4 to 5 per cent. of mineral matter, and on analysis gives numbers corresponding with the formula $C^{18}H^{28}O^{14}$. When it is boiled with dilute sulphuric acid, white flocks are precipitated, and sugar and dextrin or gum are produced. From the results of numerous carefully conducted quantitative experiments, it would seem that the flocculent precipitate of cellulose is nearly constant after the first half-hour, however long the boiling may be continued; but the percentage of gum gradually decreases, whilst that of the sugar increases within certain limits, showing the conversion of the former into the latter. The gum is optically dextrogyrate; the sugar, which reduces cupric solution, is dextrogyrate. The flocculent precipitate, amounting to about 36 per cent., gives with iodine the reactions of cellulose, but in the analysis the carbon comes out slightly higher than that required by the formula $C^6H^{10}O^5$. This is probably due to the presence of some impurity similar to the compound found in fir-wood by J. Erdmann (*ibid.* Suppl. v. 223).

Linseed-mucilage.—Linseed treated in like manner gave numbers corresponding with the formula $C^6H^{10}O^5$, or the same as that of cellulose. When boiled with dilute sulphuric acid, it decomposes like quince mucilage, but with much greater difficulty, gum and sugar being formed, and the former being gradually converted into the latter by long-continued boiling. The insoluble residue is very much smaller than with quince mucilage, being only about 4 per cent.

Fleabane-mucilage has the formula $C^{30}H^{50}O^{20}$. Boiled with acids, it decomposes like the other mucilages, yielding gum and sugar, but in this instance, by long-continued boiling, the gum is *completely* converted into dextrorotatory sugar.

From these results it is inferred that in quince mucilage the cellulose exists in combination with the gum, since no cellulose can be distinguished as such by micro-

scopical examination; and as the two substances exist in the ratio 1 : 2, it is most probably a true chemical compound:—

It has yet to be determined whether the other two mucilages are distinct, or whether they are compounds of cellulose and gum in the proportion 1 : 2, mixed with excess of gum: the different behaviour of the fleabane mucilage when treated with acid from that of the quince would, however, seem to preclude this view.

PLANTS, RESPIRATION AND NUTRITION OF. *Formation of Oxygen by Leaves.*—From experiments by J. Boehm (*Ber.* vi. 550), it appears that the formation of oxygen by green leaves immersed in carbonic acid water does not result from the direct assumption of absorbed carbon dioxide by the chlorophyll-bearing cells, but that the leaves first become covered with an atmosphere containing carbon dioxide, and then act as under normal conditions. This conclusion is based upon the following facts: 1. Leaves of *Juglans* and other plants immersed in water containing carbonic acid, give off but little gas on exposure to sunshine if the bubbles which form on them are removed as soon as they appear. 2. The evolution of gas ceases when the absorption-coefficient of the water for carbon dioxide is increased by lowering of temperature or increase of pressure, whereas gaseous CO^2 is decomposed under similar conditions. 3. The separation of gas likewise ceases if the leaves before the experiment are injected with water, and the conditions which induce the formation of bubbles upon them are thereby lowered. Injected leaves of land-plants, however, when placed in an atmosphere of carbon dioxide, still give out a large quantity of oxygen.

Experiments on the decomposition of carbon dioxide by the green leaves of land-plants, in mixtures of that gas with hydrogen, showed that the quantity of oxygen produced is always greater than that of the carbon dioxide which disappears. This excess is due to the fact that the living tissues of land-plants, placed in an atmosphere free from oxygen, continue to give off carbon dioxide as long as they live, the quantity of that gas thus evolved depending especially on the temperature. This evolution of carbon dioxide by living plants in an atmosphere free from oxygen is regarded by Boehm as analogous to the processes which may be observed in beer-yeast, especially in its spontaneous fermentation, the organisms excluded from access of oxygen then acquiring the forces necessary for their vital processes by 'internal combustion.'

Experiments by Boehm (*Liebig's Annalen*, clxxxvi. 248) on the elimination of oxygen from green twigs under boiled water in sunlight have led to the following results:

1. When green twigs of woody plants, such as privet, are enclosed in a limited atmosphere containing oxygen, in the dark, there ensues at first a diminution, but afterwards an increase, in the volume of the enclosed gases; and this increase takes place before the oxygen present is completely absorbed.
2. The diminution in the volume of gas which takes place when green twigs are enclosed in an atmosphere containing oxygen, in faint light, is not due to assimilation of oxygen, as in the germination of seeds rich in oil, but is caused by absorption of carbon dioxide formed in normal respiration.
3. When portions of fresh plants are enclosed in an atmosphere of carbon dioxide, there takes place at first a diminution (contrary to Saussure's statements) and afterwards an increase in the volume of the gas, due to internal respiration.
4. The absorption of carbon dioxide by fresh plants is not due to the action of cellular liquids (*Zellsaft*) exclusively, since it takes place also in twigs previously dried at 100° .
5. When fresh green shoots of privet are exposed to sunlight, under boiled water, they give off more oxygen than corresponds with the volume of air contained in them. This oxygen is for the most part derived from carbon dioxide formed in the shoots by internal respiration. In prolonged experiments the evolution of oxygen becomes slower and slower, and after 3 or 4 days ceases entirely, although the shoots still appear fresh and sound. After a week, however, the shoots begin to turn brown, and butyric fermentation sets in.

Certain fleshy plants, as *Bryophyllum calycinum*, *Crassula arborescens*, *Semperivivum Cotyledon*, when exposed to light, give off oxygen even in an atmosphere free from carbon dioxide, this effect being due to the deoxidation of an organic acid (probably an isomeride of malic acid); in several experiments, the juice of the plants, after the elimination of oxygen, was found to be slightly alkaline. Leaves of *Bryophyllum* and *Crassula* kept in the dark till nearly all their starch had disappeared, and then exposed to light in an atmosphere free from carbon dioxide, again became charged with starch, whence it may be inferred that the reducible acid was in this

1640 PLANTS: RESPIRATION AND NUTRITION OF.

case converted into a carbohydrate (A. Mayer, *Ber.* viii. 1088; *Landw. Vers.-St.* xxi. 277).

Absorption of Oxygen, and Formation of Carbon Dioxide.—The observation that green leaves in the dark take up oxygen and give off carbon dioxide, and that the amount of CO² thus given off increases with the temperature, has been confirmed by Dehérain and Moissan (*Compt. rend.* lxxviii. 1112). They find that the volume of carbon dioxide given off, especially at low temperatures, is less than that of the oxygen absorbed, and thence infer that this part of the absorbed oxygen is used for the formation of oxalic and other vegetable acids. Finally, they show that the leaves still continue to give off carbon dioxide, even after all the oxygen of the surrounding atmosphere has been removed.

Corenwinder (*Compt. rend.* lxxxvi. 608) observes that young leaves take up oxygen and give out carbon dioxide even in daytime, whereas old leaves give off no carbon dioxide during the day. Cherry-laurel leaves dried at 100° were found to have the following composition:

	Young leaves	Old leaves
Nitrogenous constituents	32.47	10.75
Non-nitrogenous constituents	61.89	81.69
Phosphoric acid	1.68	0.35
Lime	0.86	3.80
Potash, silica	3.00	3.41

The young leaves, in consequence of their large amount of protoplasm, absorb oxygen and exhale carbon dioxide; the old leaves, on the other hand, contain comparatively little protoplasm, but a large quantity of chlorophyll, which retains and decomposes the carbon dioxide produced by the respiration of the protoplasm, so that oxygen is evolved.

In the respiration of water-plants in atmospheric air, less oxygen is consumed than in the respiration of land-plants under similar circumstances. In an indifferent atmosphere free from oxygen, carbon dioxide is formed by water-plants, but in smaller quantity than by land-plants. Dead water-plants absorb hydrogen gas in considerable quantity, apparently in consequence of a peculiar kind of fermentation. In land-plants this absorption of hydrogen has not been observed (Boehm, *Ber.* viii. 752).

According to Mercalante a. Colossi (*Gazz. chim. ital.* 1875, 32), no carbon dioxide is eliminated from the roots of plants, so long as they remain in normal condition, this elimination commencing only when the actual decomposition of the roots begins. Hence they infer that the carbon dioxide taken up by the leaves bears no relation to that given off from the roots; that the carbon dioxide occasionally given off by the roots has no appreciable influence on the solubility of the constituents of the soil; and that, on the other hand, the organic constituents of the soil do not act on the dissolved organic constituents in such a manner as to render them insoluble and incapable of absorption by the roots of plants.

Respiration in the Ripening Fruits of Poppy and Rape.—The amounts of oxygen consumed and of carbon dioxide evolved by poppies and rape at various stages of ripeness have been determined by Sabanin a. Laskowsky (*Land. Vers.-Stationen*, xxi. 194), flowering stems cut as short as possible being used for the purpose. The results are given in the following table, where the numbers in the first column indicate the order of ripeness, No. I in each case being a flowering-stem taken just after flowering, No. VII in the rape-series a stem bearing fully-ripened seed-pods, and No. VIII in the poppy-series an over-ripe capsule. The last four columns give the weight in milligrams of oxygen consumed and carbon dioxide formed in 24 hours by 1 gram of dry substance.

	Rape		Poppies	
	Oxygen	CO ²	Oxygen	CO ²
I . . .	65	89	91	124
II . . .	70	97	30	42
III . . .	37	51	24	33
IV . . .	14	19	24	33
V . . .	16	22	23	31
VI . . .	20	27	20	28
VII . . .	12	16	15	21
VIII . . .	—	—	8	11

It appears from these results that in both plants the consumption of oxygen falls off as the fruit ripens. From what is known of the disappearance of starch in these plants, it may be inferred that the maximum consumption of oxygen occurs just before the disappearance of starch.

Elimination of Hydrogen from Plants.—According to Selmi (*Gazz. chim. ital.* 1875, 32), mildew and larger fungi give off hydrogen, especially on the side turned away from the light; in most cases the hydrogen is burnt by the oxygen of the air, and part of it unites with atmospheric nitrogen, forming ammonia. Missaggi, on the other hand (*ibid.* 419), finds that the air surrounding a growth of mildew contains no free hydrogen. Müntz (*Compt. rend.* lxxx. 178) observes that the common mushroom (*Agaricus campestris*), in an atmosphere containing oxygen, gives off nothing but carbon dioxide, whereas in an atmosphere free from oxygen, *e.g.* in nitrogen or carbon dioxide, hydrogen is likewise eliminated; the agaric is then found to contain alcohol, and Müntz supposes that, under these conditions, the mannite contained in it is converted, with separation of hydrogen, into glucose, which is further split up into carbon dioxide and alcohol. The same reaction was found to take place in beer-yeast.

According to Pollacci (*Gazz.* 1875, 451; 1876, 258; *Ber.* ix. 84), hydrogen is evolved not only from fungi, but from all plants, and in the case of sulphured vines this hydrogen gives rise to the formation of hydrogen sulphide, which kills the *oidium*. The evolution of hydrogen is most abundant on those parts of the plant at which vegetation is most active.

Absorption of Nitrogen.—A comparison made by Grandean (*Inst.* 1875, 110) of the researches made in late years on the origin of the Nitrogen of Plants, points to the conclusion that the soil does not possess the power of bringing the nitrogen of the atmosphere into a form in which it can be assimilated by plants, and that the nitrogen in the soil which is capable of assimilation is of animal or vegetable origin.

G. Villes (*Chem. News.* xxx. 278, 287) infers from experiments in which soils were manured with various nitrogen and phosphorus compounds, *viz.* nitrites and nitrates, ammonia, methylamine, ethylamine, urea, ethyl-urea, tetramethylammonium chloride, oxamide, dimethylloxamide, diethylloxamide, potassium cyanate, ammonium oxalate, phosphates, phosphites, and hypophosphites,—that the produce depends not only on the quantity of nitrogen and phosphorus employed for manuring, but also very materially on the mode of combination in which these elements are present. See also C. A. Cameron (*ibid.* xxxi. 1).

Absorption of Ammonia.—Experiments with various plants have been made by A. Mayer (*Landw. Vers.-St.* xvii. 329), with the view of determining whether ammonia is absorbed by the aerial parts of plants. For this purpose, ammonia was presented to the plants, partly in the gaseous form, partly in solution as ammonium carbonate, while the roots received none. The experiments led to the following conclusions: (1). Plants of the higher orders are capable of absorbing ammonia presented to their green organs, either in the gaseous form or as carbonate dissolved in water. (2). This absorption of ammonia is not purely mechanical, but leads, under favourable circumstances, to a physiological action; it is, in fact, a form of assimilation of nitrogen. (3). The nutrition of a plant by ammonia thus absorbed may, in the absence of other nitrogenous food, be followed by luxuriant growth, and an increased production of organic substance. (4). Green plants in all their organs are affected by ammonium carbonate in very different degrees, and if the supply of it be too great, the parts of the plant affected by it may die off. In the case of very sensitive plants, therefore, the demonstration of the assimilation of ammonia may be very difficult or even impossible. The absorption of ammonia from the atmosphere by leaves is theoretically possible, but considering the extremely small proportion of ammonia in the air, this source of supply cannot be regarded as of much practical importance. *Papilionaceous* plants, which are generally thought to take up more ammonia from the air than other plants, were found in the experiments above described to be particularly sensitive to and injured by it, though of course they might absorb it in very dilute form.

Experiments on the absorption of atmospheric ammonia by the leaves of plants have also been made by Th. Schloesing (*Compt. rend.* lxxviii. 1700). Two tobacco-plants were grown under similar circumstances, excepting that one of them developed its leaves in air containing ammonium carbonate, the other in air free from ammonia. The experiment lasted about six weeks, at the end of which time the leaves, buds, stalks, and roots were separately collected, dried, weighed, and analysed. The plant grown in the ammoniacal atmosphere contained 2.32 per cent., that grown in the non-ammoniacal atmosphere only 1.77 per cent. nitrogen. Of the total quantity of ammonia which had access to the leaves, three-fourths was absorbed. The ammonia had no influence on the amount of nicotine in the plant.

Absorption of Alkali-salts.—Peligot (*Compt. rend.* lxxvi. 1113) has made

experiments on the growth of beans, with the view of determining whether sodium-salts are taken up by plants from the soil. The plants were grown in good garden-mould, and those in the several pots were watered with different liquids, viz. snow-water, and solutions of sodium chloride, potassium chloride, sodium nitrate, potassium nitrate, and magnesium-ammonium sulphate. The analysis of the ash of the full-grown plants showed that neither of them had taken up a sodium salt from the soil. The ashes of the plants which had been watered with potassium salts were not richer in potassium than those which had been watered with ordinary water.

Interchange of Potassium and Sodium in Plants.—Champion a. Pellet (*Compt. rend. lxxx. 1888*) infer, from a series of ash-analyses, that potassium and sodium can replace one another in plants in the ratio of their atomic weights.

Absorption of Water and Calcium-salts by the Leaves of the Scarlet-runner (Phaseolus multiflorus) (J. Boehm, *Landw. Vers.-St. xx. 51*).—Cotyledons of this plant containing starch may often be dried to a fourth, or even a fifth of their original weight, without entirely losing the power of producing and decomposing carbonic acid when placed in an atmosphere of pure hydrogen. The cotyledons, even when dried to about half their original weight, will recover their freshness if immersed, with the exception of the stems, in water. Leaves that have been thus revived, dry on exposure to the air much more quickly than freshly cut ones.

Scarlet-runner seedlings, the roots of which have been carefully wrapped in damp cloths, the leaves, however, being suffered to dry by exposure to the air, until each appears not more than half its former weight, do not revive when placed underneath a bell-jar with their roots immersed in water. They revive completely, however, when immersed, with the exception of the roots; when, therefore, a certain point is reached, the water necessary for their recovery can be taken up by the leaves only, and not by the roots. If a seedling be cut so that only the two cotyledons remain upon the stem, and one of these be dipped beneath the surface of water whilst the other is kept exposed to the air, the leaf out of the water will remain quite fresh; but if both leaves be allowed to dry before the one is immersed, the other will not again revive.

Seedlings of *Phaseolus multiflorus* possess the property of absorbing through their leaves not only water, but also the lime salts necessary for their development. Carbolic acid, in the proportion of 1 pt. per 1,000, can be added to the water used for their nourishment, without hindering growth.

Absorption of Bicarbonates.—Observations on the absorption of bicarbonates by plants from natural waters have been made by A. Barthélemy, with the following results:

1. Plants possess one set of roots for the absorption of gas, and another set for the absorption of mineral substances in solution.
2. There are two distinct periods in the life of the roots; of development, previous to the decrease of the bud; and of maturity, when the spongiole, laid bare by the exfoliation of the epidermic tissue, exhibits the phenomena of osmose.
3. Plants absorb more water than bicarbonates from natural waters, except when the leaves dry rapidly, or at the time of flowering.
4. The amount of bicarbonates absorbed is proportional to the amount of exhaled water.
5. In a water of constant composition, plants appear, during the night, to part with some of the bicarbonates absorbed during the day, while absorption of water takes place.
6. The proportion of the bicarbonate to the water absorbed varies with the nature of the plant.
7. When a plant has absorbed a certain amount of bicarbonates, it is able to part with some when placed in distilled water.
8. The absorption of bicarbonates has no direct relation to the rapidity of vegetation: this absorption therefore does not aid respiration.
9. The roots of plants reject the carbon dioxide which serves to keep the bicarbonates in solution.
10. These experiments made with healthy plants growing under normal circumstances coincide in many points with those made with concentrated solutions and in porous vessels.

Influence of various Substances on the Germination and Growth of Plants.—1. Of Carbon Monoxide. Young sprouts raised in an atmosphere of pure carbon monoxide, or of air containing 3 to 4 per cent. of that gas, or of air, hydrogen and carbon monoxide, soon became sickly, and died on the tenth or eleventh day. Hence it would appear that Baeyer's hypothesis (*Ber. iii. 63*) respecting the formation of sugar in plants by reduction of CO_2 to CO , the combination of the latter with hydrogen to COH_2 , and the subsequent condensation of this aldehyde, cannot be maintained (A. Stutzer, *Ber. ix. 1670*).

2. Of Coal-gas. See p. 543.

3. Of Ammonium Thiocyanate. O. Kohlrausch (*Dingl. pol. J. cxxii. 425*) manured a turnip-field, and a garden soil in which barley and summer-wheat were sown, with ammonium sulphate containing 2.52 per cent. thiocyanate obtained from

spent Laming's mass (mixture of lime, ferric chloride, and sawdust, used for the purification of coal-gas). In all cases the germination of the seeds was retarded, and the plants were very ill-developed, the effect being most marked with the wheat. Similar results have been obtained by C. Schumann (*Landw. Vers.-St.* 1872, 230; and P. Wagner, *Zeitschr. für die landwirthschaft. Vereine d. Grossherzogthums Hessen*, 1873).

4. Of Alkalis. Böttger (*Dingl. pol. J.* cxxii. 444) finds that moderately strong solutions of potassium or sodium hydrate greatly increase the germinative power of seeds, especially of coffee-beans, which, when drenched with a weak solution of caustic potash, throw out long white radicles even in an hour or two.

5. Of Lime. Boehm (*Ber.* viii. 682) found that seeds of the scarlet-runner, if allowed to germinate in distilled water, die sooner or later when the reserve of nourishment is exhausted, although the length of time required for this varies greatly in individual plants. This effect is prevented, however, by the presence of various calcium salts (not by calcium chloride), but no other base can be substituted for lime, magnesium carbonate acting in a decidedly injurious manner. Boehm is of opinion that lime plays a similar important part in the development of plant-life that it does in the animal economy in the transformation of cartilage into bone; but that its action in causing the transfer of starch from the parts of the plant where it is stored up to those in which it is utilised is obscure.

6. Of Salicylic acid and Thymol. According to E. Heckel (*Compt. rend.* lxxxvii. 613), germination is retarded and in some cases entirely prevented by the presence of salicylic acid, sodium salicylate, or thymol.

7. Of Camphor. The growth of many plants is accelerated by camphor, but on others it exerts either a deleterious influence or none at all. It accelerates germination. A similar influence is exerted by water containing oil of turpentine (Vogel a. Raab, *Pharm. J. Trans.* [3], iv. 1014).

8. Of Oils. Noble a. Hanlein (*Landw. Vers.-St.* xxi. 437) have made experiments on the influence exerted on vegetation by various volatile oils, especially those of lavender and curled mint, also by benzene and carbon sulphide, these liquids having been recommended for the destruction of the Phylloxera and of the Colorado beetle. The experiments showed that all these liquids exert a deleterious action on plants. Carbon sulphide is very efficient in destroying underground insects and larvæ, but its action on plants is even more destructive than that of any of the other liquids just mentioned.

Chemical Changes accompanying Germination.—The observations of Schulze, Umlauf a. Urich on the transformations of tissue attending the germination of lupine-seeds have already been noticed (p. 1243). Further experiments on the formation of sulphuric acid in germination have been made by Schulze (*Ber.* xi. 1234). Vetch-sprouts which had been growing in the dark for three weeks were found to contain a larger quantity of sulphates than the ungerminated seeds, the amount of sulphuric acid produced being about equal to that which could be formed from the sulphur of the decomposed proteids. An increase of sulphates takes place also in the germination of pumpkins. In the case of lupine sprouts of various ages it was found that in the first stages of germination the agreement between the quantity of sulphur separated from the decomposed proteids and the amount of sulphuric acid formed does not exist, but the greater the age of the sprouts, the more completely is this agreement established. This result may be explained on the supposition that the proteids are first split up under the influence of ferments, and that the products of the decomposition then undergo gradual oxidation. In the later stages of germination, the amount of sulphuric acid appears to afford a measure of the quantity of albuminoid matter decomposed.

According to Schulze a. Barbieri (*Ber.* x. 928; xi. 710), pumpkin-sprouts contain an amide of glutamic acid, together with aspartic acid, tyrosine and leucine. The process of decomposition of albuminoids in germination is therefore the same as that which takes place under the influence of acids.

Formation of Carbohydrates in Plants.—Experiments have been made by A. Stutzer (*Ber.* ix. 1395) on sprouts of *Brassica Rapa*, growing in nutritive solutions to which oxalate or tartrate of calcium had been added, the air of the vessel having been previously deprived of carbon dioxide. Under these circumstances the plants took up oxalic or tartaric acid in place of atmospheric carbon dioxide, formed new leaves, and increased in amount of dry substance. Water-plants growing in similar nutritive liquids gave off in sunshine considerable quantities of oxygen. When the conditions of the experiment were modified so that the air surrounding the plants was kept free from carbon dioxide during the whole course of the experiment, the oxalic acid was not assimilated, the plants soon died, and their dry weight was diminished. It follows, therefore, that oxalic acid—contrary to Liebig's view—cannot be regarded

as a transition-member between atmospheric carbon dioxide and the carbohydrates, but that, before it can take part in the process of nutrition, it must be oxidised to carbon dioxide. With tartaric acid, however, the case is different; for plants grow in a nutritive solution containing this acid even though surrounded by an atmosphere free from carbon dioxide, the two alcoholic groups CH^2OH in the tartaric acid serving as nutriment to the plant. Glycerin acts in the same manner as tartaric acid. These results show that carboxyl-groups, COOH , cannot serve directly for the formation of vegetable substances in plants containing chlorophyll under the influence of light, but only after oxidation; alcoholic groups, on the other hand, are directly available for this purpose. When the nutritive liquids contained acetates or succinates the plants increased in dry substance, and threw out new leaves, but they never looked so vigorous as those which were fed with tartaric acid.

Formation of Starch in the Chlorophyll-granules.—Experiments by J. Boehm (*Ber.* ix. 123) on the shortest time in which, under favourable conditions, starch is formed in the chlorophyll-granules, have led to the following results: 1. The view hitherto held, that all starch which makes its appearance in chlorophyll-granules free from starch, when these are exposed to full daylight, is a product of the direct assimilation of carbon dioxide, is erroneous. 2. Light of any intensity sufficient to enable green plants to decompose carbon dioxide, effects also a transfer of starch from the stems to the chlorophyll-granules. 3. In direct sunshine the transfer of a recognisable quantity of starch from the stems to the chlorophyll-granules of the leaves takes place in 10 or 15 minutes. 4. Experiments on the formation of starch in the chlorophyll-granules, consequent on the direct assimilation of carbon dioxide, can be made only with plants perfectly free from starch, or with detached leaves freed from starch. 5. The disappearance of starch in detached leaves in diffused daylight or in the dark takes place as rapidly as in leaves still attached to the plant. The starch in leaves not very rich in starch disappears also when such leaves are partially or entirely immersed in water in large open vessels, but not in water free from oxygen, or in pure nitrogen or in hydrogen. 6. Detached leaves of plants grown in faint light, and free from starch, when placed in an atmosphere containing 6 or 8 per cent. of carbon dioxide in full daylight, not only throw out roots from the leaf-stalks, but also increase considerably in diameter, even when simply moistened with distilled water. 7. Quite young cotyledons grown in the dark, or in faint light, contain starch. 8. Sprouts grown in distilled water, under bell-jars standing in potash-ley, scarcely attain the length of 10 cm., the stems then withering below the cotyledons. Such plants are, as a rule, destitute of starch. 9. Starch is formed in recognisable quantities in 10 or 15 minutes, by detached cotyledons, when exposed to direct sunshine in an atmosphere containing 8 per cent. of carbon dioxide. In similar leaves, freely exposed to the air, in sunshine, the same result occurs in 45 minutes. It is not improbable that the carbon of the dioxide decomposed combines directly with water to form starch. 10. Scarlet-runner sprouts take up from the soil neither organic carbon-compounds nor carbon dioxide.

Further experiments (*Ber.* x. 1804) have shown that the formation of starch in chlorophyll-granules free from that substance, at the expense of substances which have been transferred to the cells containing these granules, is a process of the organism perfectly independent of the influence of light. When growing cotyledons of the scarlet-runner, the terminal buds of which have been removed at an early stage, are partly shaded, the starch at first disappears almost wholly from the darkened parts of the leaves, but after two or three weeks the chlorophyll-granules in the parenchyma cells of the shaded parts are always found to contain starch, sometimes equal in quantity to that which would have been formed if they had been continuously exposed to light. Hence it appears that the starch which is formed in chlorophyll-granules previously free from that substance is not in all cases a direct product of assimilation of carbon dioxide and water, but may be formed from substances previously assimilated and transferred to the cells.

On the formation of Starch in the cotyledons of Cress, Radish, and Flax, see Boehm (*Chem. Centr.* 1875, pp. 202, 217, 233, 248; *Jahresb. f. Chem.* 1875, 817; *Chem. Soc. J.* xxix. 952).

Albinism in Plants.—The difference in composition and function between white and green leaves has lately been carefully studied by A. H. Church (*Chem. Soc. J.* 1879, xxxv. 33; 1880, xxxvii. 1). The leaves examined were those of a species of maple, *Acer Negundo*, the variegated holly and ivy, also of the following exotic plants: *Elaeagnus pungens*, *Plectogyne variegata*, *Cyperus alternifolius* and *Alocasia macrorrhiza*. The white leaves and white parts of leaves of these plants were found to contain about 5.58 per cent. more water than the green; they also yielded a larger proportion of ash, and this ash was richer in potash and poorer in lime than that of

the green leaves; in short, the white leaves contain a larger proportion of the more diffusible constituents. Moreover the white foliage, which contains no chlorophyll, does not possess the power of decomposing the carbon dioxide of the air, even in sunshine, but on the contrary adds largely to the normal amount of that gas in the air, acting indeed like the petals of flowers and like green leaves in darkness. In all these respects the white foliage of a plant bears to the green the same relation that a parasitic plant bears to its host, *e.g.* the dodder to the clover on which it grows. It does not elaborate its own substance; it is not a laboratory, but merely a storehouse, and draws the whole of its sustenance from the green parts of the plant in which the functions of vegetable life are in full activity. Remarkable differences are also observed in the amount of gain and loss of white and green foliage when placed in water and when exposed to the air. White holly sprays placed in water gained in two hours 0.29 per cent. of their weight; green holly under similar conditions gained 1.55 per cent. When no water was supplied, the white holly lost 0.54, the green 10.26 per cent. of its weight.

PLATINUM. *Occurrence.*—A specimen of magnetic platinum ore from Nischne-Tagilsk, in the Ural, analysed by Terreil (*Compt. rend.* lxxxii. 1116), was found to contain:

Platinum, with traces of Iridium	81.02
Osmiridium and other platinum-metals insoluble in aqua regia	3.33
Silver	traces
Copper	3.14
Iron	8.18
Nickel	0.75
Chrome-iron ore	3.13
Silicon	0.13
Silicates of Aluminium, Magnesium, and Iron	traces
	<hr/> 99.68

The occurrence in this ore of metallic iron and nickel, which had not hitherto been found in platinum ore, indicates a resemblance between platinum ores and meteorites. On this point see also Daubr e (*Compt. rend.* lxxx. 707; *Jahresb. f. Chem.* 1875, 1194).

Ferruginous platinum from Russia, analysed by Frenzel (*Jahrb. f. Min.* 1874, 684), gave:

Pt	Fe	Cu	Insoluble	Sp. gr.
76.97	10.97	1.04	1.45	14.92 at 15°.

The following table gives the results of the analysis of Russian platinum ores by S. Kern (*Chem. News*, xxxv. 88). 1-3. From the District of Goroblagodatsky. 4-6. From the District of Nischne-Tagilsk:

	Pt	Rh	Ir	Os	Pd	Fe	Cu	Osmir- idium
1.	87.50	1.20	0.05	0.01	1.05	8.60	0.65	1.50 = 100.56
2.	84.50	2.90	0.90	0.60	0.05	7.55	0.60	2.80 = 99.90
3.	80.05	1.05	2.50	trace	2.03	11.04	1.02	2.51 = 100.20
4.	80.87	4.44	0.06	trace	1.30	10.82	2.30	0.11 = 99.90
5.	71.20	1.50	2.40	0.05	1.95	13.40	6.70	2.65 = 99.85
6.	89.05	4.60	trace	trace	2.35	3.40	0.59	trace = 99.89

Also traces of Ruthenium.

Preparation.—Th. Kn sel (*Ber.* vi. 1159) separates platinum from the residues obtained in the use of platonic chloride for the estimation of potassium, by heating these residues with sodium or potassium carbonate, or sodium hydrate, in a porcelain dish over the water-bath, and gradually adding the alcoholic wash-waters. The spongy platinum thereby reduced is washed, dried, and finally boiled with hydrochloric acid to separate any remaining impurities. Du villier (*Compt. rend.* lxxxiv. 444) effects the reduction of the platinum from these residues by boiling them with an alkaline formate.

On the separation of Platinum from the Ferric Chloride obtained in the preparation of Fine Gold, see Opificius (*Dingl. pol. J.* cxxiv. 414; *Jahresb. f. Chem.* 1877, 1124).

On the separation of Platinum from Rhodium, Iridium, and Osmium by precipitation with Mercaptan, see p. 1276.

The method of working native platinum, practised at Her us' works in Hanau, is described by J. Philipp (*Dingl. pol. J.* cxx. 95; *Jahresb. f. Chem.* 1876, 1075; *Chem. Soc. J.* xxx. 176).

Reduction.—According to Pellet (*Compt. rend.* lxxvii. 112), platinum is reduced from the solutions of its salts by hydrogen containing a trace of arsenic, but not by pure hydrogen.

Platinum-black.—According to Zdrawkowitch (*Bull. Soc. Chim.* [2], xxv. 198), a platinum-black of great catalytic power may be prepared by reducing platinum with glycerol in alkaline solution. A good mode of proceeding is to mix 15 c.c. glycerol of 25° to 27° B. with 10 c.c. potash ley of sp. gr. 1.08, heat the mixture to boiling, and add 3 to 5 c.c. of ordinary solution of platonic chloride, whereupon the platinum is almost instantly separated as a black flocculent or pulverulent precipitate. If a large excess of alkali is used, the platinum is thrown down in specular form. Platinum is likewise reduced from the ordinary acid solution of platonic chloride by boiling with glycerol; but the reduced platinum thereby obtained is rather grey than black, and has but little activity.

Alloys. 1. With Iron. From synthetical experiments, as well as from the analysis of native alloys, of platinum and iron, Daubree finds that polar magnetism is exhibited only by those which contain at least 17 per cent. iron, those with lower percentages of iron being susceptible of magnetism, but not exhibiting polarity (*Compt. rend.* lxxx. 526). See also Deville (*ibid.* 589).

A portion of a sulphuric acid condenser of platinum, which was brittle and crystalline throughout, was found by E. Beichardt (*Dingl. pol. J.* ccxlii. 445) to contain 99.430 per cent. platinum, 0.473 copper, 0.013 iron, and 0.030 silicon.

2. With Iridium. G. Matthey (*Chem. News*, xxxix. 175) has described the methods by which he prepares an alloy of iridium and platinum suitable for the manufacture of the international meter and kilogram standards, and of the geodesic rule.

Preparation of Pure Platinum.—Ordinary commercial platinum is melted with six times its weight of pure lead; the alloy, after granulation, is treated with successive quantities of dilute nitric acid (1 to 8) until there is no more action; and the solution, which contains lead, iron, copper, palladium, and rhodium, is separated from the residue and treated by appropriate methods. The residue, an amorphous powder containing platinum, lead, crystalline iridium, and small proportions of other metals, is treated with weak aqua regia, which dissolves the platinum and lead, leaving the whole of the iridium in an impure state. The solution is evaporated, the lead removed by sulphuric acid, the platinum solution is again evaporated, and the platinum chloride dissolved in water and mixed with an excess of ammonium and sodium chlorides. The solution, kept at 80° for several days, deposits the ammonium platinochloride, which is removed, and after being washed with saturated ammonium chloride and then with hydrochloric acid, is dried; and as it may still contain rhodium, it is mixed with potassium-hydrogen sulphate and a little ammonium-hydrogen sulphate, and gradually heated to dull redness in a platinum capsule. The platinum is thereby reduced in the form of a black powder, the rhodium then remaining as rhodium and potassium sulphate, which is completely dissolved out by digestion with boiling water; the solution contains also a little platinum, which is recovered by evaporating to dryness and heating the residue to redness, at which temperature the platinum salt alone is decomposed. The absolutely pure platinum obtained by this process has a density of 21.46.

Preparation of Pure Iridium.—The iridium obtained from an ordinary solution of this metal (freed from osmium by long boiling in aqua regia), by precipitation with ammonium chloride, contains traces of platinum, rhodium, ruthenium, and iron; the presence of platinum is unobjectionable when iridio-platinum is to be prepared. This iridium is fused for some hours with ten times its weight of lead; the lead dissolved out from the alloy by nitric acid; the residue subjected to a prolonged digestion with aqua regia; and the crystalline mass which remains is fused at a high temperature with potassium bisulphate in order to remove rhodium. The partially purified iridium is next melted for some time with 10 pts. of dry potassium hydrate and 3 of nitre in a gold crucible. The mass treated with cold water furnishes a solution containing potassium ruthenate and a 'blue residue' of potassium iridiate, which is washed with water containing potassium hydrate and sodium hypochlorite until the washings are colourless; then with distilled water; and then mixed with a solution of sodium hypochlorite and left at rest for some time. The mixture is next transferred to a retort, warmed, and finally boiled until the distillate no longer imparts a red colour to weak alcohol acidulated with hydrochloric acid (ruthenium). To remove the last trace of ruthenium from the residue, the treatment with nitre and potash and with sodium hypochlorite is repeated. The blue powder is then dissolved in aqua regia; the solution evaporated to dryness; the residue dissolved in distilled water; and the solution is filtered and poured slowly into concentrated solution of

soda containing sodium hypochlorite (no precipitate should be formed), which is then subjected in a distilling apparatus to a current of chlorine, the distillate being tested for ruthenium. The blue oxide of iridium precipitated by the chlorine is collected, washed, dried, and reduced in a glass tube by a current of the mixed gases (CO and CO₂), obtained by gently heating a mixture of oxalic and sulphuric acids. The metallic iridium is heated to redness with potassium bisulphate to remove unreduced oxide of iron and traces of rhodium, and the insoluble portion, after many washings with water, is washed with chlorine-water to remove traces of gold, and with hydrofluoric acid to free it from silica. The remaining iridium, after calcination in a charcoal crucible, is melted to an ingot, which, after being broken up and boiled with hydrochloric acid to remove adhering iron, should, if perfectly pure, be of sp. gr. 22.39. The purest iridium prepared had a density of 22.38, and still contained almost inappreciable traces of oxygen, rhodium, ruthenium, and possibly iron.

Alloy of Iridio-platinum.—450 ounces of platinum and 55 ounces of iridium were melted together; and the resulting ingot was cut into small pieces by hydraulic machinery, then remelted and forged at a white heat under a steam hammer (the surfaces of which were cleaned and highly polished after each series of blows); passed through polished steel rollers; cut into narrow strips; and again slowly melted in a properly-shaped mould. This ingot, forged into a bar 35 cm. × 7.5 cm. × 2.5 cm., showed at zero a density = 21.522; after a second forging and rolling, the density was 21.648. After the bar had been passed through highly polished rolls until the dimensions were 40.80 cm. × 21 mm. × 5 mm., a perfectly rectangular form was given to it by drawing through a series of plates. The rule thus prepared for polishing had a density = 21.616, and gave on analysis:—

Platinum	89.40	89.42
Iridium	10.16	10.22
Rhodium	0.18	0.16
Ruthenium	0.10	0.10
Iron	0.06	0.06
		<hr/>	<hr/>
		99.90	99.96

The density calculated from the first analysis is 21.510, and from the second, 21.515, which coincides with the actual determination.

The rule thus prepared for the *Association Gèodésique Internationale* was perfectly free from flaws, susceptible of a splendid polish, and much more suitable than platinum for the dividing process.

Iridio-platinum possesses the following advantages for standard rules and weights: It is almost indestructible, has extreme rigidity, especially in the tube form, and a most beautifully polished surface can be obtained; its coefficient of elasticity is very great and its density very high. For weights, the alloy should contain not less than 20 per cent. of iridium. Such an alloy, sp. gr. 21.614, has a coefficient of elasticity = 22.2, one of the highest known, whilst its malleability and ductility are almost without limit. The kilogram prepared from it measures only 46.266 c.c., displacing 2.237 c.c. less than the kilogram of the archives of France. Alloys containing more than 20 per cent. of iridium are very difficult to work.

On the preparation of an ingot of iridio-platinum weighing 250 kilograms, see Morin (*Compt. rend.* lxxviii. 1502; *Jahresb. f. Chem.* 1874, 1065).

On the preparation of pure platinum and pure iridium, see also Deville a. Debray (*Compt. rend.* lxxxi. 839; *Chem. Soc. J.* xxix. 523). The same paper contains the following data of the specific gravities of iridium-platinum alloys.

Platinum	Iridium	Sp. gr.
90	10	21.615
85	15	21.618
66.67	33.3	21.874
5	95	22.384

Sp. gr. of the platinum 21.504 (uncorrected); of the iridium, 22.421.

Expansion by Heat.—The following values of the expansion-coefficient of an alloy of 90 pts. platinum and 10 iridium are given by Fizeau (*Compt. rend.* lxxviii. 1205).

Before pressing	0.00008864
After pressure under the die	9020
After one ignition at 1300°	8905
After two ignitions	8896

According to Deville a. Debray (*N. Arch. ph. nat.* xlviii. 45) an alloy of 90 per cent. platinum and 10 iridium has the same expansion-coefficient as the original meter

preserved in the French Archives, which is known to have been made with impure platinum.

Chlorides. When platinum is heated to 1400° in a current of an indifferent gas, it neither melts nor volatilises, but if a few bubbles of chlorine are added to the gas, crystals of metallic platinum are deposited on the colder part of the tube. This result is due to the formation, at a very high temperature, of a chloride of platinum which is subsequently decomposed on cooling; if a stream of cold water be passed through a glass tube placed in the axis of the red-hot tube, platinum dichloride will be deposited upon its surface (Troost a. Hautefeuille, *Compt. rend.* lxxxiv. 946).

Platinic Chloride, PtCl_4 .—S. M. Jörgensen (*J. pr. Chem.* [2], xvi. 345) finds, in accordance with Weber a. Topsøe (vi. 951), that the compound obtained by evaporating a solution of platinic chloride and drying the residue as completely as possible, consists of hydroplatinic chloride, $\text{PtCl}_4 \cdot 2\text{HCl} + 6\text{H}_2\text{O}$, and not of a hydrate of platinum tetrachloride, $\text{PtCl}_4 + 10\text{H}_2\text{O}$ [or $8\text{H}_2\text{O}$] as supposed by Bôdecker, Mathers and Prottopow (vii. 984).

Action of Silver Nitrate.—The addition of silver nitrate in excess to a cold solution of hydroplatinic chloride, throws down the whole of the platinum in the form of a yellow precipitate, having the composition $2\text{AgCl} \cdot \text{PtCl}_4$. This substance has not been obtained in the pure state, as it is slowly decomposed by cold, and rapidly by hot water, into a solution of Norton's salt, $\text{PtCl}_4 \cdot 5\text{H}_2\text{O}$ (*J. pr. Chem.* [2], ii. 469; v. 365), and an insoluble residue, consisting of impure silver chloride.

Norton's salt loses 4 mols. of water at 100° ; the fifth molecule cannot be expelled without decomposing the compound. The aqueous solution of this substance has an acid reaction, decomposes carbonates, and produces with silver nitrate a yellow precipitate of the salt $2\text{AgCl} \cdot \text{PtCl}_2(\text{OH})^2$. With ammonia, it forms a precipitate of ammonio-platinic chloride, and the filtrate yields on evaporation a black, amorphous, hygroscopic residue of platinum hydroxychloride. The relation between these bodies is shown by the following formulæ, in which the platinum is octavalent:

The action of silver nitrate on a hot solution of hydroplatinic chloride may be represented by the following equations:

The silver salt obtained by adding silver nitrate to Norton's salt is not analogous to the acid from which it is derived, since it yields by double decomposition with ammonium chloride, platinosemidiammonium chloride, $\text{Cl}^2\text{Pt}^2(\text{N}^2\text{H}^4\text{Cl})$, and silver chloride (Jörgensen, *loc. cit.*)

Reaction with Stannous Chloride.—When a solution of platinic chloride is mixed with stannous chloride, then largely diluted with water, and heated to boiling, a brown precipitate is formed, analogous to Purple of Cassius. The same precipitate is formed on immersing a plate of tin in the solution of platinic chloride. Its composition, as determined by two analyses, is as follows:

Sn	Pt	O
60.00	11.49	28.51
55.50	17.19	27.31

Chloroplatinates or Platinochlorides (Nilson, *Ber.* ix. 1056, 1142). The formulæ of normal salts of this group may all be derived from that of hydroplatinic chloride, PtCl^6H^2 or $\text{PtCl}_4 \cdot 2\text{HCl}$, or multiples thereof, by substitution of positive metals of various quantivalence for equivalent quantities of hydrogen; thus:

Of these salts all belonging to the formulæ *a* and *b* are known except the mercuric salt (HgCl^2 does not unite with platinic chloride). The beryllium salt, which, according to Thomsen (*Ber.* iii. 827), Marignac (*ibid.* vii. 542), and Welkow (*ibid.* vii. 75), has the composition $\text{BeCl}^2 \cdot \text{PtCl}_4 + 8\text{H}_2\text{O}$, must also be referred to this group, beryllium being regarded as bivalent. The metals of higher quantivalence appear to yield only basic chloroplatinates. Of the decidedly trivalent metals, bismuth, arsenic, and

antimony, no chloroplatinates are known. The chloroplatinates of the cerium and yttrium metals are represented, according to Cleve (pp. 421, 422, 424, 736), by the following formulæ:

According to Frerichs & Smith (pp. 643, 1163), the lanthanum and didymium salts are represented by the formula $2\text{RCl}^3.3\text{PtCl}^4 + 24\text{H}^2\text{O}$.

Of the chloroplatinates of metals with combined quadrivalent atoms, only the *aluminium salt*, $\text{Al}^2\text{Cl}^6.2\text{PtCl}^4 + 30\text{H}^2\text{O}$, analysed by Welkow (p. 65), has hitherto been known. The following have been obtained by Nilson from mixtures of 1 mol. of the chloride R^2Cl^6 , with 2 mol. platonic chloride.

$\text{Fe}^2\text{Cl}^6.2\text{PtCl}^4 + 21\text{H}^2\text{O}$. Large, yellow, well-defined, oblique, four-sided, deliquescent prisms, which give off $10\text{H}^2\text{O}$ at 100° .

$\text{Cr}^2\text{Cl}^6.2\text{PtCl}^4 + 21\text{H}^2\text{O}$. Fine, green, four-sided, deliquescent prisms, which give off $10\text{H}^2\text{O}$ at 100° .

$\text{In}^2\text{Cl}^6.5\text{PtCl}^4 + 36\text{H}^2\text{O}$. Honey-yellow, oblique, four-sided prisms, with oblique end-faces, deliquescing on exposure to the air, and giving off half their water at 100° .

The ferric and chromic salts are, therefore, analogous to the aluminium salt, as are also those of the cerium and yttrium metals, if the formulæ of these salts are doubled, and they are supposed to crystallise with quantities of water, which, according to Nilson, are more in accordance with the analyses than those which are assigned to the respective salts by Cleve.

Of the chloroplatinates of quadrivalent metals, only the *thorium salt*, $\text{ThCl}^4.\text{PtCl}^4 + 12\text{H}^2\text{O}$, analysed by Cleve, has hitherto been known. Nilson has also prepared the *tin* and *zirconium salts*, and found them to be analogous in composition to the thorium salt. The *tin salt*, $\text{SnCl}^4.\text{PtCl}^4 + 12\text{H}^2\text{O}$, crystallises in small, shining, light-green, thin, four-sided, perhaps somewhat oblique plates. *Zirconium oxychloroplatinate*, $\text{ZrOCl}^4.\text{PtCl}^4 + 12\text{H}^2\text{O}$, forms small, honey-yellow, oblique, four-sided plates.

Chloroplatinites or Platinosochlorides (Nilson, *J. pr. Chem.* [2], xv. 260). These salts may be arranged in the four following groups:

Most of those here described were prepared by decomposing barium chloroplatinite with the respective sulphates; in some cases, however, by saturating the free acid, $2\text{HCl}.\text{PtCl}^2$, with oxides, hydroxides, carbonates, or chlorides.

The chloroplatinites are usually very soluble in water; they are for the most part deliquescent, and crystallise only from very concentrated solutions; most of them contain water of crystallisation. At 100° they are decomposed, with production of metallic platinum, a few evolving hydrochloric acid. By evaporating their solutions in presence of hydrochloric acid, the platinum is usually partially converted into platonic chloride. The following new chloroplatinites have been obtained:

$2\text{RbCl}.\text{PtCl}^2$. Small, four-sided, red prisms, unaltered in air, easily soluble in hot water, sparingly soluble in cold water.

$2\text{CsCl}.\text{PtCl}^2$. Long slender prisms, resembling the rubidium salt.

$2\text{TlCl}.\text{PtCl}^2$. Prisms of a light-pink colour, difficultly soluble in hot water.

$2\text{LiCl}.\text{PtCl}^2 + 6\text{H}^2\text{O}$. Dark-red four-sided prisms, with greenish lustre, resembling potassium permanganate; easily soluble in water.

$\text{CaCl}^2.\text{PtCl}^2 + 8\text{H}^2\text{O}$. Thin, flexible tables; over sulphuric acid it assumes a rose colour; melts at 100° , giving up 5 mols. of water, and then decomposing into chloroplatinate and platinum: very deliquescent.

$\text{SrCl}^2.\text{PtCl}^2 + 6\text{H}^2\text{O}$. Resembles the calcium salt: gives up two-thirds of its water at 100° .

$\text{PbCl}^2.\text{PtCl}^2 + 5\text{H}^2\text{O}$. Amorphous red powder; decomposed slowly by boiling water.

$\text{BeCl}^2.\text{PtCl}^2 + 5\text{H}^2\text{O}$. Red rhombohedrons: deliquesces in moist air: unchanged in dry air; gives up water and HCl at 100° . Easily soluble in water.

$\text{MgCl}^2.\text{PtCl}^2 + 6\text{H}^2\text{O}$. Tables, unaltered in air; give up no crystalline water at 100° .

$\text{MnCl}^2.\text{PtCl}^2 + 6\text{H}^2\text{O}$. Resembles the preceding: gives up two-thirds of its water at 100° .

$\text{CoCl}^2.\text{PtCl}^2 + 6\text{H}^2\text{O}$. Red four- or six-sided tables: gives up 5 mols. H^2O at 100° .

$\text{NiCl}^2.\text{PtCl}^2 + 6\text{H}^2\text{O}$. Dark-brown tables: gives up 3 mols. H^2O at 100° .

$\text{CuCl}^2.\text{PtCl}^2 + 6\text{H}^2\text{O}$. Olive-brown or nearly black tables: gives up 5 mols. H^2O at 100° .

$\text{ZnCl}^2.\text{PtCl}^2 + 6\text{H}^2\text{O}$. Tables: gives up 6 mols. H^2O at 100° , decomposing also into chloroplatinate and platinum.

$\text{FeCl}_2 \cdot \text{PtCl}_2 + 7\text{H}_2\text{O}$. Dark-red prisms: gives up 5 mols. H_2O at 100° .

Cadmium chloroplatinite could not be obtained.

$\text{Al}^3\text{Cl}^6 \cdot 2\text{PtCl}_2 + 21\text{H}_2\text{O}$. Large brilliant four-sided prisms: melts at 100° , and gives up 19 mols. H_2O .

$\text{Cr}^2\text{Cl}^6 \cdot 3\text{PtCl}_2 + 18\text{H}_2\text{O}$. Thin, red, deliquescent prisms, giving up water and hydrochloric acid at 100° .

$\text{Y}^2\text{Cl}^6 \cdot 3\text{PtCl}_2 + 24\text{H}_2\text{O}$. Dark-red, four-sided prisms: melts at 100° , and gives up 10 mols. H_2O .

$\text{Er}^2\text{Cl}^6 \cdot 2\text{PtCl}_2 + 27\text{H}_2\text{O}$. Dark-red prisms: at 100° gives up 17 mols. H_2O .

$\text{Er}^2\text{Cl}^6 \cdot 3\text{PtCl}_2 + 24\text{H}_2\text{O}$. Long four-sided prisms: loses 11 mols H_2O at 100° .

$\text{Ce}^2\text{Cl}^6 \cdot 4\text{PtCl}_2 + 21\text{H}_2\text{O}$. Thin four-sided prisms: loses 15 mols. H_2O at 100° .

$\text{La}^2\text{Cl}^6 \cdot 3\text{PtCl}_2 + 18\text{H}_2\text{O}$. Like the last.

$\text{La}^2\text{Cl}^6 \cdot 3\text{PtCl}_2 + 27\text{H}_2\text{O}$. Prisms: gives up 16 mols. H_2O at 100° .

$\text{Dl}^2\text{Cl}^6 \cdot 4\text{PtCl}_2 + 21\text{H}_2\text{O}$. Prisms or tables: deliquescent in air.

$\text{Dl}^2\text{Cl}^6 \cdot 3\text{PtCl}_2 + 18\text{H}_2\text{O}$. Long thin prisms.

$2\text{ThCl}^4 \cdot 3\text{PtCl}_2 + 24\text{H}_2\text{O}$. Rhombohedrons: gives up one-fourth of its water at 100° without melting.

$\text{ZrOCl}_2 \cdot \text{PtCl}_2 + 8\text{H}_2\text{O}$. Large quadratic prisms.

$2\text{HCl} \cdot \text{PtCl}_2 + x\text{H}_2\text{O}$. Produced by decomposing the barium salt with the equivalent quantity of sulphuric acid, and evaporating in a vacuum. The solution, after reaching a certain degree of concentration, evolves hydrochloric acid, leaving a dark-brown amorphous mass, easily soluble in water, giving up water and hydrochloric acid at 100° .

J. Thomsen (*J. pr. Chem.* [2], xv. 204) prepares *potassium chloroplatinite* from the chloroplatinate by reduction with cuprous chloride. The moist chloroplatinite is mixed with water to a pasty consistence, the mass is warmed, and moist cuprous chloride is cautiously added in such quantity as to leave a small portion of the potassium chloroplatinate undissolved. A nearly black solution is thereby formed, from which, after filtration and cooling, the chloroplatinite is deposited in fine red crystals, which may be purified by washing with alcohol. *Hydrogen chloroplatinite*, PtCl^4H^2 , is easily obtained by mixing a concentrated solution of the potassium salt with platinic chloride. Potassium chloroplatinate then separates out, and the red solution contains the hydrogen chloroplatinite, which may be used immediately to prepare the other chloroplatinites. The *ammonium salt*, $\text{PtCl}^4(\text{NH}^4)^2$, easily obtained by mixing the solution of the hydrogen salt with ammonium chloride and evaporating, crystallises in large red needles.

Potassium Bromoplatinite, PtBr^4K^2 , is formed when potassium chloroplatinite and sodium bromide are boiled together with so small a quantity of water that the greater part of the resulting sodium chloride separates out. On leaving the hot filtrate to cool, the bromoplatinite separates in large nearly black rhombic octohedrons, or, if quickly cooled, in brown-red very soluble needles.

Sodium bromoplatinite, PtBr^4Na^2 , is most readily obtained by heating a concentrated solution of platinic chloride with hydrobromic acid, driving off the resulting hydrochloric acid by evaporation, then adding sodium bromide, evaporating to dryness, and purifying the saline mass by recrystallisation (Thomsen).

On *Cyanides of Platinum*, see p. 616. On *Ammonio-platinic* and *Potassio-platinic Thiocyanate*, see p. 603.

Platinous Hydroxide, $\text{Pt}(\text{OH})^2$, is formed as a black precipitate on boiling a very dilute solution of potassium chloroplatinite with a sufficient quantity of dilute soda-ley. It dissolves readily at a gentle heat in dilute hydrochloric or hydrobromic acid, and is reduced by dilute formic acid, with evolution of carbon dioxide, to metallic platinum (Thomsen, *J. pr. Chem.* [2], xvi. 294).

Platinoso-platinic Oxide, Pt^3O_4 , is prepared by heating dehydrated sodium chloroplatinate with sodium carbonate till the mass begins to melt, and boiling the melt with water and dilute nitric acid. When dried at 100° it is blue-black in lumps, pure black in powder; it is not attacked by hydrochloric, nitric, or nitrohydrochloric acid, even after prolonged boiling. It slowly gives off its oxygen at a red heat. Hydrogen and coal-gas, even at ordinary temperatures, reduce it, with vivid ignition and formation of water. Formic acid at a gentle heat reduces it, with evolution of carbon dioxide, to platinum black (Jørgensen, *J. pr. Chem.* [2], xvi. 344).

NITROGEN-COMPOUNDS OF PLATINUM.

Platinosemidiammonium Chloride, $\text{Cl}^2\text{Pt} < \begin{smallmatrix} \text{N}^2\text{H}^6\text{Cl} \\ \text{Cl} \end{smallmatrix}$.—This compound, which Cleve obtained by the action of chlorine on platosemidiammonium chloride, $\text{Cl} \cdot \text{Pt} \cdot \text{N}^2\text{H}^6\text{Cl}$ (vii. 997), is also formed by the action of a cold strong solution of ammonium chloride

on the salt $\text{PtH}_2^{\text{Cl}_4}$ (p. 1648). The corresponding *iodide*, PtI_4H_2 , formed by treating the chloride with potassium iodide, separates from a solution containing ammonium chloride in small shining crystals resembling iodine, appearing under the microscope as multiform groups of apparently regular six-sided plates; from aqueous solution it separates in powdery crystals having an iodine-grey colour, and appearing under the microscope as rectangular prisms bevelled by a dome (Jørgensen, *J. pr. Chem.* [2], xvi. 345).

Fulmiplatinums (E. v. Meyer, *J. pr. Chem.* [2], xviii. 324). *Knallplatine*.—These are compounds obtained by the action of potash on ammonium chloroplatinate, $\text{PtCl}_4(\text{NH}_4\text{Cl})_2$. They are nearly insoluble in water, and do not form definite compounds with either acids or alkalis. The nitrogen contained in them is so firmly held in combination that they give off no ammonia when boiled with strong potash solution. When heated *per se* they undergo total decomposition, generally with explosive violence, owing to the sudden liberation of a large quantity of nitrogen.

When ammonium chloroplatinate is boiled with a quantity of aqueous potash insufficient for complete decomposition, added very slowly, a product of the formula $\text{PtNClO}^3\text{H}^6$ is obtained, the formation of which may be represented thus:

The chemical behaviour of this body, and the existence of other bodies standing in simple relation to it, show, however, that the foregoing formula must be quadrupled, making it $\text{Pt}^4\text{N}^4\text{Cl}^4\text{O}^{12}\text{H}^{24}$ (*tetrachlorofulmiplatinum*). Its relations to the other fulmiplatinums may then be exhibited by the following equations, which indicate the derivation from it of (1) *trichlorohydroxyfulmiplatinum*, (2) *dichlorofulmiplatinum*, and (3) *chlorohydroxyfulmiplatinum*:

The constitution of these bodies is as yet undetermined.

Tetrachlorofulmiplatinum, $\text{Pt}^4\text{N}^4\text{Cl}^4\text{O}^{12}\text{H}^{24}$.—The preparation of this compound in the pure state is attended with great difficulty, one of its atoms of chlorine being very easily eliminated. It is formed on heating ammonium chloroplatinate with aqueous potash (4.6 mols.), added very slowly until a temporary alkaline reaction is produced. The pale yellow precipitate is purified by repeated boiling with very dilute acetic acid and water. A slight excess of potash determines the formation of bodies containing less chlorine.

It gives up half its chlorine when digested with aqueous ammonia, and three-fourths when evaporated with ammonia over the water-bath: whence it appears that two atoms of chlorine are eliminated easily, and a third less easily, whilst the first is firmly held in combination. The bodies formed from it by the action of ammonia explode violently when heated; they have not been fully investigated. When gently heated with oxalic acid in presence of dilute sulphuric acid, tetrachlorofulmiplatinum gives off a quantity of carbon dioxide corresponding to a loss of 3 atoms of oxygen from each mol. At 150° it gives off 4 mols. of water.

Trichlorofulmiplatinum, $\text{Pt}^4\text{N}^4\text{Cl}^3(\text{OH})\text{O}^{12}\text{H}^{24}$, is formed when ammonium chloroplatinate is decomposed with an insufficient quantity of potash (4.5-5 mols.), added in small portions somewhat rapidly. At 150°, it loses 3 mols. of water, and when more strongly heated, it explodes, giving off gases which consist mainly of nitrogen, but contain also free oxygen. When treated with ammonia, it gives up 2 atoms of chlorine. It is acted on by oxalic acid in the same manner as the previous compound, the carbon dioxide evolved corresponding with the loss of 3 atoms of oxygen from each molecule. After the reaction the liquid contains a black precipitate, which gives off ammonia when heated with soda. When gently heated in hydrogen, the trichloro-compound undergoes violent decomposition, yielding water, ammonia, and free nitrogen.

Dichlorofulmiplatinum, $\text{Pt}^4\text{N}^4\text{Cl}^2\text{O}^{12}\text{H}^{22}$, is formed on heating ammonium chloroplatinate with aqueous potash, added in moderate quantities until the liquid remains slightly alkaline and ceases to evolve ammonia. It is a fine yellow body, closely resembling the compound last described in most of its reactions. It is completely decomposed by treatment with zinc and sulphuric acid, the platinum being thrown down in a finely divided metallic state, whilst the whole of the chlorine goes into solution. Sulphur dioxide passed into water in which the compound is suspended, gradually dissolves it, forming a nearly colourless solution, which when neutralised

with sodium carbonate and evaporated, yields crystals of Birnbaum's salt, $(\text{PtSO}_4 \cdot 3\text{Na}_2\text{SO}_4) \cdot 3\text{H}_2\text{O}$ (*Liebig's Annalen*, cxxxix. 169).

Chlorohydroxyfulmiplatinum, $\text{Pt} \cdot \text{N} \cdot \text{Cl}(\text{OH})\text{O}^{12}\text{H}^{22}$, is obtained as a dark yellow powder by heating ammonium chloroplatinate with 4.7 mols. of aqueous potash added at once, until ammonia is no longer evolved. It loses 4 mols. of water at 152° . When it is gradually heated to 260° with sodium carbonate, nearly the whole of the hydrogen is oxidised to water, whilst the hydrogen is for the most part set free. It is not appreciably acted upon by oxalic acid. With nascent hydrogen, it behaves like the dichloro-compound.

The foregoing results show that the decomposition of ammonium chloroplatinate by potash results in the formation of bodies containing equal numbers of atoms of platinum and nitrogen, whence it follows that ammonium chloroplatinate cannot be regarded as a double salt of platinic chloride and ammonium chloride, $\text{PtCl}_4(\text{NH}_4\text{Cl})_2$, the 2 atoms of nitrogen having essentially different functions in the compound. Direct experiment shows that when ammonium chloroplatinate is heated even with a large excess of potash, only half the nitrogen is eliminated in the form of ammonia.

Platonitrites and Diplatonitrites (Nilson, *J. pr. Chem.* [2], xvi. 241-278). Lang in 1861 discovered a double salt of platinum, which was produced on heating mixed solutions of potassium chloroplatinate and potassium nitrite (iv. 672). The composition of the salt was found to agree with the formula $\text{K}^2\text{Pt}(\text{NO}^2)_4$, but its constitution was not then understood. Blomstrand in 1871 (*J. pr. Chem.* [2], iii. 186) assigned to the salt, on theoretical grounds, the formula $(\text{K}-\text{O}-\text{NO}=\text{NO}-\text{O})^2\text{Pt}$, in which the platinum was supposed to play the part of a diatomic element; and this formula was supported by the fact, discovered by Blomstrand, that the salt readily takes up 2 atoms of chlorine or bromine to form a compound of tetratomic platinum. On this view the salt may be regarded as containing the negative radielo *platotetranitrosyl*:

and accordingly the corresponding acid (Lang's *acid platinous nitrite*) may be called *Platotetranitrous*, *Platinotetranitrosylic*, or simply *Platonitrous acid*, and its salts *Platonitrites*.

The following platonitrites have been prepared and analysed by Nilson. Except where otherwise stated, they were obtained by decomposing barium platonitrite with the sulphates of the respective bases.

The *potassium salt*, $\text{K}^2(\text{NO}^2)_4\text{Pt}$, crystallises from mixed solutions of potassium platinochloride and potassium nitrite in small colourless brilliant four- or six-sided prisms; it crystallises without water from a solution of potassium chloride, but with 2 mols. of water from aqueous solution.

The *rubidium and cesium salts*, $\text{Rb}^2(\text{NO}^2)_4\text{Pt}$ and $\text{Cs}^2(\text{NO}^2)_4\text{Pt}$, obtained by decomposing silver platonitrite with rubidium or cesium chloride, crystallise in small colourless or faintly-yellow transparent needles, which are permanent in the air and at 100° , and dissolve sparingly in water. The rubidium salt separates from a dilute solution on spontaneous evaporation in crystals containing 2 mols. of water.

Ammonium salt, $(\text{NH}_4)^2(\text{NO}^2)_4\text{Pt} + 2\text{H}_2\text{O}$.—Formed by triturating equivalent proportions of silver platonitrite and ammonium chloride with a little water. Crystallises in brilliant colourless or yellowish six-sided rhombic prisms, which are permanent in the air, but lose their water over sulphuric acid. The salt is decomposed with explosive violence when heated in the slightest degree over an open flame, leaving a bulky residue of spongy platinum.

Thallium salt, $\text{Tl}^2(\text{NO}^2)_4\text{Pt}$.—Crystallises in small brilliant, colourless, semi-transparent prisms, very sparingly soluble in cold water, and stable in the air and at 100° .

Sodium salt, $\text{Na}^2(\text{NO}^2)_4\text{Pt}$.—From the silver salt and sodium chloride. Crystallises in long colourless six-sided rhombic prisms, easily soluble in water, and permanent at 100° .

Lithium salt, $\text{Li}^2(\text{NO}^2)_4\text{Pt} + 3\text{H}_2\text{O}$.—Obtained as the last. Crystallises in beautiful short rhombic prisms, which dissolve easily in water, turn moist in the air, and give off their water of crystallisation at 100° .

Silver salt, $\text{Ag}^2(\text{NO}^2)_4\text{Pt}$.—Obtained by decomposing potassium platonitrite with silver nitrate, and crystallising the product repeatedly in presence of excess of silver nitrate. Small yellowish monoclinic four-sided prisms, permanent in the air, and sparingly soluble in cold water.

Calcium salt, $\text{Ca}(\text{NO}^2)_4\text{Pt} + 5\text{H}_2\text{O}$.—Obtained by double decomposition of the

silver salt and calcium chloride. Forms thin yellowish oblique four-sided prisms, which are permanent in moist air, but effloresce over sulphuric acid, and lose the whole of their water at 100° . The salt is very easily soluble.

Strontium salt, $\text{Sr}(\text{NO}_3)_4\text{Pt} + 3\text{H}_2\text{O}$.—Obtained as the last. Forms large colourless or yellowish six-sided prisms, which dissolve easily in water, lose two-thirds of their water at 100° , and bear a high temperature without decomposition.

Barium salt, $\text{Ba}(\text{NO}_3)_4\text{Pt} + 3\text{H}_2\text{O}$.—Obtained as the calcium salt. Crystallises very readily in colourless brilliant tables or prisms, sparingly soluble in cold water, and permanent in the air.

Lead salt, $\text{Pb}(\text{NO}_3)_4\text{Pt} + 3\text{H}_2\text{O}$.—Obtained as the calcium salt. Crystallises over sulphuric acid in yellow opaque six-sided monoclinic prisms, which lose their water at 100° .

Magnesium salt, $\text{Mg}(\text{NO}_3)_4\text{Pt} + 5\text{H}_2\text{O}$.—Colourless transparent six-sided monoclinic prisms, easily soluble in water, permanent in the air and at 100° , but decomposed with great tumefaction by gentle heating.

Manganese salt, $\text{Mn}(\text{NO}_3)_4\text{Pt} + 8\text{H}_2\text{O}$.—Crystallises in beautiful large rose-red triclinic prisms, which gradually turn darker in the air. Blackens at 100° , evolving nitric oxide.

Cobalt salt, $\text{Co}(\text{NO}_3)_4\text{Pt} + 8\text{H}_2\text{O}$.—Large red prisms, isomorphous with the last. Easily soluble in water; permanent in the air; decomposed at 100° .

Nickel salt, $\text{Ni}(\text{NO}_3)_4\text{Pt} + 8\text{H}_2\text{O}$.—Beautiful green transparent very thin tables or laminae, which are easily soluble in water and permanent in the air, but decomposed at 100° , giving off red vapours.

Copper salt (basic), $[\text{Cu}(\text{NO}_3)_4\text{Pt}]^3 \cdot \text{CuO} + 18\text{H}_2\text{O}$.—From the barium salt and cupric sulphate. Crystallises in golden-yellow delicate needles, which are decomposed by water, giving a green solution and a dark-coloured precipitate.

Copper salt (normal), $\text{Cu}(\text{NO}_3)_4\text{Pt} + 3\text{H}_2\text{O}$.—Crystallises from the mother-liquor of the preceding salt in very small green needles, which dissolve easily in water. Decomposed at 100° .

Zinc salt, $\text{Zn}(\text{NO}_3)_4\text{Pt} + 8\text{H}_2\text{O}$.—Large colourless or yellowish transparent crystals, isomorphous with those of the manganese, cobalt, and nickel salts. Easily soluble in water. Decomposed at 100° .

Cadmium salt, $\text{Cd}(\text{NO}_3)_4\text{Pt} + 3\text{H}_2\text{O}$.—Large yellow transparent monoclinic prisms, easily soluble in water, and efflorescent in the air. Gives off its water at 100° without further decomposition.

Mercurous salt, $\text{Hg}_2(\text{NO}_3)_4\text{Pt} \cdot \text{Hg}_2\text{O} + \text{H}_2\text{O}$.—Precipitated on mixing solutions of potassium platonitrite and mercurous nitrate. Small pointed prisms nearly insoluble in water, and becoming anhydrous at 60° .

Aluminium salt, $\text{Al}^3[(\text{NO}_3)_4\text{Pt}]^3 + 14\text{H}_2\text{O}$.—Large colourless apparently cubical crystals, very easily turning red owing to formation of diplatonitrite (see below). Decomposed at 100° .

Yttrium salt, $\text{Y}^3[(\text{NO}_3)_4\text{Pt}]^3 + 9\text{H}_2\text{O}$.—Small lemon-yellow, oblique four-sided prisms, permanent in the air and easily soluble in water. The mother-liquor deposits a salt with 21 mols. water, in long colourless or yellowish crystals, which lose 18 mols. of water at 100° .

Erbium salt, $\text{Er}^3[(\text{NO}_3)_4\text{Pt}]^3 + 9\text{H}_2\text{O}$.—Small yellow oblique four-sided prisms, easily soluble in water and permanent in the air. Another salt containing 21 mols. water is deposited from the mother-liquor in large reddish crystals.

Cerium salt, $\text{Ce}^3[(\text{NO}_3)_4\text{Pt}]^3 + 18\text{H}_2\text{O}$.—Yellowish oblique four-sided tables or rhombohedrons, easily soluble in water. The salt quickly undergoes alteration in the air and loses 15 mols. water at 100° .

Lanthanum salt, $\text{La}^3[(\text{NO}_3)_4\text{Pt}]^3 + 18\text{H}_2\text{O}$.—Closely resembles the preceding. Dissolves very easily in water, and deliquesces in moist air.

Didymium salt, $\text{Dy}^3[(\text{NO}_3)_4\text{Pt}]^3 + 18\text{H}_2\text{O}$.—Resembles the two last. Easily soluble in water; permanent in dry air; loses five-sixths of its water at 100° .

Plato-iodonitrites, $\text{R}^2\text{N}^2\text{O} \cdot \text{I}^2\text{Pt} = \text{R}^2(\text{NO}_3)_2\text{I}^2\text{Pt}$ (Nilson, *Ber.* x. 930; xi. 879). These salts are formed by the action of iodine and alcohol on the platonitrites. When 1 mol. iodine in alcoholic solution is brought in contact with 1 mol. platonitrite of potassium or barium, a dark brown-red liquid is formed, which, when left to evaporate, deposits small black crystals, probably of an addition-product; but on heating the liquid to 30° – 40° , it rapidly gives off gas, including aldehyde-vapour, becomes lighter in colour and finally amber-yellow, and when left to evaporate yields crystals of the plato-iodonitrite. The *potassium salt*, $\text{K}^2\text{N}^2\text{O} \cdot \text{I}^2\text{Pt} + 2\text{H}_2\text{O}$, crystallises in large four-

sided, shining, amber-yellow prisms, which are permanent in the air, and give off nothing but their water of crystallisation at 100°. The platinum in this salt is not precipitated by hydrogen sulphide, or the iodine by silver nitrate. The *barium salt*, $\text{BaN}^2\text{O}^4\text{I}^2\text{Pt} + 4\text{H}^2\text{O}$, crystallises in beautiful oblique four-sided prisms having an amber-yellow colour and diamond lustre, permanent in the air, and giving off part of their water at 100°. The *silver salt* is thrown down on adding silver nitrate to the solution of either of the preceding salts, as a lemon-yellow precipitate which is very slightly soluble in water, and when left upon filter-paper, acquires a blood-red colour, being probably resolved into silver iodide and a platinotrixylic acid.

The other plato-iodonitrites are mostly prepared by the action of a metallic sulphate on barium platoidonitrite. The silver, lead, and hydrogen-compounds are, however, precipitated from the barium salt by their respective nitrates, and the calcium and strontium platoidonitrites are obtained from the platonitrites by the action of iodine and alcohol. The silver, lead, thallium, and hydrogen salts are insoluble in water, the remaining salts are soluble. Most of the platoidonitrites are very stable, and do not decompose at 100°; others, however, split up into nitrite and platinous iodide.

Rubidium platoidonitrite, $\text{Rb}^2\text{N}^2\text{O}^4\text{I}^2\text{Pt} + 2\text{H}^2\text{O}$, forms large shining tabular crystals, which lose their water of crystallisation at 100°. The *caesium salt*, $\text{Cs}^2\text{N}^2\text{O}^4\text{I}^2\text{Pt} + 2\text{H}^2\text{O}$, crystallises in small prisms, which lose their 2 mols of water at 100°. The *ammonium salt*, $(\text{NH}^4)^2\text{N}^2\text{O}^4\text{I}^2\text{Pt} + 2\text{H}^2\text{O}$, forms large tabular crystals, which decompose slowly at 70°, but rapidly at 100° into water, nitrogen, and platinous iodide. *Thallium platoidonitrite*, $\text{Tl}^2\text{N}^2\text{O}^4\text{I}^2\text{Pt}$, separates out as an insoluble crystalline precipitate, when sodium platoidonitrite is added to a solution of thallium sulphate. The *sodium salt*, $\text{Na}^2\text{N}^2\text{O}^4\text{I}^2\text{Pt} + 4\text{H}^2\text{O}$, crystallises in large prisms, which lose their water at 100°. The *lithium salt*, $\text{Li}^2\text{N}^2\text{O}^4\text{I}^2\text{Pt} + 6\text{H}^2\text{O}$, forms long deliquescent prisms, which lose 5 mols. water at 100°. The *calcium salt*, $\text{CaN}^2\text{O}^4\text{I}^2\text{Pt} + 6\text{H}^2\text{O}$, crystallises in large prisms, which only lose 1 mol. water at 100°. The *strontium salt*, $\text{SrN}^2\text{O}^4\text{I}^2\text{Pt} + 8\text{H}^2\text{O}$, forms large four-sided prisms which give off 6 mols. water at 100°. The *lead salt*, $\text{PbN}^2\text{O}^4\text{I}^2\text{Pt} + \text{PbO}^2\text{H}^2$, is precipitated on the addition of lead nitrate to the barium salt. The *magnesium salt*, $\text{MgN}^2\text{O}^4\text{I}^2\text{Pt} + 8\text{H}^2\text{O}$, crystallises in large four-sided tables; the *manganese salt*, $\text{MnN}^2\text{O}^4\text{I}^2\text{Pt} + 8\text{H}^2\text{O}$, is deposited in irregular six-sided prisms, which are completely decomposed at 100°. *Nickel and cobalt platoidonitrites* form respectively green and yellow four-sided prisms, containing 8 mols. water, and decomposing at 100°. The *ferrous salt* crystallises in greenish-yellow four-sided prisms, containing 8 mols. water, and is decomposed at 100°. The *copper salt* has not been obtained in the pure state. *Zinc platoidonitrite*, $\text{ZnN}^2\text{O}^4\text{I}^2\text{Pt} + 8\text{H}^2\text{O}$, forms four-sided prisms, which are decomposed at 100°. The *cadmium-compound*, $\text{CdN}^2\text{O}^4\text{I}^2\text{Pt} + 2\text{H}^2\text{O}$, does not change when heated at 100°.

When mercuric chloride is added to barium platoidonitrite, mercuric iodide is precipitated; mercurous nitrate produces a dark-brown precipitate having the formula $\text{Hg}^2\text{N}^2\text{O}^4\text{I}^2\text{Pt} + \text{Hg}^2\text{O} + 9\text{H}^2\text{O}$.

Beryllium platoidonitrite, $\text{Be}^2(\text{N}^2\text{O}^4\text{I}^2\text{Pt})^3 + 18\text{H}^2\text{O}$, $[\text{Be} = 13.8]$, or $\text{BeN}^2\text{O}^4\text{I}^2\text{Pt} + 6\text{H}^2\text{O}$ $[\text{Be} = 9.2]$, forms small yellow crystals, which decompose at 100°. The aluminium salt contains 27 mols. of water, and in other respects resembles the preceding compound. The solution of the *chromium salt* decomposes on evaporation in a vacuum. *Ferric platoidonitrite*, $\text{Fe}^2(\text{N}^2\text{O}^4\text{I}^2\text{Pt})^3 + 6\text{H}^2\text{O}$, crystallises in greenish-yellow needles, which decompose at 100°.

Yttrium platoidonitrite, $\text{Y}^2(\text{N}^2\text{O}^4\text{I}^2\text{Pt})^3 + 27\text{H}^2\text{O}$, is a yellowish-green deliquescent crystalline mass, which decomposes at 100°. The erbium and cerium salts contain 18 mols. of water, lanthanum and didymium contain 24; in other respects these platoidonitrites resemble the yttrium-compound.

Diplatonitrites, $\text{R}^2[(\text{NO}^2)^2\text{Pt}]^2\text{O}$, or $\frac{\text{R.O.NO}=\text{NO.O.Pt}}{\text{R.O.NO}=\text{NO.O.Pt}} > \text{O}$, R denoting a univalent metal. On attempting to prepare the platonitrites of beryllium, iron, and indium in the manner above described, it was found that these salts could not be obtained, but that, instead of them, the corresponding diplatonitrites were produced, being formed from the platonitrites, with evolution of nitrogen trioxide, as shown by the equation

Some of the platonitrites above described are also partially converted into diplatonitrites when their solutions are heated. The following diplatonitrites have been analysed:

Beryllium salt, $\text{Be}[(\text{NO}^2)^2\text{Pt}]^2\text{O} + 9\text{H}^2\text{O}$.—Red prismatic crystals, sparingly soluble in water, forming a bright-yellow solution. Loses two-thirds of its water at 100°.

Ferric salt, $\text{Fe}^2[(\text{NO}^2)^2\text{Pt}]^4\text{O}^8 + 30\text{H}^2\text{O}$.—Resembles the beryllium salt. Easily soluble in hot water. Loses four-fifths of its water at 100° .

Indium salt, $\text{In}^2(\text{OH})^2[(\text{NO}^2)^2\text{Pt}]^4\text{O}^2 + 10\text{H}^2\text{O}$.—Very small red needles sparingly soluble in water, forming an orange-red solution.

Silver salt, $\text{Ag}^2[(\text{NO}^2)^2\text{Pt}]^4\text{O}$.—Tufts of greenish very small four-sided prisms, insoluble in water.

Aluminium salt, $\text{Al}^2(\text{OH})^2[(\text{NO}^2)^2\text{Pt}]^4\text{O}^2 + 10\text{H}^2\text{O}$.—Brilliant orange-red small needles, permanent in the air, easily soluble in hot water and alcohol.

Chromium salt, $\text{Cr}^2(\text{OH})^2[(\text{NO}^2)^2\text{Pt}]^4\text{O}^2 + 24\text{H}^2\text{O}$.—Small red crystals forming a greenish-violet solution in water. Gives off 18 mols. water at 100° .

Triplatocetonitrosylic acid, $\text{Pt}^3\text{O}(\text{NO}^2)^3\text{H}^4$, is formed, with evolution of nitrogen trioxide, when an aqueous solution of platinonitrous or platinotetranitrosylic acid is left to evaporate:

It is permanent at 100° , and forms a potassium salt, $\text{Pt}^3\text{O}(\text{NO}^2)^3\text{K}^4 + 2\text{H}^2\text{O}$, which crystallises in small oblique elongated four-sided plates, having a chrome-yellow colour and nacreous lustre, dissolves with moderate facility in warm water, and crystallises out again immediately on cooling. It is permanent in the air, and gives off nothing but its water of crystallisation at 100° .

PHOSPHOPLATINIC COMPOUNDS.

G. Quesneville (*Monit. scient.* [3], vi. 659) has studied the action of ammonia and aromatic amines (aniline, toluidine) on the compounds $\text{Cl}^3\text{P} = \text{PtCl}^2$ and $\text{Cl}^3\text{P} \begin{matrix} \text{Cl}^3\text{P} \\ | \\ \text{Cl}^3\text{P} \end{matrix} \text{PtCl}^2$, first obtained by Baudrimont, and further examined by Schützenberger (vii. 987, 990).

On adding ammonia to a solution of phosphoplatinic chloride, $\text{PtCl}^3\text{PtCl}^2$, in benzol, a white precipitate is formed, having the composition $\text{P}(\text{NH}^2)^3\text{PtN}^2\text{H}^4.2\text{HCl} + 3\text{NH}^4\text{Cl}$, but whether the ammonium chloride and the phosphoplatinum compound are chemically combined or merely mixed has not yet been decided, as the two appear to be about equally soluble in water. The *ethyllic ether*, $\text{P}(\text{OC}^2\text{H}^3)^3\text{PtCl}^2$, obtained from the chloride by the action of alcohol, is acted on by ammonia in a similar manner, yielding the compound $\text{P}(\text{OC}^2\text{H}^3)^3\text{PtN}^2\text{H}^4.2\text{HCl}$. The chloride, $(\text{PtCl}^3)^2\text{PtCl}^2$, gives with ammonia the compound $\text{P}^2(\text{NH}^2)^6\text{PtN}^2\text{H}^4.2\text{HCl} + 6\text{NH}^4\text{Cl}$; and the corresponding ether, $\text{P}^2(\text{OC}^2\text{H}^3)^6\text{PtCl}^2$, yields the compound $\text{P}^2(\text{OC}^2\text{H}^3)^6\text{PtN}^2\text{H}^4.2\text{HCl}$.

The action of the aromatic amines on the phosphoplatinic chlorides is somewhat different, yielding compounds soluble in benzene, but insoluble in water, and represented by the formulæ:

They are decomposed by water, yielding respectively the compounds:

A similar action is exerted by aniline and toluidine on the ethers of phosphoplatinic chloride, the product being the aniline-compound $\text{P}(\text{OC}^2\text{H}^3)^3\text{PtCl}^2.\text{NH}(\text{OC}^6\text{H}^5)$, being converted by the action of potassium hydrate into $\text{P}(\text{OC}^2\text{H}^3)^3\text{Pt}(\text{OH})^2.\text{NH}(\text{OC}^6\text{H}^5)$.

Amongst the products of the action of aniline on diphosphoplatinic chloride, $(\text{PtCl}^3)^2\text{PtCl}^2$, only the compound $\text{P}^2\text{O}(\text{NHC}^6\text{H}^5)^4\text{PtClOH}$ could be obtained pure; it is formed when the alcoholic solution of the immediate product of the reaction is precipitated with water.

Compt. rend. lxxxvi. 1402).—This compound is formed by fusing phosphoplatinic chloride with platinous chloride. A considerable rise of temperature takes place, and the mass thickens, becoming nearly solid towards the end of the operation. The product dissolves in alcohol, forming the ether $\text{P}(\text{OC}^2\text{H}^3)^3.2\text{PtCl}^2$. The deep-red solution forms no precipitate with water or with ether, but with *aniline, toluidine, &c.*, a reaction takes place, the mixture, when heated on the water-bath and then left to cool, depositing greenish or yellowish crystals which are free from phosphorus, and consist of $\text{PtCl}^2.2\text{C}^6\text{H}^5\text{N}$ or $\text{PtCl}^2.2\text{C}^7\text{H}^7\text{N}$ respectively. The liquid separated from the crystals yields, on addition of water, a copious crystalline precipitate, consisting

of the compound $P(OC^6H^5)^3.Pt(C^6H^5NH)^2.2HCl$ or $P(OC^6H^5)^3.Pt(C^7H^7NH)^2.2HCl$ respectively.

The methylic and ethylic ethers of diphosphoplatinic chloride, $(PCl^3)^2PtCl^2$, yield with aniline and toluidine the following crystallised compounds:

Platino-tungstates and Platino-molybdates (W. Gibbs, *Ber.* x. 1384; *Sill. Am. J.* [3], xiv. 61). These salts, analogous to Marignac's silico-tungstates (v. 915), are formed by boiling an acid tungstate or molybdate with platinic hydroxide.

Sodium Platino-tungstate, $10WO^3.PtO^2.4Na^2O + 25H^2O$, is obtained in this manner from sodium silico-tungstate, as a green solution, which turns red when concentrated, and ultimately deposits the salt in fine large olive-green crystals. It is easily soluble in water, and forms flocculent or indistinctly crystalline precipitates with the salts of the heavy metals and those of the higher alkaloïds.

Simultaneously with this green sodium salt, there is also produced an isomeric or metameric compound, which separates in large crystals having a honey-yellow colour and diamond lustre, and forms the starting point of a second or yellow series of platino-tungstates. The *potassium* and *ammonium* salts of this yellow series are represented by the formulæ $10WO^3.PtO^2.4K^2O + 9H^2O$ and $10WO^3.PtO^2.4(NH^4)^2O + 12H^2O$.

Sodium Platino-molybdate, $10MoO^3.PtO^2.4Na^2O + 29H^2O$, obtained by boiling acid sodium molybdate with platinic hydroxide, likewise forms a green solution, and separates therefrom in amber-yellow tabular crystals. It dissolves readily in water, and gives precipitates with salts of the heavy metals and alkaloïds. The *silver* salt is pale green and crystalline. A second sodium salt, probably an isomeride, has likewise been obtained.

The free acids, obtained by decomposing the respective silver salts with hydrochloric acid, are greenish or yellow-green compounds.

PLEONAST. The pleonasts of Latium exhibit, according to J. Strüver (*Zeitschr. Kryst.* i. 233), the forms 0, $\infty O \infty$, ∞O , 303, 202, 606, 30, 70, $\infty O3$, $5O\frac{1}{2}$, among which 30, 70, $\infty O3$, 202, 606, and $5O\frac{1}{2}$ are new for spinel. The crystals are rarely separate, being mostly imbedded in ejected blocks.

PLUMBOMANGANITE. A sulphide of lead and manganese (in the collection of the University of Glasgow), found in a 'pocket' in gneiss below a deposit of argentite. Sp. gr. = 4.01. Structure somewhat crystalline. Colour dark steel-grey with a bronze tinge when weathered. Easily oxidised by nitric acid, slowly attacked by boiling sulphuric and hydrochloric acids. Analysis gave 40.00 per cent. manganese, 30.68 lead, and 20.73 S, agreeing very nearly with the formula $PbS.3MnS$ (J. B. Hannay, *Mineralogical Magazine*, 1877, 149).

PLUMIERIC ACID, $C^{10}H^{10}O^5$ (A. C. Oudemans, *Liebig's Annalen*, clxxxi. 154). An acid obtained from the milky juice of *Plumieria acutifolia*, an apocyanaceous shrub largely grown in Java and the other Sunda islands. The material examined by Oudemans was collected by de Vrij, who evaporated the fresh juice to dryness at 100° , and obtained 30.5 per cent. of residue consisting chiefly of an organic calcium salt, a kind of caoutchouc, and resins. To isolate the calcium salt, the substance was exhausted with petroleum-naphtha and the residue heated with dilute acetic acid, which dissolved the salt, while parts of the plant and a humus-like mass remained behind. On concentrating the solution, calcium salts of different forms separate out, all, however, containing the same acid. The free acid is obtained by converting the calcium salt into potassium plumierate, decomposing the latter with sulphuric acid, and extracting the solution with ether. It is readily soluble in alcohol and freely but slowly in ether. In cold water it dissolves but very sparingly, and from a hot solution it separates in microscopic crystals, or on slow evaporation in indistinct crusts. It melts at 139° , and decomposes at a temperature a few degrees higher, giving off first water and acetic acid, then an oily distillate having the odour of cinnamic aldehyde, while a small quantity of a crystalline substance sublimes. When the oil is oxidised, a crystalline acid is formed. On melting plumieric acid with potash, $\frac{1}{2}n$ acid is formed, giving the characteristic reactions of salicylic acid.

Plumieric acid is most probably a *methoxyl-hydroxycinnamic acid*, $C^6H^2(OH)^2(CH^2OH)(COOH)$, and forms four series of salts, according as only the carboxylic hydrogen, or in addition one or more of the three hydroxylic hydrogens, is replaced by a metal. The *tetrapotassic salt*, $C^{10}H^6K^4O^5 + 3H^2O$, forms monoclinic crystals, ∞P , $\infty P \infty$, and $0P$, and is very soluble and deliquescent. On dissolving

the acid in ammonia and evaporating the solution under an exsiccator, crystals of a deliquescent salt are frequently formed, which give, with silver nitrate, a precipitate containing 3 atoms of silver. On standing longer, the crystals disappear, and an amorphous residue is obtained, which is readily soluble and gives a *silver salt* containing 2 atoms of the metal. The *calcium salt*, $(C^{10}H^9O^3)^2Ca + 8H^2O$, is obtained by dissolving molecular proportions of the acid and the dicalcic salt in water and evaporating, when the salt crystallises in small hexagonal pinacoids. It dissolves in 200 pts. of water at 20° , and much more freely in boiling water. $C^{10}H^9CaO^3 + 5H^2O$ exists in the juice of the plant and forms rhombic crystals, showing the faces ∞P , $\infty \bar{P}$, ∞ in OP . 1 pt. dissolves at 20° in 400 pts. of water; in boiling water it is a little more soluble, easily forming supersaturated solutions. $(C^{10}H^9O^3)^2Ca^3 + 8H^2O$ was obtained in small thick prisms by adding lime-water to a hot solution of the last salt. A salt with 10 mols. of water was once obtained by exhausting the crude calcium salt with hot water. *Silver salts*.— $C^{10}H^9Ag^2O^3 + H^2O$ is a white crystalline precipitate; $C^{10}H^9Ag^2O^3 + 1\frac{1}{2}H^2O$ is a similar body crystallising from hot water in needles.

When plumieric acid is oxidised by a dilute solution of chromic acid, it is resolved into formic acid (or carbon dioxide), and the acid, $C^9H^8O^4$, which is very sparingly soluble in water; its *silver salt*, $C^9H^8Ag^2O^4$, separates from a warm solution in fibrous crystals.

When plumieric acid is heated with water and *sodium-amalgam* on a water-bath, it combines slowly with hydrogen to form hydroplumieric acid, $C^{10}H^{12}O^3$, which on evaporation of its ethereal solution, separates as a varnish, becoming crystalline on standing, and freely soluble in water.

PODOCARPIC ACID, $C^{17}H^{22}O^3$ (Oudemans, *Ber.* vii. 1122, 1125; *Liebig's Annalen*, clxx. 213). A resin-acid, forming the principal part (at least 98 per cent.) of a resin found by J. E. de Vrij in the trunk of an old tree, *Podocarpus Cupressina*, var. *imbricata* (Blume), growing in Java. To obtain the acid, the resin is dissolved in alcohol, and the solution, mixed with as much water as can be added without producing turbidity, is left at rest for a few hours, whereupon it deposits white needle-shaped crystals, which may be nearly purified by four or five crystallisations from dilute alcohol. To obtain the acid quite pure, however, it must be converted into the sodium salt and separated therefrom.

Podocarpic acid crystallises from dilute alcoholic solution, either in thin rhombic plates exhibiting the combination $OP \cdot \infty P \cdot \infty \bar{P}$, or in more massive crystals formed of a prism $\infty \bar{P}_n$ of about 60° – 65° , the basal face OP , and several alternately developed macrodomes \bar{P} , which produce a striated ventricose surface. It is insoluble in water, very slightly soluble in benzene, carbon sulphide, and chloroform, somewhat more soluble in dilute acetic acid, very easily in alcohol, ether, and glacial acetic acid. It is optically active, its specific rotatory power at 15° for sodium light being $+136^\circ$. It melts at 187° – 188° , and resolidifies to an amorphous glass. When heated above its melting point, it volatilises slowly, diffusing a peculiar aromatic odour. At about 130° it is resolved into its anhydride and water: $2C^{17}H^{22}O^3 = H^2O + C^{34}H^{42}O^3$, and at a higher temperature it is decomposed in the same manner as its calcium salt (*infra*), excepting that in the case of the free acid the volatile products (carpene and paracresol) occur only in traces.

Podocarpic acid forms three series of salts, represented by the formulæ :

It decomposes the carbonates of the alkali-metals when heated therewith, forming exclusively salts of the first kind, even in presence of excess of alkali. The neutral solution of the acid in ammonia, from which silver nitrate throws down the salt $C^{17}H^{21}AgO^3$, gives off ammonia on exposure to the air, and is converted into a hyper-acid salt; with the fixed alkalis similar salts could not be obtained. Of the *sodium salts*, the only one which has a constant composition is $C^{17}H^{21}NaO^3 + 7H^2O$. This salt forms long shining needles with rhombic transverse section, which give off 5 mol. water over sulphuric acid, and dissolve in about 3 pts. water at 21° . For its specific rotatory power the following values have been obtained :

In aqueous solution	(Concentration 0.046	$[\alpha]_D = +82.1^\circ$
	(Concentration 0.064	$[\alpha]_D = +78.8$
	(Concentration 0.138	$[\alpha]_D = +73.3$
In alcoholic solution;	Concentration 0.09	$[\alpha]_D = +86.1$

The following podocarpatcs have also been analysed :

The *methylic ether*, $\text{C}^{17}\text{H}^{21}\text{O}^3(\text{CH}^3)$, prepared from the silver salt, forms small granules, easily soluble in alcohol, melting at 174° ; the *ethylic ether*, $\text{C}^{17}\text{H}^{21}\text{O}^3(\text{C}^2\text{H}^5)$, slender needles, easily soluble in alcohol and chloroform, melting at 143° – 146° .

Decomposition of Podocarpic Acid by Heat.—When calcium podocarpate is subjected to dry distillation from short combustion-tubes, a tarry liquid is obtained, which, when distilled with small quantities of water as long as oil-drops continue to pass over, yields first a mobile liquid lighter than water, then a thicker liquid which sinks in water and dissolves in alkalis, whilst the greater part of the tar remains behind.

The two volatile substances, which may be completely separated by means of potash, consist of a hydrocarbon, C^9H^{14} , called *carpene*, and a cresol, which from its odour, its boiling point (202°), and the melting point (68°) of its benzoyl-derivative, appears to be paracresol.

Carpene is a mobile liquid which is lighter than water, smells like oil of turpentine and cinnamene, and boils at 155° – 157° . It dissolves readily in alcohol, carbon sulphide, and benzene, absorbs oxygen rapidly from the air, and is converted thereby into an amorphous resinous body ($\text{C}^{18}\text{H}^{28}\text{O}^3$?). *Monobromo-carpene*, $\text{C}^9\text{H}^{13}\text{Br}$, is formed, with evolution of HBr , on slowly mixing a solution of carpene (1 mol.) in carbon sulphide with bromine (1 mol.), also dissolved in carbon sulphide, and remains on evaporation as a syrupy liquid, stable at ordinary temperatures. *Di bromocarpene*, $\text{C}^9\text{H}^{12}\text{Br}_2$, produced by the further action of bromine, decomposes gradually, with formation of dark-coloured products. The vapours of both these bromine-compounds strongly attack the nose and eyes. The oxidation of carpene with chromic acid mixture or nitric acid does not yield terephthalic acid; whether any other aromatic acids are formed is a point not yet determined.

Hydrocarpol, $\text{C}^{16}\text{H}^{20}\text{O}$.—The tar which remains after the carpene and cresol have passed over, boils in a vacuum at 220° , yielding a viscid yellow strongly refracting distillate, which has a faint aromatic odour, and, when exposed to the air, gradually becomes darker without notable decomposition. This liquid is hydrocarpol; it is insoluble in water, but dissolves easily in alcohol, ether, benzene, and carbon sulphide; also in alkalis, and is separated therefrom by hydrochloric acid. When boiled with nitric acid, it yields an easily decomposable nitro-product, which has an odour of musk and crystallises from alcohol with great difficulty in brown-red granules. Hydrocarpol when distilled under ordinary pressure partly goes over unaltered, and is partly resolved at about 360° – 400° into carpene, metacresol, and small quantities of a solid phenolic substance, which makes its appearance towards the end of the distillation. The same products are obtained from the original tarry residue if it be distilled under ordinary pressure instead of in a vacuum: hence this tarry matter consists mainly of hydrocarpol. The solid phenolic body, methanthrol, $\text{C}^{16}\text{H}^{20}\text{O}$, melts at 122° .

Free podocarpic acid when heated is first resolved at about 330° into water and the anhydride $\text{C}^{34}\text{H}^{42}\text{O}^6$. On continuing the heat, the same products are obtained as from the calcium salt, excepting that the volatile products, carpene and metacresol, are obtained only in traces. The gases formed at the same time consist of CO^2 (rather more than 1 mol. to 1 mol. of the anhydride), CO (about 0.7 mol. to the same quantity), and methane. Oudemans thinks it probable that in the distillation of calcium podocarpate there is first formed a phenol, $\text{C}^{16}\text{H}^{22}\text{O}$, together with hydrocarpol, $\text{C}^{16}\text{H}^{20}\text{O}$, and that this phenol is then resolved partly into carpene and paracresol, partly into hydrogen (which is given off in the form of water) and hydrocarpol, which forms by far the largest portion of the product. These reactions may be represented by the following equations:

* The same equation, with omission of CaO , will apply to the decomposition of podocarpic anhydride, $\text{C}^{34}\text{H}^{42}\text{O}^6$.

The methanthrol, $C^{15}H^{12}O^2$, is formed by a secondary reaction, probably thus

which likewise accounts for the occurrence of methane.

Podocarpic acid, distilled with *zinc-dust*, yields methanthrene, $C^{15}H^{12}$ (p. 1301).

Nitropodocarpic Acids. By the action of nitric acid on podocarpic acid two nitro-acids are produced, which also form with the alkalis salts containing 1 and 2 atoms of metal; the monometallic salts are of a fine red colour; the bi-metallic salts are honey-yellow and less stable. The ammonium salts readily give off the whole of their ammonia.

Mononitropodocarpic acid, $C^{17}H^{21}(NO^2)O^3$, is best prepared by prolonged heating of podocarpic acid with dilute nitric acid (1 pt. nitric acid, sp. gr. 1.34 to 5 or 6 pts. water). It forms small irregular crystals, insoluble in water and in carbon sulphide, very slightly soluble in chloroform and benzene, sparingly in cold, somewhat more freely in boiling alcohol, melting at 205° . The *dipotassium salt*, $C^{17}H^{19}(NO^2)O^3K^2 + 5\frac{1}{2}H^2O$, crystallises only from solutions containing excess of alkali, in red needles with green reflex, easily soluble in water and in alcohol. The *monopotassium salt* exists only in alcoholic solution, being decomposed, on evaporation or on addition of water, into the free acid and the dipotassium salt. The *disodium salt*, $C^{17}H^{19}(NO^2)O^3Na^2 + 9H^2O$, forms cinnabar-red laminæ, easily soluble in water and in alcohol. The *diammonium salt*, $C^{17}H^{19}NO^2O^3(NH^4)^2 + 4H^2O$, forms garnet-red monoclinic crystals, which are decomposed by contact with the air and by water. The *monobarium salt*, $C^{17}H^{19}(NO^2)O^3Ba + 7H^2O$, is obtained in red needles an inch long, on cooling a mixture of the warm solutions of the dipotassium salt and barium chloride. It also crystallises with 3 mols. water in small brown spherical groups, or is precipitated on adding barium chloride to a very strong solution of the nitro-acid in ammonia, as a fine dark carmine-coloured powder, which, while suspended in the liquid, gives it the appearance of arterial blood. The *hemibarium salt*, $[C^{17}H^{20}(NO^2)O^3]^2Ba + 4H^2O$, forms yellow needles, sparingly soluble in water and in cold alcohol. The *monocalcium salt*, $C^{17}H^{19}(NO^2)O^3Ca + 4H^2O$, crystallises in slender orange-red needles, nearly insoluble in water.

Dinitropodocarpic acid, $C^{17}H^{20}(NO^2)^2O^3$, is produced by cautiously heating podocarpic acid with nitric acid of sp. gr. 1.34, or in a state of greater purity, by boiling sulphopodocarpic acid with nitric acid. It forms pale yellow crystals similar in shape to those of potassium ferrocyanide, but probably belonging to the orthorhombic system. It is insoluble in water, sparingly soluble in chloroform, benzene, and carbon sulphide, moderately soluble in alcohol. Melts at 203° . Becomes brownish in sunshine. The *dipotassium salt*, $C^{17}H^{18}K^2(NO^2)^2O^3 + 5H^2O$, crystallises only in presence of free alkali. It is very soluble. The *monobarium salt*, $C^{17}H^{18}Ba(NO^2)^2O^3 + 4H^2O$, separates from a moderately concentrated ammoniacal solution of the dinitro-acid mixed with barium chloride, in shining, brown-red, strongly polarising rhombic laminæ. It is nearly insoluble in water and in alcohol. The *diargentic salt*, $C^{17}H^{18}Ag^2(NO^2)^2O^3 + 4H^2O$, is precipitated by silver nitrate from a boiling solution of the barium salt in orange-red coloured flocks.

Amidopodocarpic Acids are formed by treating the nitro-acids in alcoholic solution with tin and hydrochloric acid, but they are very unstable, and have not been obtained in a state of purity. *Hydrochloride of monoamidopodocarpic acid* has the composition $C^{17}H^{21}(NH^2)O^3.HCl + \frac{1}{2}H^2O$.

Sulphopodocarpic Acid, $C^{17}H^{21}(SO^3H)O^3$, is formed by gently heating podocarpic acid with 3 pts. sulphuric acid. On adding water, the unaltered podocarpic acid separates out, and the sulpho-acid remaining in solution may be freed from excess of sulphuric acid by means of baryta. The red aqueous solution of sulphopodocarpic acid exhibits a splendid fluorescence, red, blue, or emerald-green, according to the particular conditions of the preparation. The solution of the *pure* acid is not fluorescent; it dries up in the exsiccator to an amorphous mass having the composition $C^{17}H^{21}(SO^3H)O^3 + 8H^2O$. Even very dilute solutions of this acid give, when boiled with traces of nitric acid, a precipitate of dinitropodocarpic acid.

Sulphopodocarpic acid is a strong acid, and forms two series of salts. The *disodium salt*, $C^{17}H^{19}Na^2(SO^3H)O^3 + 7H^2O$, forms rosettes of easily soluble crystals. The *monobarium salt*, $C^{17}H^{19}Ba(SO^3H)O^3 + 8H^2O$, crystallises in white laminæ, unctuous to the touch, very soluble in boiling water and alcohol, less soluble in cold water. The *hemibarium salt*, $[C^{17}H^{20}(SO^3H)O^3]^2Ba + 8H^2O$, prepared by treating the preceding salt with acetic acid, is much less soluble. The *monocalcium salt*, $C^{17}H^{19}Ca(SO^3H)O^3 + 7H^2O$, forms thin laminæ, for the most part concentrically grouped.

Ethylbromopodocarpic Acid, $C^{17}H^{20}(C^2H^5)BrO^3$. When bromine (2 mols.) is added to podocarpic acid (1 mol.) immersed in carbon sulphide, streams of hydrogen

bromide are given off, and the resulting bromo-substitution-product dissolves in the liquid; but the solution when evaporated leaves a residue which cannot be made to crystallise. When, on the other hand, solutions of podocarpic acid and bromine in ether containing alcohol are mixed together, the mixture, which becomes warm and soon loses its colour, leaves on evaporation a resinous residue which suddenly becomes crystalline. The product thus obtained separates from warm alcohol in rather large shining crystals consisting of an *alcoholate* of *ethylbromopodocarpic acid*, $C^{17}H^{20}(C^2H^3)BrO^3.C^6H^6O$. This compound melts at a temperature above 80° , and after prolonged heating leaves ethylbromopodocarpic acid as a white crystalline powder, which melts at 158° , and forms with alkali-solutions salts which dry up to gelatinous masses.

Acetylpodocarpic Acid, $C^{17}H^{21}(C^2H^3O)O^3$, formed by the action of acetyl chloride on podocarpic acid, crystallises in small needles, melts between 150° and 152° , and resolidifies to a transparent resin.

Constitution of Podocarpic Acid.—From the formation of the substitution-derivatives above described, and from its mode of decomposition when heated alone, and with zinc-dust, Oudemans infers that the constitution of podocarpic acid may be most simply represented by the formula:

moreover, that the radicle C^9H^{15} is most probably an addition-product of benzene, so that this formula may be resolved into one of the following, which represent it as a derivative of diphenyl:

The resolution of calcium podocarpate by heat into $CaCO^3$, C^9H^{14} , and C^9H^8O may perhaps be most readily explained by assigning to podocarpic acid the structure represented by the following formula:

The formation of paracresol by the decomposition of podocarpic acid shows that the radicles OH and CH^3 must be in the relative positions 1 : 4.

PODOPHYLLUM. On the constituents of *Podophyllum peltatum*, see W. C. Busch (*Pharm. J. Trans.* [3], viii. 424; *Chem. Soc. J.* xxxiv. 325). On the Colour of Podophyllum resin, as affected by its state of aggregation, see Senier a. Lowe (*Pharm. J. Trans.* [3], viii. 443; *Chem. Soc. J.* xxxiv. 326). According to F. B. Power (*Pharm. J. Trans.* [3], v. 244), the resin extracted from podophyllum by alcohol may be separated into two different substances, one of which is soluble in ether, the other insoluble. The soluble portion acts on the organism much more powerfully than that which is insoluble in ether.

POLYDYMITE. A native sulphide of nickel, crystallising in the regular system, in octohedrons which are polysynthetically twinned, the twin-plane being a face of the octohedron. Most of the crystals are tabular, through predominance of the face parallel to the twin-plane, and there are also prismatically developed octohedrons. Cleavage incompletely cubical. Fracture uneven to conchoidal. Hardness = 4–5. Sp. gr. 4·808–4·816. Somewhat sectile. Colour on freshly broken surfaces light steel-grey, becoming very soon dark-grey or yellow. Decrepitates before the blowpipe; fuses on charcoal to a blackish-green magnetic bead. Dissolves in nitric acid with separation of sulphur; does not dissolve in hydrochloric acid, but enclosed bismuth-glance is dissolved out by this acid. Strong metallic lustre. Chemical composition as follows:

Ni	Co	Fe	S	As	Sb
53·508	0·606	3·844	40·270	1·041	0·508 = 99·777

This analysis leads to the general formula, R^3S^2 . Polydymite is found in veins of other ores at Sayn-Altenkirchen, accompanied by millerite, bismuth-glance, zinc-blende,

gersdorffite, and ullmannite, lying on a layer of spathic iron and quartz. On one specimen the crystals were found to have lost their metallic lustre, and to have been converted into a reddish-brown substance. On breaking some of these pseudomorphs, it was observed that they were penetrated by fresh acicular millerite. A careful examination of these crystals leads to the inference that the polydymite and millerite were formed simultaneously (H. Laspeyres, *J. pr. Chem.* [2], xiv. 397; *Jahrb. f. Min.* 1876, 737; 1877, 296).

POLYHALITE. This mineral, from Stebnik in Galicia, has been analysed by M. v. Lill. A. gives the direct results of analysis; B. the corrected values, after deduction of ferric oxide and sodium chloride:

	CaSO ⁴	MgSO ⁴	K ² SO ⁴	NaCl	Fe ² O ³	H ² O
A.	44.47	20.22	27.14	1.61	0.04	6.25 = 99.73
B.	45.22	20.56	27.60	—	—	6.35 = 99.73

G. Krause (*Arch. Pharm.* [3], vi. 325) has analysed polyhalite from Stassfurt, with the following results, A. and B. denoting as above:

	CaSO ⁴	MgSO ⁴	K ² SO ⁴	NaCl	Insol.	H ² O
A.	32.53	13.11	24.82	18.17	0.95	10.58 = 100.16
B.	40.14	16.17	30.62	—	—	13.05 = 99.98

POLYMERISM. On Physical Polymerism and Isomerism, see O. Lehmann (*Zeitschr. Kryst.* 1877, i. 97-131; *Jahresb. f. Chem.* 1877, 31-40).

On the influence of Polymerisation on Chemical Compounds, see J. Löwenthal (*Chem. Centr.* 1877, 193; *Chem. Soc. J.* xxxiv. 108).

POLYMORPHISM. On the polymorphism of Elementary Bodies, see R. Hermann (*J. pr. Chem.* [2], xvii. 289; *Chem. Soc. J.* xxxiv. 702).

POLYPORUS. G. Fleury (*Pharm. J. Trans.* [3], vi. 869) found in *Polyporus officinalis* the following constituents:

Water	9.200
Resin and Agaric acid	60.584
Another resin with Magnesium Sulphate	7.282
Resinous body with Lime and Magnesia	2.514
Nitrogenous substance with Salts	1.900
Oxalates, Malates, and Phosphates of Calcium and Iron	1.058
Nitrogenous substance, soluble in Potash	7.776
Fungin	9.686

100

POLYPORIC ACID, C⁹H⁷O² (C. Stahlschmidt, *Liebig's Annalen*, clxxxvii. 177). An acid contained in a fungus belonging to the genus *Polyporus*, which grows on the bark of diseased or dead oaks: it occurs in large quantity, amounting to 43.5 per cent. of the dry fungus. The fungus is semicircular, and rests directly on the bark without a stalk; it is of an ochre-yellow colour when dry, brownish-yellow in the moist state, and is coloured deep violet by dilute ammonia, whence Stahlschmidt proposes to call it *Polyporus purpuraceus*. The violet coloration is due to the formation of ammonium polyporate.

To prepare the acid, the fungus is washed with water, and then steeped in dilute ammonia for twenty-four hours. By this means the acid is converted into its ammonium salt, which is soluble in water, though the acid itself is totally insoluble. The ammonium polyporate is next decomposed by hydrochloric acid, and the precipitated acid, after filtering and washing, is treated with caustic potash, and thus converted into potassium polyporate, which is washed for some time with caustic potash, in which it is insoluble. It is then washed with alcohol till free, as far as possible, from potash, and dissolved in hot water. Carbon dioxide is passed into the liquid to convert any remaining traces of potash into the carbonate, and it is then crystallised several times. The polyporic acid is finally precipitated by hydrochloric acid.

Polyporic acid has the colour of the fungus, and is totally insoluble in water, so that the slightest trace of a soluble polyporate shows a turbidity on addition of an acid. The soluble polyporates might, therefore, be used as indicators in alkalimetry. The acid is also insoluble in ether, benzene, bisulphide of carbon, and acetic acid. It dissolves very slightly in chloroform, amyl alcohol, and boiling (95 per cent.) ethyl alcohol. From the latter solvent it crystallises in small rhombic plates, which exhibit a lively bronze colour when dry. It contains no water of crystallisation, and becomes strongly electrical when rubbed in the dry state. It may be heated without change to 220°, but at a higher temperature it melts, and sublimes with partial

decomposition, evolving a smell of heated or burning oak-branches, and after a while that of bitter almond oil.

Reactions.—1. When polyporic acid is added to a cold mixture of potassium chlorate and hydrochloric acid, it is converted into a bright-yellow compound, soluble in alcohol: but if the acid is added to boiling hydrochloric acid, and potassium chlorate is introduced little by little, an oily body gradually forms at the bottom of the vessel, becoming solid on cooling. This body is partly soluble in boiling water, and the solution deposits snow-white feathery crystals easily soluble in caustic potash, and apparently consisting of a chlorinated acid (34·5 per cent. Cl). The part which is insoluble in water dissolves easily in alcohol, and crystallises with great facility in long slender needles of a golden-yellow colour. Heated with caustic potash, it evolves a smell of bitter almonds, and forms a dark-red substance totally insoluble in alcohol, ether, alkalis, &c. The yellow compound (containing 38·7 per cent. of chlorine) is decomposed on heating, and emits a smell of benzoyl chloride. A third body is found in the alcoholic mother-liquor of the original solution, and remains behind as a thick oil on evaporation of the alcohol.

2. When potassium polyporate is boiled for some time with excess of concentrated caustic potash, the violet colour of the solution gives way to a yellowish-red, and the smell of bitter almonds becomes perceptible. On cooling, fine colourless needles are deposited. The alkaline solution becomes turbid on addition of hydrochloric acid, and on standing a dull-yellow body separates, which is soluble in alcohol, and unites with alkalis.

3. Addition of zinc-dust to an alkaline solution of potassium polyporate renders the solution colourless, but it becomes red again on exposure to air. When ammonium polyporate, mixed with excess of ammonia, is left at rest, a decomposition or alteration of the acid takes place, and the liquid becomes blue and fluorescent. At a higher temperature the change takes place more quickly, and a brown insoluble body is formed.

4. By heating potassium polyporate to a high temperature with zinc-dust, benzene is produced, a reaction which when viewed in connection with the behaviour of the acid to caustic potash, points to the conclusion that polyporic acid belongs to the aromatic group.

Salts of Polyporic Acid.—Polyporic acid forms salts with all the bases. The easily soluble salts—those of the alkali-metals and ammonia—form violet solutions, which cannot be distinguished in appearance from a concentrated solution of potassium permanganate. All the salts are decomposed by the stronger acids, even by acetic acid, at ordinary temperatures, with perfect separation of the polyporic acid; but when polyporic acid is boiled with potassium or sodium acetate, the acetic acid is expelled, and a polyporate is formed. All the polyporates, except that of ammonium, can be heated above 200°, without decomposition.

Potassium polyporate, $C^9H^6O^2K + H^2O$, crystallises in the form of gypsum. It does not give off its water of crystallisation when dried over sulphuric acid, but loses it completely when heated to 120°. The *sodium salt*, $C^9H^6O^2Na + H^2O$, obtained by neutralising the acid with dilute caustic soda, is insoluble in concentrated caustic soda, and loses its water of crystallisation at 180°. The *ammonium salt*, $C^9H^6O^2NH^4 + H^2O$, loses not only its water of crystallisation, but also the whole of its ammonia, by long standing in the air, or by heating to 100°. The *barium salt*, $(C^9H^6O^2)^2Ba + 4H^2O$, loses 2 mols. of water at 120°, and the other two at 150° to 160°. If the salt containing 4 mols. of water is boiled for a time, another salt is precipitated, which has the composition $(C^9H^6O^2)^2Ba + 2H^2O$. This is also quite insoluble in water, has a metallic lustre, and loses its water of crystallisation at 180°. The *strontium salt*, $(C^9H^6O^2)^2Sr + 4H^2O$, is insoluble in water. It is not altered by boiling, but is converted by a heat of 120° into a salt of the composition $(C^9H^6O^2)^2Sr + H^2O$. It loses the last molecule of water at 180°–200°. The *calcium salt*, $(C^9H^6O^2)^2Ca + 3H^2O$, is slightly soluble in water. At 120° it loses 2 mols. of water, and leaves a salt of the composition $(C^9H^6O^2)^2Ca + H^2O$. At 180° it becomes anhydrous. The *magnesium salt*, $(C^9H^6O^2)^2Mg + 3H^2O$, is so sparingly soluble that ammonium polyporate can be used for the separation of magnesia from the alkalis. The *silver salt*, $C^9H^6O^2Ag$, is quite insoluble in water, and cannot be distinguished in appearance from the acid itself. It is anhydrous, and undergoes no change by boiling with water or heating to 150°. All the other metallic polyporates are insoluble amorphous precipitates.

Methyl polyporate, $C^9H^6O^2CH^3$, obtained by the action of methyl iodide on silver polyporate, may be crystallised from boiling alcohol of 95 per cent.; it melts at 187°, and is decomposed by heating with potash or ammonia, yielding the corresponding polyporate. The *ethyl ether*, prepared in like manner, melts at 134°.

Acetopolyporic acid, $C^8H^6O^2.C^2H^3O$, is formed when polyporic acid is heated to 150° – 170° in closed tubes, with excess of acetic anhydride. It melts at about 205° .

Polyporic acid is violently acted on by concentrated nitric acid, but the products of the reaction have not yet been fully investigated.

POLYTHIONIC ACIDS. See SULPHUR, OXYGEN-ACIDS OF.

POLYTHYMOQUINONE. See THYMOQUINONE.

POMEGRANATE, ALKALOIDS OF (Tanret, *Compt. rend.* lxxxvi. 1270; lxxxvii. 358; lxxxviii. 716; *J. Pharm.* [4], xxviii. 384). 1. *Pelletierine*, $C^8H^{12}NO$. This base, which appears to be the ténicide principle of the pomegranate, is prepared as follows: The bark of the tree is roughly powdered, and mixed with milk of lime to a thick paste, which is washed with water; the liquid is shaken with chloroform; and the chloroform solution is treated with a dilute acid, whereby a salt of pelletierine is formed, from which the free base may be separated by treatment with potassium carbonate and agitation with chloroform, the resulting solution, when evaporated, leaving the base as a colourless oily mass boiling at about 180° . It may be purified by dissolving it in ether, distilling the ethereal solution in a current of hydrogen, keeping the residue at a temperature from 130° – 140° , until water is no longer given off, and then raising the heat to 180° – 186° , at which the alkaloid begins to distil. It is thus obtained as a colourless liquid, which quickly becomes coloured in the air. Its sp. gr. is 0.999 at 0° , and 0.985 at 21° . It dissolves in water, with contraction, a mixture of 1 pt. of pelletierine and 2.5 pts. of water having a sp. gr. = 1.021 at 21° . The alkaloid is dextrogyrate, its power of rotation $[\alpha] = +8$, and in the form of the pure sulphate +15.9. With potassium dichromate and sulphuric acid it gives a deep green coloration. With hydrochloric acid it fumes like ammonia.

Pelletierine is a mono-acid base, the formula of its hydrochloride being $C^8H^{12}NO.HCl$, and that of its sulphate $(C^8H^{12}NO)^2H^2SO^4$. Its salts are very hygroscopic, pure white when crystallised in dry air, otherwise coloured; they have a faint odour of the base, easily become acid, and have a bitter and aromatic taste.

2. Pomegranate bark contains three other volatile alkaloids, which may be separated in the following manner. The powdered bark is mixed with milk of lime and treated with water; and the solution is shaken with chloroform, which in its turn is shaken with a dilute acid. A solution containing a mixture of the alkaloids is thus obtained, which is dextrogyrate, lævogyrate, or inactive, according to the bark used. To separate these alkaloids, the solution is treated with sodium bicarbonate and saturated with carbonic anhydride; it is then shaken with chloroform, and the latter with dilute sulphuric acid. This solution, which is dextrogyrate, contains the sulphate of a dextrogyrate liquid alkaloid and of an inactive solid alkaloid.

By treating the solution in a similar manner, but using caustic soda instead of sodium bicarbonate, a lævogyrate solution is obtained, which, after evaporation in a vacuum over sulphuric acid, leaves a crystalline sulphate of a lævogyrate liquid base, and an uncrystallisable sulphate of an inactive base. These may be separated by filtration. The active sulphate possesses the rotatory power $[\alpha]_D = -30^{\circ}$.

Crystalline Base.—By decomposing with an alkali the dextrogyrate solution above described, treating the product with chloroform, and evaporating off the latter, crystals are obtained, which may be purified by recrystallisation. From an aqueous solution, prismatic crystals are deposited, having the formula $C^8H^{12}NO + 4H^2O$. The hydrated base melts at 46° , but can be cooled to 37° without solidifying. It boils at 246° , and is soluble in alcohol, ether (9 pts. at 10°), water (2.5 at 10°), and chloroform, which extracts it from its aqueous solution. It is a strong base, expelling ammonia from its salts, and precipitating alumina, baryta, and lime, but not magnesia. It gives all the characteristic reactions for the alkaloids, and with sulphuric acid and potassium dichromate gives, like pelletierine, a deep green colour.

The *hydrochloride*, $C^8H^{12}NO.HCl$, crystallises in rhombohedrons, and is soluble in its own weight of water at 10° . The *sulphate*, $C^8H^{12}NO.HSO^4 + 4H^2O$, crystallises with 4 mols of water, which it loses over sulphuric acid. At 10° it is soluble in less than twice its weight of water. The *platinochloride* $(C^8H^{12}NO.HCl)_2.PtCl_4$, crystallises in reddish-yellow needles.

A base called *granatine* is mentioned by Durand (*J. Pharm.* [4], xxviii. 168) as obtained from dried pomegranate bark which had been kept for a year.

POONAHLITE. A variety of scolecite occurring, together with apophyllite, in melaphyre-conglomerate, at Poonah in India. Its analysis (A) agrees with the scolecite formula, $CaO.Al^2O^3.3SiO^2 + 3H^2O$ (B).

	SiO ²	Al ² O ³	CaO	Na ² O	K ² O	H ² O
A.	46.91	26.03	13.33	0.22	0.08	13.83 = 100.40
B.	45.80	26.21	14.25	—	—	13.74 = 100

(Petersen, *Jahrb. f. Min.* 1873, 852).

POPLAR. The buds of several species of poplar yield by distillation a volatile oil, the greater part of which boils at 260°–261°, and agrees in composition with the formula C^8H^8 (Picard, *Ber.* vi. 1160).

On *Chrysin* and *Methyl-chrysin*, or *Tecto-chrysin*, obtained from poplar buds, see p. 465 of this volume. *Populin* and *Salicin* have also been obtained from these buds (Picard).

POPPY. According to Hesse (*Lieb. Ann.* clxxxv. 329), the milky juice of the unripe capsules of the red poppy (*Papaver Rhæas*) leaves on evaporation about 34 per cent. of dry matter, in which no trace of morphine or any similar alkaloid can be detected. It contains, however, 2.1 per cent. *rhæadine*, and traces of other partially crystallisable alkaloids.

The composition of the ash of poppy-petals has been determined by C. J. Warden (*Chem. News*, xxxiv. 27) with the following results, after deduction of CO_2 , sand and charcoal:

K ₂ O	KCl	NaCl	CaO	MgO	Fe ² O ³	Al ² O ³	SiO ²	P ₂ O ₅	SiO ²
41.76	12.29	1.21	10.72	5.61	3.86	1.23	3.85	5.61	13.86 = 100

On *Respiration in the Ripening Fruits of the Poppy*, see PLANTS (p. 1640).

PORCELAIN. Remarks on the structure of porcelain have been made by H. Behrens (*Pogg. Ann.* cl. 386). He considers that, in the firing of porcelain, only the quartz-grains in the mixture remain unaltered, whilst all the other constituents are fused at the high temperature of the furnace, and partly yield products of devitrification. The translucent Japanese porcelains have essentially the same quantitative composition as the European, but the undecomposed vitreous mass predominates in them.

According to Salvétat (*Moniteur de la Céramique*, 1873, No. 11; *Dingl. pol. J.* ccix. 468), porcelain is so porous that its entire mass may be coloured by prolonged contact with the solution of a colouring matter. Porcelain which had stood for some days with its unglazed foot in a solution of fuchsine, exhibited in reflected light the white colour of the glaze, but appeared of a fine red by transmitted light.

On the preparation and composition of Japanese porcelain, see H. Wurtz (*Amer. Chemist*, vii. 218). On the history and manufacture of Chinese porcelain: A. Heintz (*Dingl. pol. J.* ccxxi. 156).

PORPHYRY. The porphyries of Lake Lugano have been examined by B. Studer (*Jahrb. f. Min.* 1875, 881). The following are analyses of a red porphyry (A) and a black porphyry (B) from the railway-tunnel near Maroggia: 1. Analyses by Schwarzenbach. 2. By v. Fellenberg. 3. The same, corrected, after deduction of bases (as carbonates) extractable by cold acids.

	SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	MnO	K ² O	Na ² O	X ⁽¹⁾	Y ⁽²⁾

(¹) Water or Loss by Ignition.

(²) Carbonates.

Sp. gr. according to v. Fellenberg: A = 2.645; B = 2.6598 at 15°.

The mineralogical composition of these porphyries has been calculated by v. Fellenberg from his own analyses, with the following results: 1. With the carbonates; 2. After deduction thereof.

	A 1.	A 2.	B 1.	B 2.
Orthoclase	33.78	35.67	59.21	61.03
Oligoclase	27.01	28.53	30.35	31.29
Quartz	30.76	32.39	—	—
Magnetic Iron oxide	—	—	6.22	6.41
Ferric oxide	2.40	2.53	—	—
Water	0.93	0.98	1.23	1.27
Carbonates	5.31	—	4.44	—
	100.19	100	101.45	100

The following are analyses of porphyry from various localities: (1-5) from the Vicentine (A. v. Lasaulx, *Min. Mitth.* 1873, 70): 1. *Non-quartziferous Porphyry* from Pieve. Sp. gr. 2·59. (2). *Porphyrite* from the Guizzo di Schio. Sp. gr. 2·67. (3). *Porphyry* from Fongara. The indurated argillaceous ground-mass contains feldspar and mica, but no quartz. Sp. gr. 2·586. (4). Decomposed rock from the Rasta del Recoaro, probably a decomposition-product of No. 3. Sp. gr. 2·589. (5). *Pitchstone-porphyry* from La Rasta. Sp. gr. 2·466.

(6-8). From the neighbourhood of Roanne, Loire, France (A. Guyardet, *Bull. Soc. Chim. geol.* [3], i. 499). 6. *Porphyry* from Saint-Just-en-Chevalet. The orthoclastic ground-mass encloses large orthoclases, small oligoclases, black mica, and very frequently lamellæ of a green talc (pinitoid?). Sp. gr. 2·23. 7. *Porphyry* from Boen-sur-Lignon. The feldspathic ground-mass (probably oligoclase) encloses oligoclase, numerous black micas, talc (pinitoid), and rarely quartz crystallised in double pyramids. Sp. gr. 2·85. 8. Grey porphyritic *Eurite* from La Bombarde near St. Romain d'Urfé. The ground-mass, probably anorthite, encloses anorthite, oligoclase, hornblende, and quartz. Sp. gr. 2·17.

9. From Rockhampton in Queensland (Daintree, *Geol. Soc. Qu. J.* xxviii. 271). 10. *Hornstone-porphyry* of the Salband from the vein in the Kestenthalrücken in the Harz. Sp. gr. 2·697-2·701. 11. Rock resembling *granite-porphyry* from the middle of the vein. Sp. gr. 2·68 (Lossen, *Zeitschr. geol. Ges.* 1874, xxvi. 866).

12. *Granite-porphyry* from Beucha, near Leipzig. 13. The same from Altenberg, in the Erzgebirge (Baranowski, *Zeitschr. geol. Ges.* xxvi. 522).

(14-15). *Porphyry* from Muldenstein, between Bitterfeld and Jessnitz (E. Reichardt, *Arch. Pharm.* [3], v. 310). 14. Solid rock, greyish-white, with rusty spots on the fractured surfaces. 15. The same weathered and easily crumbled.

(16, 17). From South Tyrol (C. v. Hauer, *Ver. geol. Reichsanst.* 1875, 331). 16. *Red orthoclase-porphyry* from the Canzocoli, near Predazzo. 17. The same from Carnon, near Predazzo.

18. *Mica-porphyry* from Rohrbach, in the Black Forest of Baden. The dense ground-mass encloses specks of blackish-green mica. 19. *Hornstone-porphyry* from Kesselberg, in the Black Forest; analysis by F. Geremont: *a.* Total analysis; *b.* Portion soluble in hydrochloric acid. 20. *Porphyritic rock* near St. Märgen, in the Black Forest; analysed by E. Meisinger: *a* and *b* as above (Vogelgesang, *Jahresb. f. Chem.* 1873, 1218).

(¹) Loss by ignition.

(²) Water: 0·725 combined; 0·300 hygroscopic.

The granitic porphyrites of Saxony, occurring near Altenberg in the Erzgebirge, near Beucha, in the neighbourhood of Leipzig, and on the Tammelberg, have been described and analysed by Baranowski (*Jahrb. f. Min.* 1875, 199). The ground-mass of these porphyries, which are perfectly identical, consists of separate grains of quartz, feldspars, hornblende, and chlorite, associated with magnetic iron oxide and apatite. Among the microscopic constituents, quartz and feldspar are especially abundant. The occurrence of quartz in the pyramidal form in the granular ground-mass is characteristic of the granite-porphyries. The quartz is further distinguished by the numerous microscopic enclosures, partly vitreous, partly liquid, which it contains. The large crystals of orthoclase are accompanied by small plagioclases. Especially remarkable is the occurrence of vitreous particles, enclosed in the feldspars, inasmuch as such enclosures, though known to occur in the feldspars of trachyte and quartz-porphyry, have not hitherto been observed in granites. Hornblende and chlorite

must also be enumerated as essential constituents of the granite-porphyrries. The chlorite is evidently a transformation-product of the hornblende, inasmuch as crystals are found, consisting of a layer of chlorite enclosing a nucleus of hornblende. Magnetic iron oxide appears in thin sections of the rocks in small isolated octohedrons, more frequently in granules irregularly distributed through the mass. Lastly, the presence of apatite is remarkable, since this mineral has hitherto been found more frequently in basic rocks than in those which are rich in quartz.

The following are analyses of two granitic porphyries: *a*, from Beucha; *b*, from Altenberg:

	SiO ^a	Al ^a O ^a	Fe ^a O ^a	CaO	MgO	K ^a O	Na ^a O	H ^a O
<i>a.</i>	66.3	15.4	7.0	2.3	1.5	4.4	3.5	0.8 = 101.2
<i>b.</i>	67.1	12.1	8.7	2.5	1.6	5.3	2.4	0.6 = 100.3

A microscopic examination of the porphyrites of Ilefeld by A. Streng (*Jahrb. f. Min.* 1875, 623) shows that these rocks are composed of a fine-grained ground-mass consisting of orthoclase, plagioclase, small quantities of hornblende and quartz, magnetic iron oxide, a small quantity of apatite, sometimes also graphites, titanite iron and specular iron, or pyrolusite, and enclosing porphyritically separated plagioclase, hornblende (often apparently formed from augite), quartz, titanite iron, graphite, magnetic iron oxide, and accessorially garnet, more rarely iron pyrites. These porphyrites, therefore, are intermediate between the quartz-porphyrries and the melaphyres (p. 1272).

POSIDONIA OCEANICA. This plant, used as manure, has been examined by F. Sestini (*Gazz. chim. ital.* 1874, 182). The air-dried plant was found to contain:

Water	Fats	Proteids	Carbohydrates	Mineral substance
26.15	2.55	3.77	61.26	6.27 = 100

The ash contains:

K ^a O	Na ^a O	CaO	MgO	Fe ^a O ^a	SO ^a	P ^a O ^a	SiO ^a *	Cl, I, &c.
4.07	8.61	36.89	14.50	7.62	3.05	2.54	20.86	1.84 = 99.98

* And other substances insoluble in hydrochloric acid.

POTASSIUM. According to Dolbear (*Chem. News*, xxvi. 33) and Kern (*Ber.* vi. 1208), this metal may be obtained by igniting its sulphide with iron-turnings.

Vapour-density.—Experiments by Dewar and Dittmar (*Proc. Roy. Soc.* xxi. 203) have shown that the vapour-density of potassium at the temperature of melting zinc does not exceed 45 [*H* = 1]. Consequently the molecule of potassium contains two atoms.

Reactions serving to distinguish Potassium from Sodium.—These metals may be distinguished from one another by their reaction with bromine. Sodium may be kept in bromine for months and even for years without perceptible alteration, and is but slightly corroded when heated therewith to 100°–200°, whereas potassium when thrown into bromine immediately takes fire, producing a violent explosion which often shatters the containing vessel. In like manner, sodium may be fused with iodine, without notable reaction, but potassium, when fused with iodine, explodes and flies to pieces in a jet of fire. Sodium immersed in aniline, even at the boiling heat, remains quite bright, while any crusts that may have formed upon its surface fall off, leaving it with the most splendid metallic lustre; potassium, on the other hand, reacts violently with aniline (Merz and Weith, *Ber.* vi. 1518).

Estimation of Potassium.—F. Mohr (*Zeitschr. anal. Chem.* 1873, 137) heats the precipitate of potassium chloroplatinate to fusion with twice its weight of sodium oxalate, and after washing and neutralisation with acetic acid, titrates with decinormal silver solution.

To avoid the troublesome employment of a weighed filter for collecting the precipitate of potassium chloroplatinate, Fresenius (*ibid.* 1877, 63) collects the precipitate in the ordinary way; transfers it when dry to a watch-glass; dissolves the small portion of the salt which adheres to the filter in a little hot water; evaporates the solution to dryness in a platinum capsule; then adds the rest of the salt; and dries the whole at 130°. It is absolutely necessary to test the potassium chloroplatinate as to its purity; when precipitated from solutions containing alkaline earths, it is sure to be impure. See also G. Krause (*Arch. Pharm.* [3], v. 407; *Jahresb. f. Chem.* 1874, 978).

Schloesing's method of estimating potassium by means of soluble perchlorates (vii. 1006) has been subjected to an experimental examination by Kraut, Ortmann, and Küsel (*Zeitschr. anal. Chem.* 1875, 152), who have arrived at the following

results. Instead of using ammonium perchlorates and nitrohydrochloric acid, it is preferable to treat the potassium salt under examination with an excess of pure distilled perchloric acid, and evaporate the mixture to dryness on the water-bath. The cooled residue is treated with alcohol of sp. gr. 0.835 to remove the free acid, then dissolved in hot water, the solution again evaporated on the water-bath, and the residue transferred by washing with alcohol of the same strength, to a filter previously weighed and moistened with alcohol. The presence of salts of sodium, barium, and other bases does not interfere with the result.

For the detection of small quantities of potassium in mixtures, A. Carnot (*Compt. rend.* lxxxiii. 290, 338) makes use of a mixture of 1 pt. *basic bismuth nitrate* and about 2 pts. crystallised *sodium thiosulphate*. A solution of this mixture colours solid potassium salts yellow, and forms with potassium solutions a yellow precipitate consisting of a thiosulphate of bismuth and potassium, $\text{Bi}^2(\text{S}^2\text{O}^3)^3 \cdot 3\text{K}^2\text{S}^2\text{O}^3 + 2\text{H}^2\text{O}$. The reaction is extremely delicate, and may be used for the quantitative estimation of potassium if in the state of nitrate or chloride; sulphates, if present, must be first converted into chlorides. To perform the analysis, the potassium salt is strongly concentrated, and mixed with $2\frac{1}{2}$ pts. *basic bismuth nitrate* (equiv. to 2 pts. bismuth), and 7 pts. crystallised sodium thiosulphate for every 1 pt. of potassium hydrate supposed to be present in the solution; the mixture is then quickly stirred, and 250 c.c. of strong alcohol poured upon it. After a quarter of an hour, the yellow precipitate is collected on a filter and carefully washed with alcohol. The quantity of potassium present may then be estimated by converting the bismuth in the precipitate into sulphide, weighing it in that form, and calculating the potassium from the formula above given.

In subsequent communications (*Compt. rend.* lxxxiv. 1504; lxxxv. 301) Carnot gives the following modification of the method for solutions containing sulphuric acid. The concentrated liquid is mixed with a solution of *calcium thiosulphate*, and a sufficient quantity of the bismuth solution; alcohol is added; and the resulting precipitate, a mixture of calcium sulphate and bismuth-potassium thiosulphate, is collected on a filter. On treating this precipitate with water, the bismuth-salt is dissolved, together with a small quantity of gypsum. The bismuth is then determined as above, and the potassium calculated therefrom.

The method of precipitation as bismuth-potassium thiosulphate serves admirably for the quantitative separation of potassium from many metals, e.g. sodium, lithium, ammonium, calcium, magnesium, aluminium, manganese, iron (as ferric salt), &c., inasmuch as, with the exception of the chlorides of barium, strontium, and those metals which are precipitated by hydrogen sulphide, no metallic chlorides give with bismuth salts and sodium thiosulphate a precipitate like that above mentioned.

P. Casamajor (*Chem. News*, xxxiv. 231, 242) estimates potassium volumetrically in the form of *acid tartrate*. The method is especially applicable to technical purposes. To separate the salt more effectually, the liquid is mixed with alcohol in such quantity as to form about 60 per cent. of the whole. If the potash is combined with strong acids, an excess of sodium acetate is added. The presence of sodium salts does not interfere with the attainment of accurate results. The acid tartrate may also, but less advantageously, be determined gravimetrically.

To separate potassium from a large excess of sodium salts, R. H. Loughridge mixes the nitrates of the two alkali-metals with *oxalic acid*, evaporates at 100° , whereby they are converted into acid oxalates, and treats the mixed salts with a small quantity of water, which dissolves the potassium oxalate, leaving the much less soluble sodium oxalate undissolved. The whole of the potassium salt is thus obtained in solution, together with only a small quantity of sodium salt, and the separation may then be completed by precipitating the potassium as chloroplatinate (*Amer. Chemist*, iii. 369).

Potassium Fluoride. This compound unites with *chromic anhydride*. On boiling a strong solution of potassium dichromate with hydrofluoric acid, octohedral and-cubical crystals are obtained, having the composition $\text{KF} \cdot 2\text{CrO}^3$. This salt may be recrystallised from a small quantity of water, but is decomposed by a large excess. The crystals are efflorescent and attack glass. They are decomposed by sulphuric acid, with liberation of hydrofluoric and chromic acids. Treated with alkalis, they yield potassium fluoride and chromate (*L. Varenne, Compt. rend.* lxxxix. 358).

Iodide. G. Langbein (*Ber.* vii. 765) recommends the use of cuprous iodide, now largely imported from Peru, for the preparation of potassium iodide. The cuprous iodide is washed, suspended in water in the form of fine powder, and decomposed by hydrogen sulphide, and the resulting solution of hydriodic acid, freed from excess of hydrogen sulphide by addition of iodine, is neutralised with normal or acid carbonate of potassium. To prepare potassium iodide having a perfectly neutral reaction, T. B. Groves (*Pharm. J. Trans.* [3], iv. 669) dissolves the commercial salt, which

mostly has an alkaline reaction, in the exact quantity of water required, neutralises it with sulphuric acid, and throws down the potassium sulphate with alcohol. The decanted liquid, when evaporated, yields perfectly pure colourless crystals of potassium iodide.

A process for preparing potassium iodide free from iodate is given by G. Pellagri (*Ber.* viii. 1857), depending on the fact that the iodate in dilute solution is reduced by agitation with iron filings or zinc-powder (not by copper or tin) whilst the metal is directly oxidised. Agitation with iron filings in a warm solution produces complete reduction, without dissolution of the iron or transference of the iodine to the precipitate. If the solution is too concentrated, and a considerable quantity of ferric oxide has been formed, this oxide may exert an oxidising action on the potassium iodide. When an iron and a copper plate are immersed in a strong solution of potassium iodate, and connected externally by a wire, so as to form a galvanic couple, complete reduction takes place even at ordinary temperatures. Under these circumstances, only the iron is oxidised, and, the surface being small, the reduction takes several days to complete. No contamination of the product or loss of iodine takes place. Zinc-powder acts more energetically than iron filings, but for complete reduction a zinc-copper couple is necessary. *Potassium bromate* is completely reduced to bromide by an iron-copper couple; the *chlorate* very slowly and incompletely to chloride; but, by agitation with iron filings in a warm solution, this salt is quickly reduced. The formation of potassium iodate by the action of iodine on potash-solution is not prevented by the presence of suspended iron filings.

Polyiodides. A *tri-iodide*, KI^3 , is obtained, by slowly evaporating a saturated solution of iodine in potassium iodide over sulphuric acid, in shining, dark-blue, prismatic crystals, often 2 in. long. The crystals are very hygroscopic, and deliquesce completely after a short time to a dark-brown liquid; they dissolve also in alcohol. Their specific gravity, which is difficult to determine, on account of their great tendency to deliquesce, was found, on the average, to be 3.498 at 15°. The salt, when cautiously heated, melts at 45°; at a higher temperature it gives off iodine (1 mol.), and leaves ordinary potassium iodide (G. S. Johnson, *Chem. Soc. J.* xxxi. 249).

To determine whether the true formula of this salt is KI^3 , or a multiple thereof, Johnson (*ibid.* xxxiii. 183) has prepared polyiodides containing two or more different metals. When a solution of silver iodide and potassium iodide in the ratio of 1 mol. AgI to 1 mol. KI is mixed with iodine, a precipitate is formed, long before sufficient iodine has been added to form the compound $AgKI^3$, consisting of silver iodide, which may be redissolved by simply adding fresh quantities of potassium iodide. It is only when the iodides of silver and potassium and free iodine have been brought together in the proportion to form the compound AgK^2I^{12} that a clear solution is formed, which, on spontaneous evaporation, first deposits crystals of potassium-silver iodide, then of potassium tri-iodide, and finally crystals of a potassium-silver polyiodide having the composition $AgK^2I^{12}.KI + 5H^2O$. These crystals are mostly black and have a peculiar lustre; they are very deliquescent, but, nevertheless, effloresce over sulphuric acid. In attempting to prepare the corresponding potassium-thallium polyiodide, TlK^2I^{12} , Johnson obtained only the polyiodide discovered by Wilm (v. 751), which, in accordance with Wilm, he finds to be represented by the formula $TlKI^4$, and not by $Tl^2K^2I^8 + 3H^2O$, as stated by Rammelsberg (vii. 1151); Johnson is, however, of opinion that it contains 2 mols. H^2O . Lastly, Johnson has examined the precipitate formed on adding an iodised solution of potassium iodide to lead acetate, and finds it to be represented by the complex formula $Pb^2C^2H^2O^{28}K^2I^{17}$.

Hydride, K^2H . Fused potassium begins to absorb hydrogen at a temperature above 200°, the absorption becoming more rapid between 350° and 400°. The product obtained by keeping the metal in the gas for a long time is very brittle, has the aspect, lustre, and crystallo-granular structure of silver-amalgam, and indeed looks very much like a true alloy. It may be fused without alteration in hydrogen or in a vacuum. In contact with the air it immediately takes fire. When heated in a vacuum at 200° it begins to decompose, and from that temperature to 430° a regular dissociation takes place; in an atmosphere of hydrogen the decomposition takes place at 411°. The analysis of this compound gave 126 vols. H to 1 vol. K; the formula K^2H (which is of course only empirical) requiring 124.6 vols. H to 1 vol. K (Troost and Hautefeuille, *Ann. Chim. Phys.* [5], ii. 273).

Oxides (S. Lupton, *Chem. Soc. J.* xxx. 565). Potassium heated in air at about 65° for six hours is oxidised to a greenish powder mixed with small blue and yellow lumps. The blue lumps when separated were found to have the composition $K^2O^3 = 3K^2O + K^2O^2$. After the action had been continued for six hours more, the blue lumps gave numbers agreeing with the formula $K^4O^3 = K^2O + K^2O^2$. Similar blue lumps obtained with nitrogen monoxide as the oxidising agent, were found to consist of $K^2O^4 = 2K^2O + K^2O^2$. From these results it is probable that the blue oxide, which forms on a freshly-cut surface of potassium, is not a suboxide, as commonly

supposed, but a molecular compound of the monoxide and dioxide of potassium in various proportions, and that the grey oxide $K'O$ (theoretically improbable) described by Berzelius, must have contained metallic potassium. The yellow lumps, when likewise picked out, were found to have the composition of potassium dioxide. The green powder was found to contain a quantity of potassium greater than that required by the formula of that oxide, and appears to be a mixture of the dioxide with the blue oxides, but after fusion in a porcelain crucible it has exactly the composition of the dioxide $K'O^2$. When a platinum crucible lined with gold is used, the oxidation proceeds still further, oxides being formed which contain from 66 to 68 per cent. potassium. The dioxide is likewise obtained when potassium is heated for a considerable time in nitrogen monoxide. These results fully establish the existence of a dioxide of potassium, the occurrence of which in aqueous solution was pointed out by Harcourt in 1861 (iv. 706).

The following reactions of the green mixture are worthy of notice. When it is treated with hydrochloric and sulphurous acids, a certain quantity of sulphate is formed. With absolute alcohol it yields a yellow flocculent precipitate, which dissolves very slowly. Heated on a carbon boat in a stream of nitrogen, it assumes a yellow colour changing to orange-red, glows at the moment of fusion, and yields a speculum of metallic potassium, together with carbonate: $3K'O^2 + C^2 = K^2 + 2K'CO^2$. Heated with magnesia in a stream of nitrogen, it forms at first an orange-coloured viscid mass, which melts at a higher temperature, then suddenly gives off nitrogen, and is converted into a white mass—a reaction which appears to depend on the formation, in the first instance, of magnesium dioxide, which is then resolved at a higher temperature into magnesia and oxygen. When the brownish-yellow dioxide is exposed to moist air, it becomes continually lighter in colour, the lemon-yellow trioxide $K'O^3$ being first formed, then the sulphur-yellow tetroxide $K'O^4$, which is again converted into trioxide, and finally into hydroxide. Attempts to prepare a definite oxide by heating potassium nitrate did not yield satisfactory results.

POTATO. *Solanum tuberosum*.—A series of investigations of the amounts of starch and dry substance in potatoes of various kinds has been made by L. Raab (*N. Jahrb. Pharm.* xxxvii. 204; xxxix. 15), showing that the proportion of starch varies from 8·8 to 26 per cent., and that of dry substance from 15·6 to 34 per cent.

Solanine in Potatoes.—According to O. Bach (*J. pr. Chem.* [2], vii. 248), solanine is found in sprouted potatoes only in the rind and at the roots of the sprouts. In the water, either fresh or salt, poured off from the boiled potatoes, the presence of solanine could be detected only by evaporating very large quantities.

Ash.—The ash of three sorts of potato has been analysed by J. B. Haunay (*Chem. News*, xxvii. 147). No. 1. Healthy potatoes from black dry soil gave 3·8 per cent. ash. No. 2. Diseased potatoes from the same soil, unfit for food, either for man or beast, gave 3·9 per cent. No. 3. Less diseased, from a loamy soil.

	No. 1.	No. 2.	No. 3.
<i>Soluble:</i>			
Potassium	36·77	37·86	43·11
Sodium	3·24	3·12	0·68
Magnesium	1·87	—	0·04
Carbonic anhydride	15·83	15·57	15·45
Phosphoric „	8·37	6·90	5·55

A. S. Wilson (*Chem. News*, xxviii. 91) found the ash of diseased potatoes to be composed as follows:

K	Na	Mg	Ca	P ² O ⁵	SO ³	CO ²	Cl	Fe ² O ³	SiO ²	O
44·51	0·25	2·36	1·12	1·48	5·57	15·80	1·37	0·53	2·89	11·22 = 100·10

The following table of the relations between the amount of starch in potatoes and their specific gravity has been drawn up by F. Heidepriem (*Landw. Vers.-St.* xx. 1) from the results of experiments made in 1875 by the Agricultural Society of Cöthen.

Relations between the amount of Starch in Potatoes and the Specific Gravity.

Weight of 5 kilograms under water	Starch per cent.	Dry substance per cent.	Weight of 5 kilograms under water	Starch per cent.	Dry substance per cent.
630	25.07	32.29	455	15.97	23.19
625	24.81	32.03	450	15.71	22.93
620	24.55	31.77	445	15.45	22.37

475	17.01	24.23	300	7.91	15.13
470	16.75	23.97	299	7.65	14.87
465	16.49	23.71	290	7.39	14.61
460	16.23	23.45	285	7.13	14.35

Similar determinations have been made by A. Marke (*Dingl. pol. J.* ccxxv. 517), who found the specific gravity to vary between 1.108 and 1.120; the total dry substance between 28.36 and 31.36 per cent., and the starch between 20.61 and 23.52 per cent.

Effect of Cooking on the Nutritive Power of Potatoes.—P. Wagner a. K. Schafer (*Ber. v. Landw.-Versuchsst., Darmstadt, 1874*) have endeavoured to determine what mode of cooking potatoes is attended with the greatest loss of nutritive salts. For this purpose, they boiled peeled and unpeeled potatoes for three-quarters of an hour in quantities of water just enough to cover them, and at the same time steamed samples of the same potatoes in a tin-plate sieve fixed in the boiler above the water. The following are the results:

1 kg. unpeeled potatoes contained .	Ash	K ² O	P ² O ⁵
1 kg. „ peeled „ „ .	7.70 g.	4.30 g.	1.79 g.
	7.45	3.75	1.53

	The boiled water poured off from 1 kg. potatoes contained in grams:			Hence the potatoes lost, in 100 parts of their original contents		
	Ash	K ² O	P ² O ⁵	Ash	K ² O	P ² O ⁵
1. Unpeeled potatoes boiled in water	0.28	0.10	0.02	3.64	2.52	1.12
2. Unpeeled potatoes steamed .	0.09	0.03	0.005	1.17	0.69	0.03
3. Peeled potatoes boiled in water .	2.15	1.25	0.35	28.86	33.33	22.87
4. Peeled potatoes steamed .	0.55	0.26	0.07	7.38	6.93	4.57

For unpeeled potatoes, therefore, the loss of nutritive salts in boiling and steaming is but small; but for peeled potatoes, steaming has decidedly the advantage over boiling.

PREDAZZITE. This name was originally given to a mineral from Predazzo, in South Tyrol, supposed to be a definite compound of calcite and brucite, MgH^2O^2 (iv. 714). Microscopical observation, however, shows that it is merely a mixture of these two minerals, the particles of which may be separately distinguished; moreover, Lemberg has shown that when a cut plate of predazzite is heated nearly to redness, and then immersed in solution of silver nitrate, the particles of brucite (converted by the heat into MgO) are blackened by separation of silver oxide, while those of calcite remain white (Rammelsberg, *Mineral-Chemie*, 2 Auflage, 1875, ii. 242).

The mineral from Predazzo having thus been shown to be a mixture, A. Cossa (*Gazz. chim. ital.* 1877, 393) proposes to transfer the name *Predazzite* to the rock of Monte Somma, also a mixture of calcite and brucite, which forms the matrix of periclase. Analyses of this rock gave:

CO^2	CaO	MgO	FeO	H^2O	Sp. gr.
36.21	43.56	12.81	0.12	5.23 =	2.857
39.45	45.02	11.28	0.32	4.37 =	to
40.28	45.73	9.22	0.41	3.97 =	2.903

PREHNITIC ACID, $\text{C}^6\text{H}^2(\text{CO}^2\text{H})^4$, is formed, by separation of 6 at. hydrogen and 2 mols. CO^2 , when hydromellitic acid, $\text{C}^6\text{H}^6(\text{CO}^2\text{H})^6$, is heated with strong sulphuric acid (vi. 809). Prehnitic anhydride, $\text{C}^6\text{H}^2(\text{CO}^2\text{H})^2\text{C}^2\text{O}^2\text{O}$, is formed by the action of heat on prehnitic acid (vii. 785).

PRICHITE. See CRYPTOMORPHITE (p. 589).

PROPANE, $\text{C}^3\text{H}^8 = \text{CH}^3.\text{CH}^2.\text{CH}^3$. This hydrocarbon is formed, together with several others of the paraffin series, by the action of superheated steam on the distillation-products of the fatty acids. The crude product is agitated with strong sulphuric acid, and the oil which floats on the surface of the acid is treated with sodium carbonate, dried, and rectified (Cahours a. Demarçay, *Compt. rend.* lxxx. 1568).

Chloro- and Bromo-propanes.

Dichloropropanes, or Propylene Dichlorides, $\text{C}^3\text{H}^4\text{Cl}^2$ (Reboul, *Ann. Chim. Phys.* [5], xiv. 453). *α*-Dichloropropane, $\text{CH}^3.\text{CCl}^2.\text{CH}^3$, is generally prepared by the action of phosphoric chloride on acetone, but may also be obtained by direct combination of HCl with allylene. It boils at 69° – 70° , is converted by alcoholic potash into the chloropropylene, $\text{CH}^2=\text{CCl}.\text{CH}^3$, boiling at 23° – 25° , and by silver benzoate into the di-benzoic compound, $\text{CH}^3.\text{C}(\text{C}^6\text{H}^5\text{O}^2)^2.\text{CH}^3$.

β-Dichloropropane, $\text{CH}^3.\text{CH}^2.\text{CHCl}^2$, is prepared by the action of phosphoric chloride on propaldehyde, but a considerable quantity of the chloropropylene, $\text{CH}^3.\text{CH}=\text{CHCl}$, is formed at the same time. Its boiling point is 85° – 87° , and its density 1.143 at 10° . With alcoholic potash it yields the chloropropylene just mentioned, which at a higher temperature (130°), under the influence of the same reagent, is converted into allylene, $\text{CH}^2.\text{C}=\text{CH}$. It yields no diacetyl compound when treated with potassium acetate.

γ-Dichloropropane, $\text{CH}^3.\text{CHCl}.\text{CH}^2\text{Cl}$.—The action of HCl on allyl chloride, $\text{CH}^2=\text{CH}.\text{CH}^2\text{Cl}$, does not yield, like that of HBr on the bromide, a mixture of the two chloro-compounds, but only the *γ*-dichloropropane. Allyl chloride is heated for eighteen hours at 100° , with very concentrated hydrochloric acid, and the upper layer of the product, which is of a violet-black colour, is separated and submitted to fractional distillation. The greater part of it consists of ordinary or *γ*-dichloropropane, boiling at 96° – 97° . The difference (22°) between the boiling points of the symmetrical and unsymmetrical dichloropropanes is the same as the difference between those of the corresponding dibromopropanes.

δ-Dichloropropane, or Trimethylene chloride, $\text{CH}^2\text{Cl}.\text{CH}^2.\text{CH}^2\text{Cl}$, may be obtained from the corresponding dibromide by heating it with mercuric chloride in sealed tubes at 180° for several hours, or by treating symmetrical propyl glycol with HCl . In the latter case, a monochlorhydrin of the glycol, $\text{CH}^2(\text{OH}).\text{CH}^2.\text{CH}^2\text{Cl}$, is formed at the same time. The two compounds are, however, easily separated, since the dichloropropane boils at 119° , and the monochlorhydrin at 162° . The density of the dichloropropane is 1.201 at 15° .

Dibromopropanes, or Propylene Dibromides. *α*-Dibromopropane, $\text{CH}^3.\text{CBr}^2.\text{CH}^3$.—It appears to be almost impossible to prepare this body by the action

of PBr^3 on acetone, but it can be easily prepared by the direct addition of HBr to allylene, or to α -bromopropylene. When hydrobromic acid of not less than 66°B. is added to allylene enclosed in a vessel over mercury, the absorption of the gas is complete in about four or six hours at 0° , and by replacing the gas as it is absorbed, very considerable quantities of the dibromide can be obtained. The product is, however, contaminated with a little α -bromopropylene, from which it can be readily separated by a few distillations.

The action of HBr on α -bromopropylene also gives a very pure product; but it is more convenient to work upon the mixture of propylenes given by ordinary dibromopropane in the manner which will be described under β -bromopropylene (p. 1679). The density of α -dibromopropane at 10° is 1.875, and its boiling point 114° – 114.5° under 740 mm.

β -Dibromopropane, $\text{CH}^3.\text{CH}^2.\text{CHBr}^2$.—Although the existence of this bromide can be shown independently of theoretical considerations, it has never been satisfactorily isolated. The action of PBr^3 on propyl aldehyde closely resembles the corresponding action on acetone; torrents of HBr are evolved from the commencement of the operation, but as soon as distillation is proceeded with, the liquid turns black, evolves more HBr , and leaves finally an abundant carbonaceous residue. From the distillate, after the removal of phosphorus oxybromide, a little β -bromopropylene can be separated, but no β -dibromopropane can be obtained. The operation is not more successful when the oxybromide is removed by means of water, without previous distillation.

By combining HBr with the bromopropylene, $\text{CH}^3.\text{CH}=\text{CHBr}$, in the cold, the two dibromopropanes are simultaneously produced. Fractional distillation, however, fails to separate them, on account of the proximity of their boiling points. On submitting the washed and dried liquid to distillation, the boiling point quickly rises to 135° , and the whole passes over between 135° and 143° , the greater portion distilling between 139° and 140° . The boiling point of the β -compound should be 131° – 133° , while that of the ordinary or γ -dibromopropane, $\text{CH}^3.\text{CHBr}.\text{CH}^2\text{Br}$, is 143° (vii. 1017). The same result is obtained if the combination of HBr with the bromopropylene takes place at 100° .

δ -Dibromopropane, or *Trimethylene bromide*, $\text{CH}^2\text{Br}.\text{CH}^2.\text{CH}^2\text{Br}$.—The action of HBr on allyl bromide forms simultaneously two isomerides, the normal or δ -dibromopropane and the ordinary or γ -dibromopropane. The relative proportion of the two bromides varies with the concentration of the acid, with the temperature, and with the duration of the action. The best method of operating is as follows: 1 vol. of allyl bromide and $3\frac{1}{2}$ vols. of fuming hydrobromic acid are heated under pressure at 100° for fifteen to twenty minutes, and the dark-coloured oily product subsequently washed and distilled. A good deal of unaltered allyl bromide passes over first, and then the thermometer rapidly rises to 140° – 145° . The distillate is collected from this point up to 175° . On submitting this portion to repeated fractional distillation, the δ -dibromopropane can be easily separated, boiling at 164° – 165° , the yield being a little more than one-half the allyl bromide used. If the solution of hydrobromic acid is not saturated, or if the time of heating be prolonged, a largely increased yield of ordinary dibromide is obtained at the expense of the normal or δ -compound; even with a strongly fuming acid, it is not advisable to heat the mixture longer than twenty minutes, for no increased yield of the desired product is obtained. Its density is 1.9839 at 13.5° . It is much more susceptible of double decomposition than the ordinary dibromide, forming with great facility the compound ethers of the corresponding glycol.

According to Erlenmeyer (*Liebig's Annalen*, cxvii. 184), the conditions most favourable to the formation of trimethylene bromide are as follows: (1) Dry hydrobromic acid in large excess should be kept in contact with the allyl bromide until the reaction is ended, and the temperature should be maintained at 30° – 40° ; (2) the more diluted the hydrobromic acid becomes, either by water or by trimethylene bromide, the larger is the quantity of ordinary propylene dibromide formed. When the required dilution has been produced by the formation of trimethylene bromide, the remaining hydrobromic acid unites with allyl bromide to form ordinary propylene bromide, this reaction taking place more quickly at high than at low temperatures; (3) the formation of trimethylene bromide takes place first at temperatures from 0° – 30° , and, in the case of sufficiently concentrated solutions, even at temperatures above 100° . The formation of ordinary propylene bromide commences in dilute hydrobromic acid solutions at low rather than at high temperatures.

Chlorobromopropanes, or **Propylene Chlorobromides**. Five chlorobromopropanes ought theoretically to exist, viz. α , β , and δ , analogous to the chlorides and bromides α , β , and δ , and two others, γ and γ' , analogous to the chloride γ .

α-Chlorobromopropane, $\text{CH}^3.\text{CClBr}.\text{CH}^3$, is very easily obtained by the action in the cold of excess of concentrated hydrobromic acid on *α*-chloropropylene. The γ -modification, $\text{CH}^3.\text{CCl}.\text{CH}^2\text{Br}$, is not produced in the cold, but only on heating. The α -compound boils at 93° – 93.5° , and its density is 1.474 at 21° .

Bromiodopropane may be prepared in a similar manner by the action of HI on α -bromopropylene. On distillation nearly the whole product passes over at 147° , slightly coloured by free iodine. Its density is 2.2 at 11° .

β-Chlorobromopropane, $\text{CH}^3.\text{CH}^2.\text{CHClBr}$, results from the addition of HBr to β -chloropropylene without application of heat. It is generally accompanied by a small quantity of the γ -compound, $\text{CH}^3.\text{CHBr}.\text{CH}^2\text{Cl}$, but the latter is easily separated by distillation. Its density is 1.59 at 20° , and its boiling point 110° – 112° .

γ-Chlorobromopropanes, $\text{CH}^3.\text{CHCl}.\text{CH}^2\text{Br}$ and γ $\text{CH}^3.\text{CHBr}.\text{CH}^2\text{Cl}$.—By maintaining for some hours at the boiling point a mixture of ordinary dibromopropane and mercuric chloride in an apparatus fitted with an inverted condenser, Friedel a. Silva obtained a chlorobromide boiling at 119° – 121° , which they considered to be the compound $\text{CH}^3.\text{CHCl}.\text{CH}^2\text{Br}$, because when decomposed with alcoholic potash it yielded *α*-chloropropane boiling at 25° – 30° . Reboul, however, points out that the chlorobromide made in this manner is in reality a mixture of the two isomerides.

δ-Chlorobromopropane, $\text{CH}^2\text{Cl}.\text{CH}^2.\text{CH}^2\text{Br}$, is prepared by heating allyl chloride for seven or eight hours at 100° in a closed vessel, with a concentrated solution of hydrobromic acid, then washing, drying, and fractionating. When quite free from allyl chloride, it distils at 140° – 142° , and has a density of 1.63 at 8° ; it is, however, very difficult to free it entirely from a trace of the γ -compound, $\text{CH}^3.\text{CHBr}.\text{CH}^2\text{Cl}$, and of δ -dibromopropane, which are formed at the same time.

By the action of sodium on the isomeric bromopropanes, one and the same propylene is always formed, namely, $\text{CH}^3.\text{CH}=\text{CH}^2$.

When the two chlorine or bromine atoms in the dichloro- and dibromopropanes are attached to the same carbon-atoms, they cannot be replaced by acid radicles; when the propane-derivatives thus constituted are treated with silver acetate, they lose HCl or HBr and are converted into monochloro- or monobromopropylene. In the case of *α*-dibromopropane, $\text{CH}^3.\text{CBr}^2.\text{CH}^3$, it is possible to obtain a dibenzoyl-compound, but water resolves it into acetone and benzoic acid.

PROPARGYL-COMPOUNDS (vii. 1006). The following additional observations on these compounds have been published by L. Henry (*Ber.* viii. 398). *Propargyl Alcohol* is wholly resolved by the action of potassium hydroxide into acetylene and formic acid:

Propargyl chloride, $\text{C}^3\text{H}^3\text{Cl}$, produced by the action of phosphorus trichloride on the alcohol, is a mobile liquid, having a disagreeable odour, insoluble in water, boiling at 65° , and having a density of 1.0454 at 5° .

The *iodide*, $\text{C}^3\text{H}^3\text{I}$, formed from the alcohol by the action of iodine and amorphous phosphorus, crystallises in small needles, melts at 48° – 49° , dissolves slightly in water, abundantly in alcohol and ether, and is decomposed by distillation.

PROPARGYLENE. See ALLYLENE (p. 63).

PROPIONIC ACID, $\text{C}^3\text{H}^5\text{O}^2 = \text{CH}^3.\text{CH}^2.\text{COOH}$. In preparing this acid from ethyl cyanide (iv. 730), Th. D. Barry (*Inaug. Diss.* Halle, 1874) finds that a better product is obtained by boiling the ethyl cyanide with alcoholic potash than with dilute sulphuric acid. From 2 kg. potassium ethylsulphate and 2 kg. potassium cyanide he obtained 471 g. crude ethyl cyanide yielding 390 g. potassium propionate.

Propionic acid is also formed by heating potassium oxalate with dry sodium ethylate, the reaction being analogous to that by which formic acid is obtained from oxalic acid and potassium hydroxide:

Oily products distil over, and on lixiviating the residue with water, supersaturating it with sulphuric acid, and distilling, a strongly acid distillate is obtained, containing formic and propionic acids (*J. van 't Hoff, Ber.* vi. 1107).

The supposed formation of a propionate by the action of carbon monoxide on a metallic ethylate has been already noted (vii. 1009). According to Berthelot, however (*Bull. Soc. Chim.* [2], xix. 160), the barium-compound obtained by passing carbon monoxide into a solution of barium alcoholate in absolute alcohol, though identical in composition with barium propionate, $\text{C}^3\text{H}^5\text{BaO}^2$ [$\text{ba} = 68.7$], differs from that salt in

being soluble in alcohol and in being decomposed by water, with formation of ethyl alcohol and barium formate:

Berthelot therefore regards this salt as isomeric with barium propionate, and designates it as *ethylformate*. But ethyl-formic acid, $\text{C}^2\text{H}^5\text{COOH}$, as is well known, is nothing else than propionic acid, and according to the generally received views of the constitution of acids, no isomeric form of propionic acid of the general type $\text{C}^n\text{H}^{2n+1}\text{COOH}$ is possible. Kolbe therefore regards Berthelot's salt as *formylated barium ethylate*, $\text{CH}^3\text{CH}(\text{CHO})\text{Oba}$ (*J. pr. Chem.* [2], viii. 27).

Propionic acid, heated in a sealed tube with iodine trichloride, yields perchlorethane, together with CO^2 and HCl , which escape on opening the tube (F. Krafft, *Ber.* ix. 1085). The reaction may perhaps be represented by the equation:

Bromopropionic Acids. The two dibromopropionic acids, represented by the formulæ

have been already described (vii. 1010–1012); also the two bromacrylic acids, $\text{CH}^2=\text{CBr}-\text{COH}$ and $\text{CHBr}=\text{CH}-\text{COOH}$, obtained from them by the action of boiling alcoholic potash (viii. 44).

Dichloropropionic Acids, $\text{C}^2\text{H}^3\text{Cl}^2\text{COOH}$. Two of these acids are known, analogous in constitution to the dibromopropionic acids.

The α -acid, $\text{CH}^2\text{Cl}^2\text{COOH}$, which Klimenko obtained by the action of alcohol on the chloride formed by treating pyroracemic acid, $\text{CH}^3\text{CO}\cdot\text{COOH}$, with phosphorus pentachloride (vii. 1012), is also produced by the action of strong hydrochloric or moderately strong sulphuric acid on dichloropropionitril, $\text{CH}^3\text{Cl}^2\text{CN}$ (iv. 736). The easiest way of preparing it is to heat 1 pt. of the nitril with 2 or 3 pts. of a mixture of sulphuric acid and water in equal volumes, in a reflux apparatus at about 20° . As soon as the layer of oil floating on the surface of the acid ceases to boil, it must be pipetted off and rectified with a thermometer in the liquid. Stronger acid or a larger quantity gives rise to the formation of brown decomposition-products (Beckurts a. Otto, *Ber.* ix. 1876).

α -Dichloropropionic acid boils without decomposition between 185° and 190° , and does not solidify at -8° . It volatilises with vapour of water. Its salts, excepting the silver salt, are permanent in the dry state at ordinary temperatures, but at higher temperatures, or when their solutions are heated (especially in contact with excess of base), they decompose, with separation of metallic chlorides. Most of them dissolve readily in water and in alcohol.

The *potassium salt*, $\text{C}^2\text{H}^3\text{Cl}^2\text{KO}^2 + 6\text{H}^2\text{O}$, forms shining needles or tufts, decomposing at 60° – 70° ; the *ammonium salt*, $\text{C}^2\text{H}^3\text{Cl}^2(\text{NH}^4)\text{O}^2$, thin, white, fatty laminae; the *silver salt*, $\text{C}^2\text{H}^3\text{Cl}^2\text{AgO}^2$, small white needles, soluble with difficulty in water; decomposed at ordinary temperatures; the *calcium salt*, $(\text{C}^2\text{H}^3\text{Cl}^2\text{O}^2)^2\text{Ca} + 3\text{H}^2\text{O}$, white, cheaf-like needles, of glassy or silky aspect; decomposed at 120° ; the *barium salt*, $(\text{C}^2\text{H}^3\text{Cl}^2\text{O}^2)^2\text{Ba} + \text{H}^2\text{O}$, glassy, rhombic laminae, which lose their water of crystallisation at 80° and become opaque; the *zinc salt*, $(\text{C}^2\text{H}^3\text{Cl}^2\text{O}^2)^2\text{Zn} + \text{H}^2\text{O}$, transparent needles resembling the sulphate; they lose their water of crystallisation at 60° , and are decomposed at 80° .

The ethers of α -dichloropropionic acid are easily prepared by the action of hydrochloric acid on the solution of the acid in the corresponding alcohol. The *methyl ether* is a colourless liquid having a fruity odour, and boiling at 143° – 144° (uncorr.) The *ethyl ether*, identical with the ether formed from α -dichloropropionitril and alcohol in presence of sulphuric acid, boils at 156° – 157° . The *allyl ether* is a faint yellow liquid, which is decomposed on distillation, with separation of hydrochloric acid. It has a fruit-like smell, and boils at 176° – 178° . The *isobutyl ether* resembles the foregoing, is not completely decomposed at 183° – 185° ; has a pleasant pine-apple odour. Starting from the methyl ether, the boiling points of these ethers rise by intervals of about 10° .

Behaviour of α -Dichloropropionic Acid to Nascent Hydrogen.—By the action of zinc and dilute sulphuric acid at ordinary temperatures, the acid is converted into propionic acid. The ethylic ether of α -dichloropropionic acid is also converted by similar treatment into the ethylic ether of propionic acid.

Conversion of α -Dichloropropionic Acid into Menochloracrylic Acid.—The aqueous solution of the silver salt of α -dichloropropionic acid becomes turbid at ordinary temperatures, and gradually deposits the whole of the silver as chloride; the change

is completed in a few minutes by boiling. The filtrate from the silver chloride contains an acid of the composition of monochloroacrylic acid. It may be formed thus: $C^3H^2Cl^2AgO^2 = C^3H^2ClO^2 + AgCl$. The dry silver salt, even in closed vessels, suffers the same change at ordinary temperatures.

The potassium salt of monochloroacrylic acid may also be obtained by heating an alcoholic solution of α -dichloropropionic acid (1 mol.) with a solution of potassium hydrate (2 to 3 mols.) This acid is not identical with the β -monochloroacrylic acid of Werigo and Werner, but corresponds with the α -monobromoacrylic acid of Philipp and Tollens.

Conversion of α -Dichloropropionic Acid into Acetic and Carbacetoxylic Acids.—When an aqueous solution of α -dichloropropionic acid is heated with freshly precipitated silver oxide, the following change takes place:

By treating an aqueous solution of α -dichloropropionic acid with silver carbonate, a salt is obtained in small brown needles which is probably the silver salt of carbacetoxylic acid (Beckurts a. Otto, *loc. cit.*)

Conversion of α -Dichloropropionic acid into Chloracrylic and Pyroracemic acids.—An aqueous solution of the silver salt of this acid is converted by boiling for a few minutes into a solution of monochloracrylic acid, with deposition of silver chloride: $\text{C}^3\text{H}^2\text{Cl}_2\text{AgO}^2 = \text{AgCl} + \text{C}^3\text{H}^3\text{ClO}^2$; and on heating the latter solution for some hours with oxide or better with carbonate of silver, the silver salt first formed is decomposed, and pyroracemic acid, $\text{C}^3\text{H}^4\text{O}^2$, is formed, according to the equation $\text{C}^3\text{H}^2\text{ClAgO}^2 + \text{H}_2\text{O} = \text{AgCl} + \text{C}^3\text{H}^4\text{O}^2$. These two reactions may be effected in one operation by simply heating a solution of α -dichloropropionic acid with an equal number of molecules of silver carbonate, till silver chloride is no longer formed, the following reaction then taking place:

(Beckurts u. Otto, *Ber.* 2, 264).

α-Dichloropropionitril, $\text{CH}_3\text{Cl}_2\text{C}\cdot\text{CN}$.—This compound exists in two physical modifications, one liquid and the other solid (iv. 736). The latter is regarded by Beckurts a. Otto as a polymeric modification of the former, inasmuch as when boiled with dilute sulphuric acid it reacts in the same manner, yielding *α*-dichloropropionic acid. Heated in a sealed tube with alcoholic ammonia, it is converted into *α*-dichloropropionamide, $\text{CH}_3\text{Cl}_2\text{C}\cdot\text{CONH}_2$ (m. p. 115° – 116°). The solid modification is produced in greatest abundance when the action of chlorine on propionitril takes place at comparatively low temperatures; also, though in small quantity only, and accompanied by various brown amorphous products, when the liquid modification is boiled for some time in a reflux apparatus with potassium, sodium, or sodium-amalgam. In this reaction metallic chlorides and cyanides are also formed. The liquid modification is also converted into the solid when kept in imperfectly closed vessels, considerable quantities of hydrochloric acid being set free at the same time. The solid modification is perhaps a derivative of cyanethine (ii. 189) (Beckurts a. Otto, *Ber.* ix. 1593; x. 263, 2040).

β-Dichloropropionic acid, $\text{CH}_2\text{Cl}.\text{CHCl}.\text{COOH}$.—Werigo a. Okulitsch, by treating glyceric chloranhydride with alcohol, obtained a product which they regarded as the ethylic ether of *β*-dichloropropionic acid (vii. 563). Subsequent experiments by Werigo a. Melikoff (*Ber.* x. 1499), however, have shown that this product when saponified does not yield *β*-dichloropropionic acid. But, if the glyceric chloranhydride be first converted by boiling with potash into chloracrylic acid, $\text{CHCl}=\text{CH}.\text{CO}_2\text{H}$, and the latter be heated with hydrochloric acid, it takes up HCl and is converted into *β*-dichloropropionic acid, melting at 50° , and yielding an ethylic ether which boils at 183° – 184° . The *β*-acid is, however, more easily obtained, together with chlorolactic acid, by heating glyceric acid in sealed tubes for three days with hydrochloric acid saturated at 0° (W. and M. *Ber.* xii. 178). L. Henry (*Ber.* vii. 414; *Bull. Soc. Chim.* [2], xxx. 161) has also obtained the *β*-acid by the action of fuming nitric acid at the heat of the water-bath on unsymmetrical dichlorhydrin, $\text{CH}_2\text{Cl}.\text{CHCl}.\text{CH}_2\text{OH}$ (p. 876). It may be extracted from the product by ether, in which it dissolves readily, as also in alcohol and water; crystallises in needles; melts at 50° ; and yields an ethylic ether which boils at 180° . The identity of the dichloropropionic acid from glyceric acid with that obtained from unsymmetrical dichlorhydrin is further shown by the fact that both yield the same *β*-chloracrylic acid melting at 64° – 65° (Werigo a. Melikoff).

Cyanopropionic Acid, $C^3H^3NO^2 = C^2H^4(CN).COOH$ (Wanklyn a. Cooper, *Phil. Mag.* [5], vii. 356). This acid is formed, together with others, when wool (1 pt.) dissolved in water containing potassium hydroxide (3 pts.) is oxidised by 2 pts. of potassium permanganate. It is obtained pure by converting it into a barium salt and decomposing the latter with sulphuric acid.

Cyanopropionic acid in the free state is an amorphous solid, brittle at ordinary temperatures, but softening at 100° . In mass, it has a pale brownish-yellow or straw colour; in powder it is almost white. It is very soluble in water and in strong alcohol; has a strongly acid taste and reaction; decomposes carbonates, and dissolves magnesium in the cold. It is oxidised by potassium dichromate and by permanganate. Heated at 140° , it gives off all its water; at higher temperatures, it is decomposed, evolving ethyl cyanide, and forming a brown mass, soluble in potash. The potassium salt, heated with twice its weight of potassium hydroxide, is completely decomposed, giving off ethylamine and leaving potassium oxalate:

Most of the metallic cyanopropionates are soluble in water, and contain water of crystallisation. *Barium cyanopropionate*, $Ba(C^2H^4NO^2)^2.3H^2O$, is a white powder, very soluble in water, but sparingly soluble in alcohol. It loses 1 mol. of water at 160° - 170° . There is also a basic salt, $[Ba(C^2H^4NO^2)^2.3H^2O]^2.BaH^2O^2$. The *silver salt*, $2C^2H^4AgNO^2.\frac{1}{2}H^2O$, is nearly insoluble in water; the dry salt quickly absorbs 2 per cent. of water. There is also a basic salt, $2C^2H^4AgNO^2.AgHO.H^2O$, obtained by adding silver nitrate to the basic barium salt. The *lead salt*, $Pb(C^2H^4NO^2)^2.H^2O$, is a white powder, nearly insoluble in water. The *magnesium salt*, $Mg(C^2H^4NO^2)^2.3H^2O$, is extremely soluble in water, drying up first to a jelly, and finally to a brittle mass, yielding a white powder. The *potassium salt*, $C^2H^4NKO^2.H^2O$, forms a straw-coloured transparent solid. Dried at 100° , it contains 5 mols. of water; at 190° , only 1; deposited from strong alcohol and dried at 100° , it contains $4H^2O$. It is very soluble in water and in 40 per cent. alcohol, sparingly in strong alcohol. The *calcium salt*, $Ca(C^2H^4NO^2)^2.4H^2O$ (dried at 100°), is very soluble in water, and is precipitated from its aqueous solution by alcohol of 84 per cent. It loses about 4 per cent. (rather less than $\frac{1}{2}$ mol.) of water at 200° .

PROPIONYL-PROPIONATE, ETHYLIC, $CH^3.CH^2.CO.CH^2.CH^2.COOC^2H^5$. This ether is formed by digesting ethyl propionate in a Frankland's apparatus (i. 521) with sodium. About $\frac{2}{3}$ of an equivalent of the metal is thereby dissolved, and on adding acetic acid to the product, ethyl propionylpropionate is separated as a liquid resembling ethyl acetate, but having a still more fragrant odour. Sp. gr. 0.9048 at 0° . B. p. 180° - 205° . It gives no colour-reaction with ferric chloride, and does not unite with mercuric oxide, whereas ethyl acetoacetate unites with that oxide, forming a white insoluble mass (Oppenheim a. Hellon, *Ber.* x. 699).

PROPIOPHENONE, $C^6H^5.CO.C^2H^3$. See KETONES (p. 1152).

PROPYL ALCOHOLS AND ETHERS. *Normal Propyl Alcohol*, $CH^3.CH^2.CH^2.OH$.—On the formation of this compound from allyl alcohol by the action of nascent hydrogen (zinc and sulphuric acid), see ALLYL ALCOHOL (p. 59). It is found, together with butyl alcohol, in the sour waters of the wheat-starch manufacture, and in the volatile products of the lactic and butyric fermentation of glucose (Bouchardat, *Compt. rend.* lxxviii. 1145). Linnemann, by heating the nitrite of normal propylamine, obtained isopropyl alcohol (vii. 1015). According to Meyer a. Forster, however (*Ber.* ix. 535), the product thus obtained is a mixture 42 per cent. normal and 58 per cent. isopropyl alcohol.

According to Klimenko (*Bull. Soc. Chim.* [2], xxv. 294), propyl alcohol is converted by oxidation with nitric acid into propyl acetate, oxalic acid, and carbon dioxide.

Bromine acts on propyl alcohol in the same manner as on ethyl alcohol (p. 744), producing the propyl-alcoholate of propyl-bromal, $C^3H^7Br^2O.C^3H^7O$, which is a slightly yellowish liquid (Hardy).

On the reaction of propyl alcohol with *urea*, see CARBAMATES (p. 385).

Propyl Chlorocarbonate, $Cl.CO.OC^3H^7$, is formed by the action of phosgene gas on normal propyl alcohol. The products, after washing with water and drying over calcium chloride, boil between 90° and 160° , the greater part distilling over at 120° - 130° , and consisting of nearly pure chlorocarbonate. This ether is a liquid, heavier than water, giving off a pungent vapour which strongly attacks the eyes, and burning with a green flame. It is easily decomposed by distillation, and cannot therefore be purified by fractionation (H. Roemer, *Ber.* vi. 1101). *Propyl Carbonate*, $CO(OC^3H^7)^2$, is formed by dropping an ethereal solution of the chlorocarbonate on sodium propyl-

ate (Roemer); also by the action of sodium on the oxalate (Cahours, *Compt. rend.* lxxxvii. 749). It is a colourless, mobile, fragrant liquid, burning with a blue flame, and boiling at 160°–165° (Roemer); 156°–160° (Cahours). Sp. gr. 0.968° at 22° (Cahours). *Propyl Carbamate*, $\text{NH}_2\text{CO.OC}^3\text{H}_7$, formed by the action of aqueous ammonia on the chlorocarbonate, crystallises in large colourless prisms, easily soluble in alcohol and ether, less soluble in water, melting at 50°; comp. Cahours (p. 385). *Propyl Phenylcarbamate*, $\text{NH}(\text{C}^6\text{H}_5)\text{CO.OC}^3\text{H}_7$, formed in like manner with an ethereal solution of aniline, crystallises in slender needles, easily soluble in alcohol, less soluble in water, melting at 57°–59° (Roemer). On *Ethylidene-Propylcarbamate*, $\text{CH}_3\text{.CH}(\text{NH.CO.OC}^3\text{H}_7)_2$, see CARBAMATES (p. 386).

Propyl Nitrite, $\text{C}^3\text{H}_7\text{.O.NO}$, formed by passing nitrogen trioxide into propyl alcohol, is a fragrant liquid, having a specific gravity of 0.935 at 21°, and boiling between 43° and 46°. On its isomeric, *nitropropane*, see p. 1491. The *oxalate*, $\text{C}^3\text{H}_7\text{O.CO.CO.C}^3\text{H}_7\text{O}$, is prepared by distilling anhydrous propyl alcohol with dry oxalic acid, either alone or mixed with $\frac{1}{2}$ pt. sulphuric acid. The distillate, on addition of water, separates into two layers, the upper of which, when washed, dried, and rectified, yields propyl oxalate as a liquid having an aromatic odour, a specific gravity of 1.018 at 22°, and boiling between 209° and 211°. Ammonia converts it into crystalline propyloxamate, $\text{C}^3\text{H}_7\text{O.CO.CO.NH}_2$, which is decomposed by water, with reproduction of propyl alcohol and oxalic acid. The *salicylate*, $\text{C}^6\text{H}_4(\text{OH}).\text{COOC}^3\text{H}_7$, prepared from propyl alcohol, salicylic acid, and strong sulphuric acid, in the proportions 2 : 2 : 1, forms, after washing, drying, and rectification, a colourless fragrant liquid, having a specific gravity of 1.021 at 21°, and boiling between 238° and 240°. It is slightly soluble in water, and dissolves in all proportions in alcohol and ether. It forms well-crystallised chloro- and bromo-derivatives, is converted by fuming nitric acid at ordinary temperatures into a nitro-derivative, and decomposed at the boiling heat with formation of picric acid. With ammonia it forms salicylamide. *Propyl Phenate*, $\text{C}^6\text{H}_5(\text{C}^3\text{H}_7)\text{O}$, is formed, together with barium carbonate, by distilling propyl salicylate with baryta; more readily, however, by heating propyl iodide with an alcoholic solution of potassium phenate in a sealed tube at 100°–110°. It is a colourless liquid, having a pleasant odour, a specific gravity of 0.968 at 20°, and boiling at 190°–191°. It is violently attacked by strong nitric acid, and forms with bromine a crystalline substitution-product (Cahours, *Compt. rend.* lxxvii. 749).

Propyl Sulphide, $(\text{C}^3\text{H}_7)_2\text{S}$, obtained by heating potassium monosulphide with propyl chloride or iodide in alcoholic solution, boils at 130°–135°, and has a density of 0.814 at 17° (Cahours, vii. 1014).

Metallic compounds of Propyl.—The compounds of propyl with *aluminium*, *glucinum*, *mercury*, *tin*, and *zinc*, discovered by Cahours, have been already described (vii. 1014).

When propyl iodide is heated with *arsenic* for twenty-four to thirty hours at 175°–185°, a brown-red liquid is formed, which solidifies at low temperatures to reddish-brown crystals of the compound $\text{AsI}^3.\text{As}(\text{C}^3\text{H}_7)_4\text{I}$. Strong potash-leys decomposes this compound, with separation of an oil, and after the excess of potash has been saturated with carbonic acid, absolute alcohol extracts from the product *tetrapropyl-arsonium iodide*, which crystallises in colourless prisms. Iodine dissolves in its warm solution, forming a *polyiodide*, which separates on cooling in blackish-brown crystals having a metallic lustre. On distilling the above-mentioned double compound with caustic potash, tripropyl-arsine, $\text{As}(\text{C}^3\text{H}_7)_3$, is obtained as a liquid which has an extremely offensive odour and unites directly with alcoholic iodides.

Zinc arsenide acts on propyl iodide at 175°–180°, forming prismatic crystals of the compound $\text{ZnI}^2.2\text{As}(\text{C}^3\text{H}_7)_4\text{I}$, which is decomposed by strong potash-ley in the same manner as the double arsenic compound. The arsenides of potassium and sodium act very violently on propyl iodide, forming, together with *tetrapropyl-arsonium iodide*, a very offensive-smelling liquid, probably containing *di-* and *tripropyl-arsine* (Cahours, *Compt. rend.* lxxvi. 1383).

Iso- or Pseudopropyl Alcohol, $\text{CH}^3.\text{CHOH}.\text{CH}^3$.—This alcohol is formed: α . By the action of heat on propylamine nitrite (vii. 1015). β . Together with pinacene, by the action of sodium on acetone in contact with a strong solution of potassium carbonate (p. 1529). γ . Together with carbon dioxide, by dry distillation of hydroxypyrotartaric acid (see PYROTARTARIC ACID):

Flavitzky (*Liebig's Annalen*, clxxv. 380) prepares isopropyl alcohol by decomposing

the corresponding iodide with water and lead oxide. Niederist (*ibid.* clxxxvi. 391) heats the iodide (20 to 25 grams) with 20 times its weight of water in a closed champagne bottle for forty hours.

Isopropyl-compounds are easily formed from haloïd propylene-compounds. Propylene-glycol is converted by hydriodic acid into isopropyl iodide, and the oxide and oxychloride of propylene; by nascent hydrogen into isopropyl alcohol (Linnemann, *Lieb. Ann.* clxi. 45).

The following table exhibits the boiling points and densities of normal propyl iodide and isopropyl iodide at those temperatures at which their vapour-tensions are equal (F. D. Brown, *Proc. Roy. Soc.* xxvi. 238).

Vapour-tension in millimeters	Boiling point of normal propyl iodide	Boiling point of isopropyl iodide	Density of normal propyl iodide	Density of isopropyl iodide	Difference of densities
200	62.37°	50.50°	1.66704	1.64550	0.02114
300	73.51	61.33	1.64493	1.62359	0.02134
400	81.95	69.70	1.62808	1.60646	0.02162
500	88.84	76.44	1.61446	1.59246	0.02200
600	94.70	82.11	1.60250	1.58068	0.02182
700	99.83	87.13	1.59221	1.57035	0.02186
760	102.63	89.86	1.58670	1.56497	0.02196

PROPYL-ACETIC ACIDS, $(C^3H^7)CH^2.COOH$. See PENTOLIC ACIDS (p. 1500). According to N. Ley (*Ber.* x. 230), isopropyl-hydroxyacetic acid is resolved by oxidation into carbon dioxide, and isopropyl aldehyde, and isobutyric acid.

PROPYL-(ISO)-ACETYLENE, $C^3H^8 = (CH^3)^2CH.C \equiv CH$, is obtained by the action of alcoholic potash on isopropylethylene dibromide, $(CH^3)^2CH.CHBr.CH^2Br$. It boils at 85° (Eltzoff, see PENTYLENES, p. 1503).

PROPYLAMINES, $C^3H^7NH^2$. Propylamine may be prepared by fermenting the digestive apparatus of cows, calves, sheep, or oxen for thirty-two to thirty-six hours at 59°–64.5° Fahr. with four or five times its weight of water and $\frac{1}{15}$ of potassium or sodium carbonate, then adding caustic soda, distilling off $\frac{1}{3}$ of the volume of liquid, converting the base therein contained into hydrochloride, distilling it with soda, and collecting the evolved vapours in water (E. Perret, *Pharm. J. Trans.* [3], iii. 884).

Isopropylamine is converted by nitrous acid into isopropyl alcohol; normal propylamine into a mixture of normal and isopropyl alcohols (p. 1676).

PROPYL-BENZENE, $C^6H^{12} = C^6H^5.CH^2.CH^2.CH^3$. This hydrocarbon, originally obtained by the action of sodium and propyl iodide on bromobenzene (vi. 295), may also be prepared by dropping benzyl chloride (about 60 g.) into zinc-ethyl previously raised to a gentle heat, decomposing the product with water, distilling in a stream of aqueous vapour, drying, and fractionating over sodium. It then boils at 156.5°–158.5° (corr.), and has a density of 0.881 at 0°. Heated with sulphuric acid (50 grams to a mixture of 40 ordinary and 50 fuming acid), it yields two isomeric propylbenzene-sulphonic acids, one of which (α) forms an anhydrous barium salt crystallising in lamellæ, while the barium salt of the β -acid crystallises with 2 mols. water in microscopic prisms, and is more soluble than the α -salt. The α -lead salt crystallises with 1 mol. water in scales, and is much more soluble than the β -salt, which contains 2 mols. water. The α -potassium salt fused with potash yields a propyl-phenol, $C^6H^4(C^3H^7)OH$, isomeric with cumophenol (p. 593), boiling at about 230°, and yielding a methyl-derivative which boils at 210°–215° (Paternò a. Spica, *Gazz. chim. ital.* 1877, 21).

When bromine-vapour is passed into propyl-benzene heated to 150°–160°, bromopropyl-benzene or phenyl-bromopropyl, $C^6H^5.C^3H^6Br$ is formed, which is resolved on boiling into hydrogen bromide and allyl-benzene, $C^6H^5.C^3H^5$, a colourless liquid having a peculiar odour, boiling under a pressure of 728 mm. at 164.5°–165.5°, having a density of 0.924 at 16°, and a vapour-density = 4.01. *Allylbenzene dibromide*, or *Phenyl-dibromopropyl*, $C^6H^5.C^3H^4Br_2$, obtained by dropping the calculated quantity of bromine into allyl-benzene diluted with chloroform, crystallises from alcohol in long white silky needles melting at 65°–66°. The same compound is obtained by the action of 2 mols. bromine on 1 mol. propyl-benzene at 160°. The action of bromine on propyl-benzene gives rise also to products of still higher boiling point, one of which boils at 220°, and appears to consist of *bromopropyl-benzene*, $C^6H^5.C^3H^6Br$ (Radziszewski, *Ber.* vii. 143).

Secondary Propyl-benzene Alcohol, or *Phenyl-ethyl Carbinol*, $C^6H^5O = C^6H^5.CHOH.C^2H^5$, formed by the action of sodium-amalgam on phenyl-ethyl ketone (propiophenone, p. 1152), boils at 212° , and has a density of 0.99 at 15° (Th. D. Barry, *Ber.* vi. 1006).

Propylisopropylbenzene, $C^{12}H^{18} = C^6H^4 \begin{smallmatrix} CH^2.CH^2.CH^3 \\ CH(CH^3)^2 \end{smallmatrix}$, is formed by the action of zinc-ethyl on cymyl chloride:

The reaction is violent, so that the zinc-ethyl must be added by drops to the cooled liquid. Propylisopropylbenzene boils between 211° and 212° (corr. at 745 mm.), and has a density of 0.8713 at 0° . By oxidation with nitric acid (4 vols. acid with 6-7 vols. water) it is converted into propylbenzoic acid, $C^6H^4.C^2H^4.COOH$ (*infra*), and homoterephthalic acid, $C^6H^4 \begin{smallmatrix} CH^2.COOH \\ COOH \end{smallmatrix}$ (p. 1616) (Paternò a. Spica, *Gazz. chim. ital.* 1876, 99; 1877, 361).

Isopropyl-allyl-benzene, $C^6H^4(C^3H^7)CH=CH-CH^3$, and *Isopropyl-butenyl-benzene*, $C^6H^4(C^3H^7)CH=CH.CH^2.C^2H^5$, are formed by the action of sodium carbonate on hydrobromocumenylcrotonic and hydrobromocumenylangelic acid respectively (p. 499).

PROPYLBENZOIC ACID, $C^6H^4.C^2H^4.COOH$, isomeric with cumic acid, is formed, as above stated, by oxidation of propylisopropyl-benzene. It crystallises in smooth colourless needles, easily soluble in ether, alcohol, benzene, and chloroform, sparingly in water; melts at 138° - 139° . Its ammonium salt is soluble in water, alcohol, and ether, and its concentrated solution gives precipitates with the salts of the heavy metals. The composition of the silver salt is $C^6H^4.C^2H^4.COOAg$; that of the barium salt, $(C^6H^4.C^2H^4.COO)^2Ba + 2H^2O$ (Paternò a. Spica).

PROPYLENE, $C^3H^6 = CH^2-CH=CH^2$. According to Kerstein (*Ber.* ix. 695), this hydrocarbon is obtained, mixed with hydrogen, by heating glycerol with zinc-dust. The dibromide obtained from it boiled at 142° .

On *Propylene Dichlorides and Dibromides*, see PROPANES, CHLORO- and BROMO- (pp. 1671-1673).

Bromopropylenes, C^3H^5Br . The α -compound, $CH^3.CBr=CH^2$, is best prepared by heating α -dibromopropane for five or six hours at 100° with sodium ethylate containing exactly the quantity of sodium necessary to remove one-half of the bromine. The product, when distilled and washed with water, gives, after several rectifications, the α -bromopropylene in a state of purity. It is a mobile liquid, boiling at 47° - 48° under a pressure of 742 mm. Its density is 1.39 at 9° , or 1.362 at 20° . With HBr it gives only one compound, namely, the dibromopropane from which it was originally prepared, boiling at 114.5° ; with bromine it yields the tribromide, $CH^3.CBr^2.CH^2Br$, boiling at 190° - 191° ; sp. gr. 2.33 at 12° .

β -Bromopropylene, $CH^3.CH=CHBr$.—Ordinary bromopropylene, derived from the ordinary dibromide (γ) by loss of HBr, is a mixture of the two bromo-derivatives, $CH^3.CBr=CH^2$ and $CH^3.CH=CHBr$, which, on account of the proximity of their boiling points, cannot be separated by fractional distillation. The separation may, however, be effected by taking advantage of the double fact that HBr attaches itself much more rapidly to α -bromopropylene than to its isomeride (β), and that the combination formed with the first compound is the more stable of the two. By thus sacrificing a portion of the β -bromopropylene, the whole of the first compound (α) may be completely removed.

The mixture of the three bromides resulting from the addition of HBr to ordinary bromopropylene may be distilled, and the portion boiling under 135° collected and decomposed by rapid distillation with concentrated alcoholic potash. Under these conditions the two isomerides of α -dibromopropane are completely destroyed, while the latter is only partially acted on. By fractionating the distillate, the α -dibromocompound boiling at 114° may be readily separated. This, when broken up by potash or by sodium ethylate, yields pure α -bromopropylene boiling at 47° - 48° .

By treating β -bromopropylene with bromine in the cold, the tribromopropane, $CH^3.CHBr.CHBr^2$, is obtained. It boils at 200° - 201° , or 10° higher than the isomeride furnished by α -bromopropylene. Its density is 2.356 at 18° (Reboul).

Chloropropylenes, C^3H^5Cl . Three of these compounds, α , β , γ , are known, produced by the action of alcoholic potash (abstraction of HCl) on the corresponding propylene dichlorides or dichloropropanes (Reboul, p. 1671).

α-Chloropropylene, $\text{CH}^3.\text{CCl}=\text{CH}^2$, thus prepared from $\text{CH}^3.\text{CCl}^2.\text{CH}^3$, boils at 25° ; unites with HBr , forming the chlorobromide, $\text{CH}^3.\text{CClBr}.\text{CH}^3$ (b. p. 93°), and with Br^2 forming the dibromide, $\text{CH}^3.\text{CClBr}.\text{CH}^3.\text{Br}$ (b. p. $169^\circ-170^\circ$).

β-Chloropropylene, $\text{CH}^3.\text{CH}=\text{CHCl}$, prepared by heating *β*-dichloropropane, $\text{CH}^3.\text{CH}^2.\text{CHCl}^2$, for four or five hours under pressure with excess of alcoholic potash, is a very mobile liquid lighter than water, and boiling at $35^\circ-36^\circ$. It unites with HBr , forming the chlorobromide, $\text{CH}^3.\text{CH}^2.\text{CHClBr}$, which boils at 110° , together with a small quantity of $\text{CH}^3.\text{CHBr}.\text{CH}^2.\text{Cl}$, which passes over at about 121° . *β*-Chloropropylene unites with bromine at 15° , forming the dibromide, $\text{CH}^3.\text{CHBr}.\text{CHClBr}$, which boils at $177^\circ-177.5^\circ$. *γ*-Dichloropropane, $\text{CH}^3.\text{CHCl}.\text{CH}^2.\text{Cl}$ (ordinary propylene chloride), in which the two chlorine-atoms belong to adjacent carbon-groups, yields a mixture of *α*- and *β*-chloropropylene, the former predominating.

γ-Chloropropylene, $\text{CH}^3=\text{CH}.\text{CH}^2.\text{Cl}$, is identical with allyl chloride.

Dichloropropylene, $\text{C}^3\text{H}^4\text{Cl}^2$ (Pinner, *Liebigs Annalen*, clxxix. 47).—This compound is formed, with separation of hydrochloric acid and carbon monoxide (production of formic acid), by the action of potash- or soda-ley on butylic chloral:

It is readily acted on by 1 mol. bromine at ordinary temperatures, yielding dichlorodibromopropylene, $\text{C}^3\text{H}^2\text{Cl}^2\text{Br}^2$, a colourless heavy oil, which boils at 188° ; when heated in a sealed tube with excess of bromine, it yields more highly brominated substitution-products:

Dichlorodibromopropylene is easily decomposed by alcoholic potash, forming a precipitate of potassium bromide; and if after the reaction is complete the alcohol be diluted with 4 to 6 vols. water, monobromodichlorallylene, $\text{C}^3\text{HCl}^2\text{Br}$, separates as a heavy oil having an agreeable odour like that of chloroform, boiling without decomposition at 143° , and capable of uniting with 2 at. bromine to form dichlorotribromopropylene, $\text{C}^3\text{HCl}^2\text{Br}^3$. This latter is a finely-crystallised body, melting at 207° , moderately soluble in cold alcohol, volatilising with alcohol, and emitting vapours which excite a copious flow of tears.

Dichlorotribromopropylene, treated with alcoholic potash, likewise forms an immediate and copious precipitate of potassium bromide, not however yielding dichlorodibromallylene, $\text{C}^3\text{Cl}^2\text{Br}^2$, by elimination of HBr , but being reconverted into monobromodichlorallylene, $\text{C}^3\text{HCl}^2\text{Br}$, by elimination of Br^2 . Neither can the last atom of hydrogen be removed from $\text{C}^3\text{HCl}^2\text{Br}^3$ by the direct action of bromine, that compound remaining unaltered when heated with bromine for a considerable time in a sealed tube.

Dichloropropylene, agitated with colourless *hypochlorous acid*, is gradually converted into a heavy not very volatile oil, which however consists of tetrachloropropylene, $\text{C}^3\text{H}^2\text{Cl}^4$, evidently resulting from the action of chlorine set free by decomposition of the hypochlorous acid.

Action of Nitric Acid.—When dichloropropylene is slowly dropped into well-cooled nitric acid, a vigorous action takes place, a clear solution being formed, from which a greenish oil is deposited on dilution with water: a portion of the dichloropropylene is however wholly destroyed, much hydrochloric acid being found in the liquid. The oily mass distils between 120° and 200° , with partial decomposition; after treatment with tin and strong hydrochloric acid, however, it does not decompose on heating; by fractional distillation the greater part is found to pass over between 130° and 140° , and at 190° to 195° . The more volatile portion is *trichloropropylene*, $\text{C}^3\text{H}^2\text{Cl}^3$, boiling at 120° , after treatment with caustic potash. The higher-boiling substance solidifies on cooling to a camphor-like mass, possessing an odour like that of chloropierin; it is very soluble in alcohol, and on analysis gives numbers agreeing with the formula $\text{C}^3\text{H}^4\text{Cl}^3\text{NO}^2$, or $\text{C}^3\text{H}^2\text{Cl}^3\text{NO}^2$, better with the latter, whence apparently the body is trichloronitropropylene; on treatment with caustic soda, it furnishes common salt and a body having the composition of dichloronitroallylene (b. p. 162°), formed from trichloronitropropylene by loss of the element of hydrochloric acid.

The reducing action of the tin converts a portion of the trichloronitropropylene into trichloramidopropylene, $\text{C}^3\text{H}^2\text{Cl}^3(\text{NH}^2)$; this is an oily base, slightly soluble in water, and forming a hydrochloride excessively soluble in water, readily soluble in alcohol; at 100° this salt decomposes into its components; it forms a platinochloride, readily soluble in water and alcohol, crystallising in yellow prisms,

PROPYLENE GLYCOLS, $C^3H^5(OH)^2$. 1. *Ordinary Propylene Glycol*, $CH^3.CHOH.CH^2OH$, boils, according to Flawitzky, at 185.3° (at 188° – 189° , Wurz, v. 892). By potassium dichromate it is ultimately oxidised to acetic acid. With dehydrating agents it yields propionic aldehyde (Flawitzky, *Ber.* xi. 1256). 2. *Normal Propylene Glycol*, or *Trimethylene Glycol*, $CH^2OH.CH^2.CH^2OH$. Reboul (*Compt. rend.* lxxix. 169) prepares this compound by heating normal propylene bromide with potassium acetate, either in a reflux apparatus or in a sealed tube at the temperature of boiling water, and saponifying the resulting diacetate, $CH^2(CH^2O.O.C^2H^3O)^2$, with barium hydroxide. This glycol boils at 216° (corr.), and forms a very thick colourless liquid having a sweet taste, a density of 1.053 at 19° , and miscible in all proportions with water and alcohol.

Normal Propylenic Ethers. The *diacetate* may be prepared as above, or better by the action of trimethylene bromide on silver acetate at 100° in presence of acetic acid. It is a colourless oily liquid, of sp. gr. 1.070 at 19° , boiling at 209° – 210° (corr.), soluble in 8 to 10 vols. of water. The *di benzoate*, $CH^2(CH^2O.C^2H^3O)^2$, is prepared, like the diacetate, with silver benzoate, with addition of anhydrous ether, and crystallises from the product—after separation of silver bromide and ether—in a vacuum over sulphuric acid. By recrystallisation from ether it is obtained in fine laminar crystals melting at 53° . The *divalerate* and *monovalerate* are formed together, in like manner, from silver valerate. They are oily liquids, of unpleasant odour, insoluble in water, the former boiling at 260° , the latter at 280° .

Propylene Chlorhydrin, $CH^2OH.CH^2.CH^2Cl$, is formed, together with the corresponding dichloride, $CH^2Cl.CH^2.CH^2Cl$ (p. 1671), by saturating the corresponding glycol with dry hydrogen chloride, heating the solution at 100° in a closed vessel for several hours, again saturating it with hydrochloric acid, and heating a second time. Two layers are then formed, the lower after rectification yielding the dichloride, while the upper, on fractional distillation, yields the chlorhydrin, C^3H^7ClO , which boils at 160° (corr.), has a density of 1.132 at 17° , and dissolves in 2 pts. of water.

Normal Propylene Oxide, $CH^2\langle\begin{smallmatrix} CH^2 \\ CH^2 \end{smallmatrix}\rangle O$, is formed on heating the chlorhydrin with potassium hydroxide, but is instantly polymerised if a little water is present. It is best therefore to use solid potassium hydroxide, and distil after the reaction into a well-cooled receiver. The distillate, when dried over potassium carbonate and rectified, forms a very mobile colourless liquid having a penetrating odour, soluble in water in all proportions, and boiling at 50° .

PROPYL-EUGENOL, $C^6H^3(OC^3H^7)(OCH^3)C^3H^5$. See EUGENOL (p. 763).

PROPYL-NITROLIC ACID, $CH^3.CH^2.C\langle\begin{smallmatrix} N.OH \\ NO^2 \end{smallmatrix}\rangle$, and **PROPYL-PSEUDONITROL**, $CH^3.C(CH^3)(NO^2)(NO)$. See PARAFFINS (NITRO-), p. 1494.

PROPYL-PHENOL, $C^6H^4\langle\begin{smallmatrix} C^3H^7 \\ OH \end{smallmatrix}\rangle$. This compound, metameric with propyl phenate, $C^6H^3.OC^3H^7$, and isomeric with cumophenol (p. 1542), is formed by fusing the potassium salt of α -propylbenzenesulphonic acid (p. 1678) with potassium hydroxide. It boils at about 230° , and forms a methyl-derivative boiling at 210° – 215° (Paternò a. Spica, *Gazz. chim. ital.* 1877, 21).

PROPYL-PHENYL KETONE, or *Butyrophenone*, $C^3H^7.CO.C^6H^5$. See KETONES (p. 1152).

PROTEIDS or ALBUMINOIDS. Nasse's experiments (*Pflüger's Archiv. f. Physiologie*, vi. 589) on the decomposition of these bodies by baryta-water, and the conclusions thence deducible as to the state of the nitrogen contained in them, have been already noticed in this Dictionary (vii. 1022). More extended researches on this mode of decomposition, and the light which it throws on the proximate constitution of the proteids, have been made by Schützenberger (*Ann. Chim. Phys.* [5], xvi. 289–419; *Chem. Soc. J.* xxxvi. 542–548).

Coagulated albumin, or other proteid, was heated with the alkaline solution for some hours in an autoclave, whereby ammonia and acetic acid were obtained, together with a light-yellow friable residue, containing all the fixed principles, such as leucine, tyrosine, &c., formed at the expense of the organic matter. The total weight of this residue amounted to about 96 per cent. of the albumin used, whence it appears that the decomposition of albumin under the influence of baryta is accompanied by fixation of the elements of water, the sum of the separate components always exhibiting an excess varying from 10 to 14 per cent. The main results of the analysis of this fixed residue are as follows:

1. The mixture of fixed principles derived from albumin by hydration contains

only amido-derivatives. 2. These derivatives may be divided into two portions, one, the weight of which amounts to about 16 to 18 per cent., containing the substances in which the ratio of nitrogen to oxygen is 1:3 or 1:4 or 2:5. This, which is the more important fraction, consists of acids of the formulæ $C^aH^{2a-1}NO^4$, $C^aH^{2a-2}NO^3$, $C^aH^{1a-1}N^2O^6$, and $C^aH^{2a-1}NO^3$, the third term being only a molecular combination of the second and fourth. The second fraction, constituting four-fifths of the fixed residue, may be represented by the general formula $\alpha C^aH^{2a}N^2O^4$, the value of α being a little less than 9. As the limit of hydration is approached, the products belonging to the type $C^mH^{2m}N^2O^4$ (where m is a multiple of n) are progressively resolved into simpler bodies, apparently belonging to the same type, and these again into bodies of the type $C^aH^{2a}N^2O^4$, which in their turn are resolved into leucines [or alanines], $C^aH^{2a+1}NO^2$, and leuceïnes, $C^aH^{2a-1}NO^2$. This interpretation is not affected by the presence of more highly oxygenated acids in the fixed residue, since they may be regarded as derived from any of these bodies by substitution of O for H².

The bodies most easily separated from the fixed residue were tyrosine and leucine, $C^9H^{11}NO^2$; the former to the amount of 2.3 to 3.5 per cent.; and the successive crystalline deposits, obtained by progressively concentrating the solutions from which the leucine, &c., had been partially separated, were composed of amido-valeric and amido-butyric acids, together with two definite, crystallisable products belonging respectively to the types $C^aH^{2a-2}NO^2$ and $C^aH^{2a-1}NO^2$, viz. tyro-leucine, $C^9H^{11}NO^2$, and a body represented by the formula $C^9H^{11}NO^2$; the quantity of tyro-leucine obtained was about 60 or 70 grams from 10 kilograms of albumin. Tyro-leucine is a white crystalline deposit of chalky aspect, nearly tasteless, soluble in about 20 pts. of water at 15°. It melts and decomposes at 240°, breaking up into a white sublimate and a volatile oily base having an odour of radish and leaving an abundant yellow vitreous residue. The analysis of the chloroplatinate of this base gives it the formula of collidine, $C^9H^{11}N$, and that of the vitreous residue gives the formula $C^{14}H^{18}N^2O^2$. The decomposition of tyro-leucine may therefore be regarded as proceeding thus—

whence it may be supposed that tyro-leucine is a compound of amido-valeric acid with a body of the formula $C^9H^{11}NO^2$, differing from tyrosine only by an atom of oxygen. This is rendered more probable by the fact that tyrosine, when heated under similar conditions, breaks up into CO^2 and a base, $C^9H^{11}NO$, which differs from collidine only by an atom of oxygen.

Among the homologues of leucine, amido-valeric and amido-butyric acids were met with in quantity, but amido-propionic acid in very small proportion only.

The leuceïnes may be regarded as amido-acids of the acrylic, or of an isomeric series. They reduce ammoniacal silver nitrate on warming, and are attacked by bromine in the cold, yielding HBr, and an acid having the formula $C^aH^{2a-1}NO^3$.

Both leucines and leuceïnes seem to be frequently produced by the splitting up on crystallisation of bodies of the formula $C^mH^{2m}N^2O^4$ ($m=10$ or 12). These bodies have a sweet taste, and are thence called by Schützenberger glucoproteïns; they crystallise less easily than the leucines, especially the lower terms; they are very soluble in water, but almost insoluble in cold absolute alcohol; alcohol of 90 per cent. however dissolves them with ease.

Another substance resulting from the decomposition of albumin, which is produced in considerable quantity, is a yellow viscous body obtained by precipitating certain mother-liquors from which leucines have been crystallised by ether. Dried at 120°, it is converted into a transparent amorphous mass, which on analysis gives numbers comprised between the formulæ $C^9H^9NO^2$ and $C^9H^7NO^2$; very often sensibly approximating to $C^9H^{10}N^2O^4$; it appears in fact to be constituted in great part of butyric leucine with an admixture of some superior homologue.

The longer the action of baryta on albumin is continued, and the more concentrated the solution, the greater is the proportion of leucines and leuceïnes formed, whilst under the contrary conditions, the intermediate bodies, or glucoproteïns, constitute the bulk of the fixed residue, representing the initial terms of the hydration of albumin; under all circumstances caproic leucine and tyrosine appear to be the ultimate terms of the decomposition.

The mechanism of the reaction would therefore appear to admit of the following explanation. The albuminoid molecule losing ammonia and carbon as carbonic, oxalic, and acetic acids, and assimilating water, is converted into a comparatively simple mixture of glucoproteïns, $C^aH^{2a}N^2O^4$, containing as its principal term $C^9H^{10}N^2O^4$: by the prolonged action of baryta, and a high temperature, these glucoproteïns split up partly into leucines and leuceïnes, and partly into double compounds formed by the union of glucoproteïns and leuceïnes with the leucines.

Schützenberger regards albumin as an imido-derivative, which by hydration is changed into a mixture of amido-derivatives.

On the reaction of Proteids with Bromine, see W. Knop (*Chem. Centr.* 1875, 395, 411, 426; *Jahresb. f. Chem.* 1875, 810).

Digestion of Proteids.—All proteids hitherto examined may be resolved by the action of acid gastric juice (pepsin and hydrochloric acid) into two bodies or groups of bodies. On the one hand, there are formed the known decomposition-products of proteids, viz., the soluble peptones, acid-albumins, &c., while, on the other, a sharply defined portion remains undigestible. This latter appears to contain, together with nitrogen and phosphorus, a compound nearly related to nuclein (A. Stutzer, *Ber.* xiii. 251).

Action of Alkaloids on Proteids.—According to M. J. Rossbach (*N. Rep. Pharm.* xxii. 512), the proteids contained in the various tissues of the body and in the protoplasm, lose their affinity for ozone under the influence of alkaloids at 30°–40°, and at higher temperatures, but below that at which ordinary albumin coagulates they are precipitated in combination with the alkaloids. These reactions are subject to numerous variations according to the particular proteids and alkaloids concerned in them. The combination of ozone with *hemoglobin* is strengthened by alkaloids, and its transference therefrom to other bodies more or less prevented. The diminution of oxidability of the protoplasm by alkaloids is therefore determined by the alteration of the proteids, and the increased stability of the combination of ozone with *hemoglobin*.

Compounds with Cupric Oxide.—Compounds of legumin, conglutin, and gluten-casein with cupric oxide have been prepared by H. Ritthausen (*J. pr. Chem.* [2], v. 215). These bodies are precipitated by solution of cupric sulphate from nearly all liquids containing proteids, provided that the acids or alkalis used to hold the proteids in solution are present only in slight excess. The three modifications of plant-casein just mentioned react very differently with cupric solutions. Legumin in combination with cupric oxide not only remains unaltered, but shows little inclination to dissolve in water; conglutin suffers partial decomposition, attended with elimination of ammonia, and becomes somewhat soluble in water; gluten-casein is but very slightly altered, but dissolves in water in considerable quantity. These observations have been extended by Ritthausen a. Pott (*J. pr. Chem.* [2], vii. 361) to the compounds of cupric oxide with milk-casein and with the proteids which are soluble in alcohol and water. These compounds dissolve in cold dilute potash-ley and are precipitated unaltered on neutralisation. The quantity of cupric oxide which a proteid can take up, with formation of a soluble compound, is distinctly limited, and of various amount for different proteids. The compounds in question are well adapted for the quantitative estimation of proteids. According to Stutzer (*Ber.* xiii. 251), the method of precipitation with cupric salts may be advantageously applied to the separation of proteids from other nitrogen-compounds occurring in plants, e.g. amygdalin, solanine, leucine, tyrosine, asparagine, alkaloids, thiocarbamides, nitrates, ammonia-salts.

Optical and Chemical Characters of certain Proteids, especially of Dialysed Albumins.—The following observations have been made by H. Haas (*Chem. Centr.* 1876, 295, 811, 824). (1). Egg-albumin and serum-albumin cannot be freed by dialysis from the whole of their inorganic salts, the dry albumin obtained from the dialysed solutions yielding on the average 1 per cent. of ash. (2). Albumin-solutions freed from salts as completely as possible, exhibit, on boiling, or on addition of alcohol, at least a strong opalescence, and in most cases strong turbidity and even precipitation. The alteration thus exhibited by albumin in presence of only small quantities of salts is the same as that exhibited by natural solutions of albumin, although the two liquids may differ in external appearance; the change which takes place in a solution of albumin, freed as far as possible from salts, must, therefore, also be regarded as coagulation. (3). The flocculent precipitation of albumin by hydrochloric acid or an acid phosphate is mainly dependent on the quantitative relation between the albumin and the precipitant, and is altogether independent of the concentration of the solution. The precipitation of albumin by acids in the form of flocks may therefore be regarded as a chemical process, whereas its precipitation by salts depends upon the proportion of water present, and must be looked upon as a physical change. (4). The albumin at the end of the dialysis often exhibits an acid reaction, even when an excess of alkali or alkaline carbonate was before present, but it is not yet determined whether the acid reaction belongs to the albumin itself or is determined by the presence of foreign substances. From his own experiments, Haas inclines to the view that the reaction of pure albumin-solutions is neutral. (5). The specific rotatory power of egg-albumin is -38.08° ; that of serum-albumin was found in two experiments to be -62° , in a third -55.75° ; that of *fibrinogen-substance*, prepared from an ascitic fluid,

was -59.75° ; that of sodium albuminate -55° . (6). The specific rotatory power of natural albumin-solutions is not altered by the salts which they contain, no matter in what quantity these salts may be present.

Comparison between Animal and Vegetable Proteids.—The following analyses of albumin, casein, and fibrin of animal and vegetable origin, agreeing nearly with those of other chemists (i. 67, 811; ii. 640; vi. 975), have been made by A. Brittner (*N. Rep. Pharm.* xxi. 66–108 and 129–150):

	C	H	N	O	S
Egg-albumin	54.00	16.55	6.99	22.82	1.63
Blood-albumin	53.50	15.60	7.14	22.46	1.30
Plant-albumin	54.98	15.84	7.31	20.65	1.22
Blood-fibrin	52.40	18.07	7.03	21.29	1.22
Plant-fibrin	53.82	16.04	7.30	21.80	1.04
Animal-casein	54.67	15.78	7.46	22.97	1.12
Plant-casein	53.94	16.47	7.16	21.93	0.50

From these numbers it is inferred that the proteids of the animal organism are merely modifications of those previously formed in the plant.

With regard to the properties characteristic of the members of these several groups, Brittner makes the following remarks: Blood-fibrin and plant-fibrin react in exactly the same manner as egg-, blood-, and plant-albumin, with strong hydrochloric and strong nitric acid at the boiling heat; with aqueous solution of iodine; with a mixture of sugar and dilute sulphuric acid on heating; with alkaline solution of cupric sulphate; and with Millon's reagent (vi. 970, footnote). Solutions of casein and legumin are precipitated, like solutions of albumin, by alcohol, tannic acids, mineral acids, and metallic salts,—also by organic acids, which is not the case with albumin. Casein dissolves both in alkaline liquids and in very dilute acids, but not in water.

Comparative observations on proteids of animal and vegetable origin have also been made by Th. Weyl (*Pflüger's Archiv. f. Physiologie*, xii. 635; *Zeitschr. physiol. Chemie*, i. 72).

Vitellin, from egg-yolk dissolved in dilute aqueous sodium chloride, coagulates at 75° if the solution is neutral; on gradually raising the temperature, partial coagulation-takes place at 70° , but if the heat be quickly increased, coagulation does not commence below 80° . A body resembling vitellin in all known reactions was found in human amniotic liquor in a case of disease. Vitellin dissolved in solution of common salt and precipitated by water is easily converted, on prolonged immersion in water, into an albuminate (casein); it is then insoluble in solution of sodium chloride, but dissolves in a 1 per cent. solution of sodium carbonate. Recently prepared vitellin, dissolved in a 1 per cent. solution of sodium carbonate, is but slowly precipitated by water alone, but on passing carbon dioxide into the solution, an abundant precipitation takes place. On adding a drop of sodium carbonate solution to water in which vitellin is suspended, the liquid immediately becomes clear, but soon again turbid, and clarifies itself on repeated addition of the alkaline carbonate, becoming turbid again soon after. This effect may be repeated three or four times in the same liquid, and appears to be peculiar to globulins dissolved in a 1 per cent. solution of sodium carbonate and reprecipitated by carbonic acid. Myosin from horse-flesh, dissolved in a 10 per cent. solution of sodium carbonate, coagulates at 55° – 60° , and is converted by prolonged contact with water into albuminate, and then becomes insoluble in dilute solution of common salt: it is not so easily precipitated by water as vitellin. Weyl has never been able to detect it in albuminous urine. Serum-globulin, prepared from the serum of ox-blood by diluting with water, neutralising with acetic acid, and passing carbon dioxide into the liquid, dissolves in a 10 per cent. solution of sodium chloride, and is precipitated therefrom by water or by saturation with sodium chloride, incompletely, however, in the latter case. The neutral solution coagulates at 75° . Serum-globulin is converted by prolonged contact with water into albuminate; after drying in a vacuum over sulphuric acid, it may be heated gradually up to 100° without alteration of its properties. Serum-casein, prepared according to Kühne's directions, agrees in all its reactions with Kühne's globulin. Since now paraglobulin (fibrinoplastic substance) differs from Kühne's globulin only by the admixture of the fibrin-ferment, and as, moreover, no difference has hitherto been made out between globulin and serum-casein, it follows that blood-serum contains only one globulin-substance, namely, serum-globulin.

The existence of vegetable proteids soluble in water, like egg-albumin, has not hitherto been demonstrated. Plant-globulins exhibit the same reactions as animal globulins and animal proteids in general. Plant-vitellin, extracted by common salt solution from the seeds of oats, maize, peas, white mustard, and Para nuts, agrees in

all its reactions with vitellin from egg-yolk. The proteids of the Para nut contain membraneless crystals consisting of vitellin, reacting like animal vitellin, and melting at 75°. The membrane of the crystals, which forms only after prolonged contact with water, is a precipitated membrane. The vitellin-crystals are doubly refractive. The ash of vitellin consists mainly of phosphates mechanically mixed with the organic substance. Elementary analysis gave for the pure vitellin, 52.43 per cent. C., 7.12 H., 18.1 N., 0.55 S. The vitellin analysed was free from nucleïn and leicithin, and may therefore be regarded as the purest globulin-substance yet known. The seeds of wheat, peas, oats, white mustard, and sweet almonds contain also a second proteid, viz. plant-myosin, which exhibits all the reactions of the myosin of non-striated muscles (iii. 1066), and coagulates at 55°-60°. Fresh seeds contain no proteids of the casein-group (albuminate). All the substances hitherto designated as plant-casein are artificial products, or have been formed in the seeds by secondary processes, having nothing to do with the natural development of the plant. In contact with water, acids, or alkalis, all globulins, animal or vegetable, are probably converted first into albuminates, afterwards into coagulated proteids.

Ritthausen (*Chem. Centr.* 1877, 567, 586) criticises these results, and likewise controverts the views of Hoppe-Seyler, who, in his 'Physiologische Chemie' (I. Theil, s. 75) regards the proteids contained in buds, young shoots, and seeds as globulin-substances, and expresses the opinion that Ritthausen's statements respecting the vegetable proteids are founded on the analysis, not of pure unaltered proteids, but of substances more or less decomposed and imperfectly purified. Ritthausen, on the other hand, defends his method of preparing vegetable proteids, and on the ground of numerous elementary analyses, regards vegetable proteids as different from those of animal origin.

Transformation of Proteids in the Bodies of Ruminants.—Experiments on goats by Stohmann, Frühling a. Rost (*Landw. Vers.-St.* xii. 396), have led to the following results: 1. The total quantity of albumin decomposed in the body appears as oxidation-products in the liquid and solid excrements. 2. The transformation of albuminous matter is dependent on the quantity of albumin contained in the circulation. 3. The transformation of nitrogenous matter is accelerated by an increase in the quantity of water imbibed. 4. The excretion of nitrogen quickly adapts itself to an increase or nitrogen in the food. 5. With an insufficiency of albumin in the food, the body becomes poorer in albumin. 6. Considerable increase in weight takes place when, together with a sufficiency of albumin, large quantities of non-nitrogenous matters are given. These experiments show that, with regard to the transformation of albuminous matters in the organism, no difference exists between carnivorous and herbivorous animals, excepting that, in the latter, part of the nitrogen leaves the body in the form of hippuric acid.

Albumin. *Reaction with Potassium Hydroxide.*—Kühne, by fusing albumin with potash, obtained a body which he regarded as an isomide of indole, and designated as *pseudo-indole*; and a similar result was obtained by Engler a. Janecke (p. 1089). According to Nencki, however (*J. pr. Chem.* [2], xvii. 97), the product thus obtained is not a single substance, but a mixture of indole with a body called *skatole* (q.v.), obtained also from excrements. Nencki also finds that when fused potash acts on albumin, leucine and tyrosine are formed, in addition to peptones, and that, by further action, volatile fatty acids, especially valeric acid, are produced, with evolution of hydrogen, indole and skatole being formed at the same time. If the fusion is continued for a long time, the amount of peptone-like bodies decreases, and the leucine and valeric acid are gradually converted into butyric acid. The tyrosine is perfectly decomposed, and phenol appears instead. The latter body is probably formed from the tyrosine, since whenever phenol is produced, whether by putrefaction or by the action of potash, tyrosine is wanting, and *vice versâ*.

On the reactions of Albumin with baryta-water, see p. 1681; with chloral, p. 439.

Oxidation.—By oxidation with ammonium permanganate albumin is converted into carbamic acid (p. 382).

Reaction with Cyanogen.—Experiments by O. Loew (*J. pr. Chem.* [2], xvi. 60) on the action of cyanogen on albumin, have led to the following results: (1). Cyanogen is directly taken up by albumin, with simultaneous formation of water. (2). The resulting addition-product, when treated with alkalis, gives up the water and part of the cyanogen, yielding peculiar non-nitrogenised bodies. (3). An atomic group of small molecular weight separates from the albumin, taking up at the same time a relatively large quantity of cyanogen and water (*oxamoidin*).

Coagulation.—Mathieu a. Urbain (*Compt. rend.* lxxvii. 706), by exhausting white of egg with the mercury-pnmp, obtained considerable quantities of carbon dioxide

together with small quantities of oxygen and nitrogen. They consider that carbon dioxide is the agent which brings about the coagulation of the egg-white on heating, and that coagulated egg-white is a compound of protein-substance with carbon dioxide, mixed with compounds, formed on coagulation, of the protein substance with salts contained in the egg-white. Albumin, exhausted by the mercury-pump of its carbon dioxide and volatile salts (ammonium carbonate and sulphide), reacts like globulin, which indeed appears to be the proteid from which the other bodies of the class are formed by addition of small quantities of various substances.

Gautier, on the other hand (*Bull. Soc. Chim.* [2], xxii. 51), found that dilute solutions of egg-albumin through which a stream of hydrogen was passed for several days still remained coagulable by heat (Urbain, *ibid.* 484, doubts whether this treatment would remove the whole of the carbon dioxide); and he further observes that white of egg dried at a low temperature loses the property of coagulating by heat, but recovers it when carbon dioxide is passed through the solution.

Regeneration of Spoilt Albumin in Print-works. In the process of calico-printing, the cloth soaked in a solution of albumin, and then printed with the dye-stuff, is finally exposed to the action of steam, whereby the albumin is coagulated and the dye-stuff fixed. The success of this process, however, requires that the albumin shall be quite fresh and unspoiled, so that a perfect solution of it may be made before the cloth is steeped in it. Albumin which has become insoluble may indeed be rendered soluble again by the action of alkalis or alkaline carbonates, but at the same time it loses the property of coagulating in the steam-bath, which is indispensable to its use in printing. J. Wagner, however, finds that 350–400 grams of spoilt albumin, placed in contact with 30 grams of cold-washed rennet, suspended in a litre of water to which 10 grams of concentrated hydrochloric acid have been added, passes into solution at a temperature of 37.5°C ., and that this liquid, if filtered after standing for twenty-five to thirty hours and neutralised with ammonia, possesses, like the aqueous solution of fresh albumin, the property of coagulating on the steam-bath, and fulfils all technical requirements. According to Witz, pig's stomach acts in this way still more energetically than rennet. It is remarkable that albumin thus dissolved in pepsin is not coagulated by acetic acid. Wagner and Witz also propose to utilise this action of pepsin for freeing spoiled printed goods from the colouring matter fixed on them by coagulated albumin. Blood-fibrin may also be dissolved by means of this reagent more readily than by hydrochloric acid, which, as observed by Bouchardat, is capable by itself of dissolving fibrin (Wagner and Witz, *Dingl. pol. J.* cxcix. 166).

Detection and Estimation of Albumin.—To detect albumin in urine, L. Siebold (*Zeitschr. anal. Chem.* 1874, 248) mixes the liquid with potash to slight alkaline reaction, filters, acidulates the filtrate with acetic acid, and heats a portion of it to boiling. If the heated liquid be now compared with a cold portion contained in another tube, the slightest turbidity in the former will be easily detected. A. Hilger (*Arch. Pharm.* [3], vi. 388) has compared the several methods proposed for the detection of albumin in urine, and gives the preference to Boedecker's method, which consists in precipitating the albumin in acetic acid solution with potassium ferrocyanide, observing however that the nitric acid test and the coagulation test with acetic acid are also worthy of notice.

For quantitative estimation, Girgensohn (*N. Repert. Pharm.* xxii. 557) mixes the solution containing the albumin with half its volume of a 20 per cent. solution of common salt; adds tannin in slight excess; collects the precipitate on a weighed filter; washes it with water till free from salt, and then with boiling alcohol, till no more tannin can be detected in the filtrate: the precipitate then consists of pure albumin. In estimating albumin in urine by this method, uric acid must first be removed by adding acetic acid and leaving the liquid in the cold.

All proteids contained in albuminous urine are precipitated by tannin added in slight excess, and the precipitate when treated with boiling alcohol gives up the whole of the tannin. The albumin in the urine of nephritic patients differs from that which occurs in accidental albuminuria, in the proportion in which it combines with tannin, the former taking up 37 and the latter 28 per cent. of that substance. The albumin of eggs, of serum, and of pathological secretions in general combines with 28 per cent. of tannin.

On Bornhardt's method of estimating albumin in solution by the difference of density of the liquid before and after the precipitation of the albumin, see *Zeitschr. anal. Chem.* 1870, 149; 1877, 124; *Jahresb. f. Chem.* 1870, 1056; 1877, 1088.

Trinitro-albumin, $\text{C}^7\text{H}^{103}(\text{NO}^2)^3\text{N}^{18}\text{SO}^{22}$, is prepared by thoroughly triturating finely-pulverised and well-dried albumin in a cooled capacious mortar with 14–16 times its weight of hydrogen nitrate, NO^2H , perfectly freed from nitrous acid, or by briskly agitating it therewith in a cooled bottle, and after ten to fifteen minutes

quickly mixing the resulting gelatinous mass with a large quantity of water, whereupon the insoluble light-yellow tasteless trinitro-compound separates out. If the gelatinous mass be left to itself for several hours at a temperature below 10° , a small quantity of nitrogen tetroxide is given off, and a solution is formed, which, when diluted with water, deposits a dark yellow tasteless hydroxytrinitroalbumin, $C^{72}H^{100}(NO_2)_3N^{16}(OH)_2(SO_2.OH)O^{22}$.

Trinitro-albumin dissolves without alteration in dilute alkalis, forming a reddish-yellow solution, from which it is precipitated in yellow flocks on addition of an acid. Its solution in strong hydrochloric acid may be boiled for a considerable time without sensible decomposition. Its solution in strong sulphuric acid, heated for some time and then mixed with water, yields a precipitate richer in sulphur than the original compound. Hydroxytrinitroalbumin exhibits similar reactions (O. Loew, *J. pr. Chem.* [2], v. 433).

On Hexnitro- and Hexamido-albumin-sulphonic acids, see vol. vii. p. 645.

Compounds of Albumin with Acids and Alkalis.—Acid compounds of albumin are formed by pouring a solution of white of egg into a parchment-paper dialyser, and leaving it for twenty-four hours in contact with a dilute acid—e.g. nitric, hydrochloric, sulphuric, orthophosphoric, metaphosphoric, citric, oxalic, acetic, or tartaric acid, contained in an outer vessel. Most of these compounds are gelatinous. For a quantity of albumin represented by Lieberkühn's formula, $C^{72}H^{112}N^{18}SO^{22}$, the compounds contain 2 mols. nitric, 2 mols. hydrochloric, 1 mol. sulphuric, $\frac{2}{3}$ mol. phosphoric acid. They are all precipitated by nitric, sulphuric, hydrochloric, metaphosphoric, and picric acid; some also by potassium ferrocyanide, ammonium chloride, basic lead acetate, mercuric chloride, barium chloride, silver nitrate, alcohol, phenol, and tannin (G. S. Johnson, *Chem. Soc. J.* xxvii. 734).

J. Soyka (*Pflüger's Archiv.* xii. 347) finds, from comparative experiments on acid-albumin and alkali-albuminate (vi. 972), that these bodies exactly resemble one another in their reactions, and that the hitherto assumed difference in their precipitability by acids in presence of an alkaline phosphate has no existence. An alkaline solution either of albuminate or of acid-albumin containing phosphate may be mixed with an acid till acid reaction becomes apparent, without formation of a precipitate. At the limit of precipitability, the still transparent solutions exhibit an amphoteric reaction and contain 9 mols. acid phosphate, (MH_2PO_4) , to 1 mol. normal phosphate, (M^2HPO_4) ; if the relative quantity of the acid phosphate is further increased, precipitation takes place. Soyka proposes to retain the names albuminate and acid-albumin, and to designate as protein the body which, in combination with acids, forms acid-albumin, and in combination with a base, albuminate. He considers that, in spite of the concordant reactions of the two, there is no ground for the assumption that acid-albumin and albuminate are identical in composition and constitution. Even if albuminate and acid-albumin prepared from albumin exhibit no differences in their precipitates, such differences become apparent when these precipitates are compared with those of syntonin and albuminate which have been prepared from flesh. Whether these differences arise from a diversity in the proteins of these substances, or are due to admixtures, is a point which cannot yet be decided, as neither the elementary analyses nor the decomposition observed by Nasse (vii. 1023) afford any satisfactory evidence relating to it. Soyka refers the acid-albumins and albuminates to one and the same albuminoid-group (both as above-mentioned containing protein united in the one case with an acid, in the other with a base), and divides the soluble proteids into three groups: *albumins*, *proteins*, and *globulins*.

According to Heynsius (*Arch. néerl.* x. 1), the alkali-albuminates differ from one another according to the concentration of the alkali used in their preparation; para-globulin is identical with the albuminate obtained with weak alkali. The acid-albumins also differ from one another according to the concentration of the acid used in preparing them.

All albuminates when dissolved in excess of glacial acetic acid, and treated with strong sulphuric acid, exhibit a splendid violet colour and faint fluorescence, and if sufficiently concentrated, an absorption in the spectrum, which, like that of urobilin and the red oxidation-product of bile-pigment (choletelin) lies between the lines B and F. Bodies not chemically related to the albuminates do not exhibit this reaction. Peptones (p. 1688) exhibit it, and must therefore be classed with the albuminates (Adam Kiewicz, *Ber.* viii. 161).

Paralbumin.—This variety of albumin, which Scherer obtained from an ovarian cyst (i. 68), exhibits, according to Huppert (*Zeitschr. anal. Chem.* xvi. 248) the following characteristic reactions: (1). It does not separate on boiling from a solution to which acetic acid has been added, differing therein from serum-albumin, which by proper regulation of the quantity of acetic acid, may be completely separated on boiling in

large flakes, the liquid becoming quite clear; a solution of paralbumin similarly treated always remains milky whatever may be the quantity of acetic acid added. (2). When a liquid containing paralbumin is digested for some time in a water-bath with hydrochloric acid of 0.1 per cent., sugar is produced. Paralbumin is not peculiar to ovarian cysts, but occurs also in other cysts, and in the liquid of ascites.

Casein. The identity of casein with potassium albuminate, on which doubts have been thrown (vi. 973), is confirmed by the following facts: (1). Both casein from milk and artificially prepared potassium albuminate are precipitated from alkaline solutions by rennet. (2). Neither of them is precipitated by sodium carbonate. (3). The filtration of the two bodies through cells of porous earthenware is influenced by the same circumstances. (4). Both are decomposed by alkaline hydroxides under otherwise similar circumstances, with formation of a sulphide of alkali-metal. (5). The differences observed in the optical rotatory power of the two are not sufficient to show that they are distinct bodies (Soxhlet, *J. pr. Chem.* [2], vi. 1).

According to Béchamp (*Compt. rend.* lxxviii. 1575), casein is decomposed at 140°, part becoming soluble in alkalis, the other not; a small portion of the latter, however, dissolves in acetic acid. A solution of casein in acetic acid yields, on evaporation in a vacuum, an inodorous horny mass having a sour taste. 100 pts. of casein take up 33.1 acetic acid. Butyric acid likewise unites easily with casein.

Conversion of Casein into Albumin.—The addition of a drop of mustard-oil to 20 grams of cow's milk prevents the coagulation of the milk, and after five to seven weeks, the casein is found to be converted into albumin, the liquid having a strong acid reaction. This transformation of casein appears to be a process of oxidation. If the milk treated with mustard-oil be poured into an earthenware cell standing in a solution of permanganate, considerable quantities of albumin are formed in a few days (Schwalbe, *Ber.* v. 286).

On the Separation of Casein from Milk by Dialysis, see MILK (p. 1326). On the Morphology of Milk-casein, see F. A. Kehrér (*Arch. f. Gynäkologie*, ii. 1; *Jahresb. f. Chem.* 1874, 931).

Fibrin. According to J. Goodman (*Rep. Br. Assoc.* 1871, 72), egg-albumin in contact with water is converted in a short time into fibrin; compare Smee (ii. 639). On the other hand, albumin may be produced by decomposition of fibrin. When blood-fibrin is dissolved in salt water, the liquid, mixed with a trace of prussic acid, to prevent putrefaction, and subjected to dialysis till the salt is almost completely removed, the solution thus freed from salt is found to contain two proteids, evidently resulting from the decomposition of the fibrin, one coagulable by heat, precipitated by mineral acids and mercuric chloride, and exhibiting the percentage composition of albumin, while the other is not coagulated by heat and yields an ash rich in calcium phosphate and magnesia (Gautier, *Compt. rend.* lxxix. 227).

Iron in Fibrin.—The proportion of iron in the fibrin, blood-corpuscles, and albumin obtained from the blood of a half-fatted cow has been determined by Boussingault (*Arch. Pharm.* [3], iii. 526). The amounts per cent. in the air-dried substances were found to be:

	Ash	Iron
Fibrin	2.151	0.0466
Corpuscles	1.325	0.3500
Albumin	8.715	0.0863

Pancreatic Digestion.—The products of the pancreatic digestion of fibrin yield a distillate exhibiting the reactions of indole (Nencki, *Ber.* vii. 1593). Other proteids similarly treated likewise yield indole (p. 1089).

On the Coagulation of Fibrin, see A. Schmidt (*Compt. rend.* lxxxiv. 78, 112; *Chem. Soc. J.* xxxi. 483, 726), and O. Hammarsten (*Pflüger's Archiv. f. Physiologie*, xiv. 211–273; *Chem. Soc. J.* xxxi. 726).

On Myosin, see p. 1684.

Peptones. The preparation and reactions of these bodies have been studied by R. Maly (*Liebig's Annalen*, clxxv. 178). To prepare them, purified dry fibrin, after maceration in dilute hydrochloric acid, is digested for two or three days with pepsin, and the resulting solution is neutralised with sodium carbonate, boiled, filtered, and evaporated. It is then subjected to prolonged dialysis to remove chlorides, and the peptone-solution removed from the dialyser is filtered, if necessary, concentrated, and fractionally precipitated with alcohol.

This peptone solution gives with acetic acid and potassium ferrocyanide a precipitate which dissolves in hydrochloric and in nitric acids—a reaction likewise exhibited

by proteids in their original state. As the mean of several analyses of various peptone-preparations, Maly found 51.40 per cent. C, 6.95 H, and 17.31 N. He regards peptone, not as a mixture of decomposition-products of proteids, but as a distinct and independent substance, differing but little in elementary composition from the proteid from which it is produced.

To determine the nutritive value of peptone, respecting which opinions have hitherto been much divided, Maly made experiments on pigeons with peptone prepared from blood-fibrin in the manner above described, the quantity given being exactly equivalent to the albumin in the food previously supplied to the birds. These experiments led to the conclusion that peptone is still an unresolved protein-molecule, capable of replacing albumin, useful and available for the organism, and a product of digestion capable of reconstruction into albumin and assimilation by the organism.

Peptones dissolved in glacial acetic acid, and treated with strong sulphuric acid, exhibit the same violet colour, fluorescence and absorption-spectrum as unaltered proteids, whereas bodies not related to the proteids do not exhibit these appearances. Hence it follows that all peptones stand to the proteids in a closer relation than the products of decomposition of those bodies, such as leucine, tyrosine, &c. (Adamkiewicz, *Ber.* viii. 161).

According to Huppert (*Ber.* vi. 1279), the so-called 'peptone,' obtained by pancreatic digestion of proteids, is a mixture of leucine, tyrosine, and at least two other substances as far removed from the proteids as the two just mentioned.

Detection in Urine.—To detect peptones in albuminous urine, Senator (*Zeitschr. anal. Chem.* vii. 474) removes the albumin in the ordinary way, by heating with or without addition of acetic acid, and mixes the filtrate with three times its bulk of alcohol, whereby the peptone is thrown down in the form of a yellow precipitate which is insoluble in alcohol but soluble in water, and is coloured yellow by nitric acid.

Appendix to Proteids.

Gelatinous Substances. From experiments by Schützenberger a. Bourgeois (*Compt. rend.* lxxxii. 262), it appears that when isinglass, ossein, gelatin, and chondrin are decomposed by the method applied by Schützenberger to proteids (p. 1681), they likewise yield ammonia, carbon dioxide, and oxalic acid, in such proportions as to show that they consist of urea and oxamide. The analysis of the mixture of amido-compounds thus produced shows that the mode of decomposition is nearly the same for isinglass, ossein, and glue, but somewhat different for chondrin. For the first three bodies it may be represented by the equation:

The mixture of amides is composed as follows:

For chondrin the mode of decomposition is:

Gelatin boiled with dilute sulphuric acid yields, according to Gaehtgens (*Zeitschr. physiol. Chem.* i. 299), aspartic and glutamic acids in small quantity, a compound $\text{C}^{11}\text{H}^{22}\text{N}^2\text{O}^6$, crystallising in prisms, and two substances agreeing nearly in composition with alanine and amidobutyric acid respectively. Gaehtgens thinks it probable that the compound $\text{C}^{11}\text{H}^{22}\text{N}^2\text{O}^6$ may be resolvable by repeated crystallisation into $\text{C}^3\text{H}^7\text{NO}^2$, $\text{C}^4\text{H}^9\text{NO}^2$, and $\text{C}^4\text{H}^7\text{NO}^2$.

According to Bizio (*Gazz. chim. ital.* 1876, 255), a slightly alkaline solution of gelatin reduces mercuric chloride and oxide, with separation of metallic silver.

Nutritive value of Gelatinogenous Tissues, &c.—From experiments by J. Etzinger (*N. Rep. Pharm.* xxxii. 535) it appears that bones, cartilage, and tendons, by virtue of

the gelatinous substance contained in them, play an important part in animal nutrition. Tendons are the most readily digested; bones pass so rapidly through the alimentary canal, that only a small portion of their organic substance is absorbed during the passage. As gelatinous tissues contain but a small proportion of albumin, their nutritive value must be proportional to the quantity of gelatin which can be obtained from them; they are capable of saving a large quantity of albumin, which would be decomposed in their absence.

C. Voit (*Zeitschr. f. Biologie*, viii. 297) finds, by feeding experiments on animals, that gelatin is not capable of entirely replacing albumin in nutrition. In the animal body a distinction must be made between circulating albumin and organic albumin. The former is subject to rapid decomposition; the latter is not decomposed as such, but is converted into circulating albumin only when the food does not contain a quantity of albumin sufficient to cover the loss of circulating albumin. If the food contains an excess of albumin, that excess is stored up as organic albumin. Now gelatin can never yield organic albumin, but it may replace the circulating albumin in so far as it prevents the conversion of organic into circulating albumin. In a large dog, 168 pts. of gelatin were found to be capable of replacing 84 pts. of albumin in the food. Gelatin also diminishes the waste of fat in the body, 200 pts. of gelatin acting in the same way as 74 pts. of fat.

PROTocatechuic Acid, or [1 : 3 : 4] **DIhydroxybenzoic**

Acid, $C^7H^6O^4 = COOH \begin{array}{c} OH \\ \diagup \quad \diagdown \\ \text{C}_6\text{H}_2 \end{array} OH$. On the formation and constitution of this acid, see vii. 431, 932, 1023; viii. 289. On its formation from Narcotine-derivatives, viii. 1884. It is also produced by the action of melting potash on iodoparahydroxybenzaldehyde, $C^6H^4I(OH)(CHO)$ (Tiemann & Herzfeld, *Ber.* x. 213), on Peruvian guaiac-resin (p. 899), and on angelica-resin (C. Brimmer, *N. Rep. Pharm.* xxiv. 641).

Action of Nitrous gas.—When this gas is passed into an ethereal solution of protocatechuic acid, nitrogen dioxide and carbon dioxide are evolved, and a complicated reaction takes place, resulting in the formation of oxalic acid, carboxytartronic acid, dinitrodihydroxyquinone, trinitrophenol, α -dinitrophenol, and nitrohydroxybenzoic acid. On shaking up the ethereal solution with water, and adding sodium carbonate to the resulting aqueous solution, sodium carboxytartronate, $C^4H^2Na^2O^7$, separates out as a heavy white crystalline powder. When the filtrate from this precipitate is neutralised with sodium carbonate, glistening yellow scales of sodium dinitrodihydroxyquinone are deposited. The mother-liquor contained oxalic acid and a nitro-product which could not be isolated.

Sodium carboxytartronate is decomposed by water (in which it is almost insoluble) at 60°, carbon dioxide being given off and sodium tartronate formed:

The same change takes place when the dry sodium salt is heated at 100°. Carboxytartronic acid has not been isolated.

Sodium-dinitrodihydroxyquinone, $C^6Na^2H^2O^8 + 2H^2O$, has a strong metallic lustre, and the colour of brass. It dissolves freely in hot water, forming a brown solution. The free acid is very unstable; it crystallises in long greenish-yellow needles, which are freely soluble in water or alcohol, and but sparingly in ether.

On evaporating the ethereal solution of the crude product of the action of nitrous gas on protocatechuic acid, a mixture of picric acid, α -dinitrophenol, and nitrohydroxybenzoic acid is deposited. The mother-liquor contains picric and oxalic acids, and a small quantity of a nitro-product which dissolves in potash with a splendid purple coloration.

The nitrohydroxybenzoic acid was separated from α -dinitrophenol by recrystallisation from cold alcohol, in which the latter is sparingly soluble, and purified by recrystallisation from hot benzene, from which it is deposited on cooling, in compact yellow needles (m. p. 178°), freely soluble in alcohol, ether, and hot water. The hydrochloride of the amidohydroxybenzoic acid, obtained by reduction of the nitro-acid with tin and hydrochloric acid, crystallises in slender needles. The sulphate forms microscopic crystals (Gruber, *Ber.* xii. 514).

HOMOLOGUES OF PROTOCATECHUIC ACID AND ALLIED COMPOUNDS (F. Tiemann, *Ber.* xi. 659).

The compounds containing the common group $\begin{array}{c} \text{O} \\ \diagup \diagdown \\ \text{C}^{\text{H}^3} \end{array} \text{—C}\equiv$, and therefore derivable from protocatechuic acid, $\begin{array}{c} \text{HO} \\ \diagup \diagdown \\ \text{C}^{\text{H}^3} \end{array} \text{CO.OH}$, may be arranged in four parallel series, viz.:

1. The *Protocatechuic series proper*, the members of which contain in the side-chain a single carbon-atom $\text{—C}\equiv$.
2. The *α -Homoprotocatechuic series*, the characteristic group of which is the side-chain $\text{—CH}^2\text{—C}\equiv$.
3. The *Hydrocaffaic series*, the members of which contain in the side-chain the group $\text{—CH}^2\text{—CH}^2\text{—C}\equiv$.
4. The *Caffeic series*, containing in the side-chain the group $\text{—CH=CH—C}\equiv$.

The first of the two following tables (p. 1692) exhibits the constitution and melting points of the known acids of these protocatechuic series, from which it will be seen that the melting point of an acid in each homologous series is for the most part lower as the position of the acid in that series is higher; and, on the other hand, that a gradual rise of melting point takes place on passing from the hydrocaffaic to the caffeic series. The second table shows the relations, in constitution and melting point, of the acids of the protocatechuic series proper to the corresponding aldehydes and alcohols, and to the phenols formed from the acids by conversion of the COOH -group into CH^3 .

The letters *m* and *p* in these tables denote that the radicles to which they are attached are in the *meta* and *para* positions with respect to the carboxyl-group.

Methyl-protocatechuic Acids:

Vanillic acid	$\text{C}^{\text{H}^3}(\text{COOH})(\text{OCH}^3)(\text{OH})$
Isovanillic acid	$\text{C}^{\text{H}^3}(\text{COOH})(\text{OH})(\text{OCH}^3)$
Veratric acid	$\text{C}^{\text{H}^3}(\text{COOH})(\text{OCH}^3)(\text{OCH}^3)$

These acids have already been described (under DIOXYBENZOIC ACIDS, pp. 289–292). The following additional observations on them have been recently published by K. U. Matsumoto (*Ber.* xi. 122).

Isovanillic acid is best prepared by heating veratric acid (2 grams) for five hours at $160^\circ\text{--}170^\circ$ with dilute hydrochloric acid (75 c.c. of a mixture of 1 pt. hydrochloric acid, sp. gr. 1.20, and 2 pts. water), and may be purified by boiling it with acetic acid, and pouring the product into water, whereupon acetisovanillin separates out, while veratric acid remains in solution. The acetyl-compound, boiled with dilute potash-solution, yields pure isovanillic acid. This acid crystallises in shining transparent prisms, like those of vanillic acid, and melts at 250° . It is soluble in alcohol and ether. Its aqueous solutions give no reaction with ferric chloride. The alkaline isovanillates are easily soluble in water, and those of barium, calcium, and magnesium are tolerably soluble salts, crystallising in needles. The lead salt is obtained as a difficultly soluble white crystalline precipitate; the silver salt is also white, and is decomposed by light less rapidly than the vanillate.

The following are the solubilities of the three methylated protocatechuic acids in water:

				Pts. of water,	
				at 14°	at 100°
1 pt. veratric acid	.	.	(m. p. $174^\circ\text{--}175^\circ$)	2100–2150	160–165
1 „ vanillic acid	.	.	(„ 207°)	850–860	39–40
1 „ isovanillic acid	.	.	(„ 250°)	1650–1700	155–160

The methyl and ethyl ethers of these acids were obtained by passing hydrochloric acid gas through a solution of the acid in the respective alcohols.

Methyl Vanillate, $\text{C}^{\text{H}^3}(\text{OCH}^3)\text{OH.COOCCH}^3$, crystallises in shining white needles melting at $62^\circ\text{--}63^\circ$. It boils at $285^\circ\text{--}287^\circ$, and is not attacked by alkalis at the ordinary temperature.

Methyl Veratrate, $\text{C}^{\text{H}^3}(\text{OCH}^3)_2\text{COOCH}^3$, is difficultly soluble in water, easily in ether and alcohol, and crystallises from its alcoholic solution in white needles. It melts at $59^\circ\text{--}60^\circ$, and boils at 300° , is odourless, and not attacked by ammonia or alkalis at the ordinary temperature. This ether may also be prepared by heating potassium hydrate, methyl iodide, and vanillic acid in sealed tubes. The product of the reaction is then shaken up with ether, and the ethereal solution treated with dilute solution of potassium hydrate to remove unaltered vanillic acid.

TABLE I.—*Acids.*

Protocatechuic series proper	Alpha-homoprotocatechuic series	Hydroprotocafic series	Caffeic series
Protocatechuic acid $C^6H^3(OH)_m(OH)_pCOOH$ M. P. 178°	Alpha-homoprotocatechuic acid $C^6H^2(OH)_m(OH)_pCH^2-COOH$ M. P. 127°	Hydroprotocafic acid $C^6H^2(OH)_m(OH)_pCH^2:CH^2:COOH$ M. P. (?)	Caffeic acid $C^6H^2(OH)_m(OH)_pCH=CH-COOH$ Decomposes without melting at any particular temperature

Ethyl Veratrate crystallises in colourless needles, soluble in alcohol and ether, melts at 43°–44°, and boils at 295°–296°.

Methyl Nitroveratrate, $C^6H^2(NO^2)(OCH^3)^2CO^2CH^3$, prepared, like the ethyl-compound (p. 290), from nitroveratric acid, is sparingly soluble in water and cold alcohol, but dissolves easily in boiling alcohol and ether, and crystallises in needles melting at 143°–144°.

Methyl Isonitroveratrate, produced by heating nitrovanillic acid with methyl iodide and potassium hydrate, dissolves sparingly in water, readily in alcohol and ether, and crystallises from dilute alcohol in hard shining needles melting at 127°–128°. The difference in properties between this and the preceding ether shows that the position of the nitro-group in nitrovanillic acid is different from that which it occupies in nitroveratric acid. The last-described ether yields by saponification isonitroveratric acid, $C^6H^2(NO^2)(OCH^3)^2COOH$, which crystallises in white anhydrous needles melting at 200°–202°.

Ethyl Amidoveratrate, $C^6H^2(NH^2)(OCH^3)^2CO^2C^2H^5$, is produced by treating the corresponding nitro-ether with tin and hydrochloric acid, and may be separated from the solution of its hydrochloride by dilute soda-ley or ammonia. It crystallises from dilute alcohol in small colourless needles melting at 88°–89°.

Acetisovanillic acid, $C^6.CO^2OH.H.CO^2H^3O.OCH^3.H^2$, prepared, like acetovanillic acid (p. 290), by digesting isovanillic acid at 100° and precipitating with water, crystallises from dilute alcohol in shining scales melting at 206°–207°, very slightly soluble in water, easily soluble in alcohol and ether.

Nitro-acetisovanillic acid, $C^6H^2(NO^2)(O.C^2H^3O)_m(OCH^3)_pCOOH$, prepared like nitro-acetovanillic acid (p. 290), crystallises in shining needles melting at 168°–169°, sparingly soluble in cold water, more freely in hot water, easily in alcohol and ether. By boiling with alkalis, it is converted into *nitroisovanillic acid*, $C^6H^2(NO^2)(OH)_m(OCH^3)_pCOOH$, which crystallises from hot water in spherical groups of needles melting at 172°–173°, easily soluble in alcohol and ether.

Bromoveratric acid, $C^6H^2Br(OCH^3)^2COOH$, first obtained, though not pure, by Kölle (vii. 432), may be prepared by adding bromine (rather more than 1 mol.) to a hot aqueous solution of 1 mol. veratric acid. A red resin then separates, and from the liquid decanted therefrom the brominated acid crystallises in colourless needles melting at 183°–184°. It is nearly insoluble in cold water, slightly soluble in hot water, easily in alcohol and ether. By fusion with potash it yields gallic acid.

The red resin contains dibromodimethylcatechol, or dibromoveratrol, $C^6H^2Br^2(OCH^3)^2$, which may be extracted from it by solution in alcohol, and separates from the alcoholic solution, first as an emulsion, afterwards crystalline. From dilute alcohol it crystallises in hard shining prisms melting at 83°–84°.

Bromoacetovanillic acid, $C^6H^2Br(OCH^3)(OC^2H^3O)COOH$, is produced, together with bromovanillic acid, by bromination of acetovanillic acid, and crystallises from hot water or dilute alcohol in anhydrous prisms melting at 165°–167°.

Bromovanillic acid, $C^6H^2Br(OCH^3)(OH)COOH$, obtained by the action of potash-ley on its aceto-derivative, is much more soluble in water than the latter, very soluble in alcohol and ether, and crystallises from hot water with 1 mol. H^2O , which is given off at 100°–110°. The dehydrated compound melts at 192°–193°. When heated with methyl iodide and potassium hydrate, it is converted into the methyl-ether of the above-described bromoveratric acid. Hence it appears that—contrary to what takes place with the nitro-group,—the bromine replaces in acetovanillic acid the same hydrogen-atom as in acetoveratric acid.

Caffeic and Ferulic Acids. The following details respecting the preparation and properties of these acids, and some of their derivatives, are given by F. Tiemann a. Nagajosi-Nagai (*Ber.* xi. 658).

Acetovanillin, $C^6H^3(COH)(O.C^6H^3)(O.C^2H^3O)$, is best prepared by allowing the sodium-compound of vanillin to remain in contact with an ethereal solution of acetic anhydride for some hours. It forms large flat needles which melt at 77°; it is easily soluble in alcohol and ether, but only sparingly in water.

Acetoferulic acid, $C^6H^3(CH=CH.CO^2OH)(O.C^6H^3)(O.C^2H^3O)$, is formed by heating either vanillin or the preceding compound with anhydrous sodium acetate and acetic anhydride. It crystallises in slender needles melting at 196°–197°; it is readily soluble in alcohol and ether, but with difficulty in water.

Ferulic acid, $C^6H^3(CH=CH.CO^2OH)(O.C^6H^3)(OH)$, results from the decomposi-

tion of the preceding compound by sodium hydrate. This synthetic acid crystallises from boiling water in brittle, high refractive prisms, melting at 168° – 169° , which is also the melting point of ferulic acid prepared from asafetida (p. 785). In order, finally, to establish the identity of these products: (1) the latter was heated with acetic anhydride, and found to yield a body identical in all respects with the acetoferulic acid described above; and (2) the acetoferulic acid thus prepared from the 'natural' acid was oxidised by potassium permanganate in acetic acid solution, and found to yield acetovanillin and acetovanillic acid.

In ferulic acid the hydrogen both of the carboxyl-group and of the phenolic hydroxyl is capable of being replaced by metals, so that it yields two classes of salts, of which the primary ammonium and secondary potassium salts have been obtained by Hlasiwetz. Ferulic acid is a hydroxyl-methoxyl-cinnamic acid, and can readily take up two hydrogen-atoms, forming hydroferulic acid.

Hydroferulic acid, $C^mH^p(OH^2.CH^2.COOH)(OCH^3)(OH)$, is easily obtained by the action of reducing agents upon ferulic acid. It crystallises from its aqueous solution in microscopic plates (m. p. 89° – 90°), which are very easily soluble in alcohol, ether, and hot water. Like the preceding it forms two classes of salts.

Dimethylcaffeic acid, $C^mH^p(CH=CH.COOH)(O.CH^3)^2$, or *Methylferulic acid*, may be prepared by replacing either the two hydroxyl-groups of caffeic or dioxy-cinnamic acid, or the single hydroxyl-group of ferulic acid with methoxyl, by heating them with potash and methyl iodide in methyl-alcohol solution. Dimethylcaffeic acid crystallises in needles which melt at 180° – 181° . It is monobasic, and forms easily soluble salts with the metals of the alkalis and alkaline earths.

Hydrodimethylcaffeic acid, $C^mH^p(CH^2.CH^2.COOH)(OCH^3)^2$, was obtained by reduction from dimethylcaffeic acid prepared either from ferulic acid or from caffeic acid: the products were identical. This acid crystallises from its aqueous solution in slender needles which melt at 96° – 97° to an oil which solidifies at 60° .

Isoferulic acid, $C^mH^p(CH=CH.COOH)(OH)(OCH^3)$, is formed by heating caffeic acid with methyl iodide and potassium hydrate in quantity less than sufficient for the complete replacement of its hydroxyl. The methyl ethers of isoferulic and dimethylcaffeic acids thereby obtained are easily separated, and the isoferulic acid may be isolated, after saponification, in the form of crystals which melt at 211° – 212° . It forms two classes of salts.

Hydroisoferulic acid, $C^mH^p(CH^2.CH^2.COOH)(OH)(OCH^3)$, is readily formed from the preceding acid by reduction. The pure acid forms slender colourless needles which melt at 146° to an oil which solidifies at 133° .

Synthesis of Caffeic Acid.—By the action of sodium acetate and acetic anhydride on protocathechuic aldehyde, the latter is converted into a diacetocaffeic acid, $C^mH^p(CH=CH.COOH)(OC^2H^3O)(OC^2H^3O)$, identical in every respect with that which is obtained by the action of acetic anhydride on caffeic acid; it crystallises in slender needles, melts at 190° – 191° , and when heated with potash-solution, is readily converted into caffeic acid.

PSEUDAACONITINE and ALLIED BASES (Wright a. Luff, *Chem. Soc. J.* xxxiii. 151; xxxv. 387; *Chem. News*, xxxvii. 67, 245; xxxix. 224).

Pseudaconitine, $C^{36}H^{49}NO^{12}$, is the chief basic constituent of *Aconitum ferox*, but is very difficult to obtain in the pure state, as in the process of extraction it is partly converted, by loss of H^2O , into *apopseudaconitine*, $C^{36}H^{47}NO^{11}$, which adheres to it with great obstinacy, and it is only after a long process of purification (described in the paper above cited) that the pseudaconitine exhibits the composition represented by the formula $C^{36}H^{49}NO^{12}$.

Pure pseudaconitine is more soluble in alcohol and ether than aconitine, and crystallises by slow evaporation from ether, or better from a mixture of ether and light petroleum, in transparent needles and sandy crystals; after rapid evaporation it remains syrupy. In the air-dried state it contains 1 mol. water of crystallisation, which is given off at 80° in a stream of air, and more quickly at 100° , the residue at the same time slightly caking together. At 104° – 105° it melts to a viscid transparent liquid. The solutions of its salts form very sparingly soluble precipitates with potassio-mercuric iodide and bromide, somewhat more soluble precipitates with mercuric chloride, auric chloride, iodised potassium iodide, alkalis and their carbonates, and tannin.

Pseudaconitine may be heated for some time at 105° without sensible alteration of weight, but when it is heated to 135° —or its acetate to 130° – 140° —then dissolved

in alcohol, precipitated by sodium carbonate, and taken up by ether, amorphous bases (forming also amorphous salts) are produced, represented by the formulæ $2C^{36}H^{49}NO^{12} - 3H^2O$ and $C^{36}H^{49}NO^{12} - 2H^2O$.

Apopsuedaconitine, $C^{36}H^{47}NO^{11}$, is formed by abstraction of water from pseudaconitine under the influence of mineral acids. The action takes place even with very dilute acids and at ordinary temperatures, but is not complete even at 100° ; it is however mainly represented by the equation $C^{36}H^{49}NO^{12} = H^2O + C^{36}H^{47}NO^{11}$, and the apopsuedaconitine may be easily separated from the product by supersaturation with sodium carbonate and agitation with ether. This base is very much like pseudaconitine, but somewhat less soluble in alcohol and ether. In the air-dried state it contains 1 mol. H^2O , which is given off at 100° . It forms a well-crystallised *nitrate*, and an *aurochloride*, $C^{36}H^{47}NO^{11} \cdot HCl \cdot AuCl^3$, very much like that of pseudaconitine.

Acetyl-apopsuedaconitine, $C^{36}H^{46}(C^2H^3O)NO^{11}$, is formed on heating pseudaconitine at 100° with acetic anhydride or glacial acetic acid, and separated from the product by agitation with ether. It is crystalline, contains in the air-dried state 1 mol. water, forms a well-crystallised *nitrate* and *aurochloride*. By saponification with alkalis it is resolved into acetic and dimethylprotocatechuic acids.

Benzoylapopsuedaconitine, $C^{36}H^{46}(C^7H^5O)NO^{11}$, formed in like manner by the action of benzoic anhydride on pseudaconitine, also contains in the air-dried state 1 mol. water of crystallisation, and is altogether very much like the acetylated base.

Pseudaconine, $C^{27}H^{41}NO^9$, is formed, together with dimethylprotocatechuic acid, by heating pseudaconitine at 100° with alcoholic soda-solution:

To separate the pseudaconine, the liquid product of the reaction is evaporated to dryness, then acidulated with hydrochloric acid, and shaken with ether; the dimethylprotocatechuic acid thereby dissolved is removed; the residue exhausted with alcohol; the alcohol distilled off; and the pseudaconine dissolved out of the residue by ether, which leaves it on evaporation as a varnish-like but apparently crystallisable mass. It melts at the heat of the water-bath; dissolves readily in water; has a strong alkaline reaction; a bitter but not caustic taste; and is distinguished from pseudaconitine by its greater solubility both in the free state and in combination with acids. It reduces gold and silver salts. Pseudaconine salts are all amorphous.

Apopsuedaconine, $C^{27}H^{39}NO^8$, is formed, together with dimethylprotocatechuic acid, by the action of alcoholic soda-solution at 140° on pseudaconitine:

Dibenzoyl-apopsuedaconine, $C^{27}H^{37}(OC^7H^5O)^2NO^8$, and the corresponding *diacetyl-derivative*, are obtained by heating pseudaconine with benzoic and acetic anhydride respectively, 1 mol. H^2O being first separated from the pseudaconine and an atom of hydrogen in the residue then replaced by benzoyl or acetyl. Both these bases are amorphous, and form amorphous salts, those of the benzoylated base being nearly insoluble, and those of the acetylated base moderately soluble in water. Both melt at 100° , and decompose at higher temperatures.

The bases above described may be represented by the following constitutional formulæ:

Aconitine, $C^{32}H^{43}NO^{12}$ (Wright a. Luff, *Chem. Soc. J.* xxxiii. 318; see also p. 40 of this volume). This is the principal alkaloid of monkshood (*Aconitum Napellus*). It reacts with acids and alkalis in the same manner as pseudaconitine, producing the following bases:

Apoaconitine, $C^{33}H^{41}NO^{11}$, is formed from aconitine by the action of dilute mineral acids or of concentrated tartaric acid (which, however, partly act in the same manner as alkalis, *infra*). It crystallises from ether, melts at 185° – 186° , forms a crystallised

nitrate, and a hydrobromide having the composition $C^{32}H^{41}NO^{11}, HBr + 2\frac{1}{2}H^2O$. This base is probably formed by decomposition of aconitine during the preparation of the latter, and to its admixture may be attributed the very discordant statements which have been made respecting the composition of aconitine.

Acetylpoaconitine, $C^{35}H^{40}(C^2H^3O)NO^{11}$, and *Benzoyl-apoaconitine*, are produced by heating aconitine with acetic and benzoic anhydride* respectively, a molecule of water being first removed, and an atom of hydrogen in the residue then replaced by acetyl or benzoyl. Acetylpoaconitine crystallises from ether, melts at 180° – 181° (corr.), and forms amorphous salts. In its preparation the temperature must not be allowed to rise above 100° , as otherwise an amorphous base will be formed.

Aconine, $C^{26}H^{39}NO^{11}$, is formed, together with benzoic acid, by the action of dilute alkalis at ordinary temperatures on aconitine, the conversion being most completely effected by the use of alcoholic soda-solution: the same change is also produced by heating aconitine with water at 140° :

This reaction of aconitine, and the corresponding reaction of pseudaconitine, are analogous to that of cocaine, which yields methyl alcohol, benzoic acid, and ecgonine (vi. 480), and to that of atropine, which yields tropic acid and tropine (vi. 249).

Aconine is easily soluble in water, alcohol, alkalis, and chloroform, but almost insoluble in ether, especially when the ether is free from alcohol. It is amorphous, as are also its salts; melts at 130° ; reduces gold and silver salts, and at the boiling heat also Fehling's solution. The *mercuriodide* has the composition $C^{26}H^{39}NO^{11}, Hg_2I^2$; the *sulphate* is $7C^{26}H^{39}NO^{11}, H_2SO^4$; the *hydrochloride*, $3C^{26}H^{39}NO^{11}, 2HCl$: these last two salts were probably mixtures. The *aurochloride*, $C^{26}H^{39}NO^{11}, HCl, AuCl^3$, is obtained as a yellow flocculent precipitate on adding gold chloride to the solution of aconine in hydrochloric acid. Aconine heated with benzoic anhydride is converted into benzoylapoaconitine.

Apoaconine, $C^{26}H^{37}NO^{10}$, is formed by abstraction of water from aconine under the influence of dilute acids, e.g. by heating a solution of the hydrochloride to 140° . Its *hydrochloride*, $C^{26}H^{37}NO^{10}, HCl$, is amorphous, soluble in water, not precipitated by alkalis.

The relations between the four bases just described may be represented by the following formulæ:

Picraconitine, $C^{31}H^{42}NO^{10}$, is the amorphous and comparatively inert alkaloid occurring, together with aconitine, in *Aconitum Napellus*. It is resolved by alkalis into benzoic acid and *picraconine*, $C^{24}H^{41}NO^9$, and may probably be represented by the formula $C^{24}H^{37}NO^5 \begin{array}{l} \text{OH} \\ \text{O} \end{array} \begin{array}{l} \text{CO} \\ \text{CO} \end{array} \text{C}^6\text{H}^5$.

Alkaloid from Japanese Aconite Roots (Wright a. Luff, *Chem. Soc. J.* xxxvi. 387). These roots appear to be different in species both from *A. Napellus* and from *A. ferox*, and are either richer in active ingredients, or else contain a more active alkaloid. To obtain the base, the roots were exhausted with alcohol containing tartaric acid; the extract was evaporated; and the residue, after addition of water and sodium carbonate, was agitated with ether. Repeated treatment with ether, however, failed to dissolve all the alkaloid present, a portion, apparently uncrystallisable, being obstinately retained by the alkaline liquid. The ethereal extract, after purification by shaking with aqueous tartaric acid, and treatment of the crude tartrate solution with soda and fresh ether, gave by spontaneous evaporation crops of crystals, all of which, when purified by fractional crystallisation, yielded on analysis numbers agreeing with the formula $C^{36}H^{48}N^2O^{27}$. As no change in the composition of this body was produced by treatment with hot concentrated tartaric acid, Wright a. Luff conclude that it is a definite compound, and not a mixture of two bases, $C^{33}H^{45}NO^{11}$ and $C^{39}H^{53}NO^{10}$.

This compound melts at 185° – 186° , and closely resembles aconitine. By saponification it is resolved into benzoic acid and *japaconine*, $C^{26}H^{43}NO^{11}$, a base which bears a close resemblance to aconine, but forms with benzoic anhydride a tetra- instead

of a di-benzoylated derivative. A tetrabenzoyl-compound is also formed by heating the base $C^{26}H^{38}N^2O^{21}$ with benzoic anhydride.

To explain the constitution of these several bases, Wright a. Luff assume the existence of a base (Japaconitine) represented by the formula

containing H^4 more than aconitine, and constituted like aconitine and pseudaconitine. The base $C^{26}H^{38}N^2O^{21}$ may then be regarded as *triapo-japaconitine*,*

and japaconine as $O=C^{26}H^{39}NO^7(OH)^2$.

All attempts to isolate japaconitine were unsuccessful.

Japanese aconite roots have also been examined by Paul a. Kingzett (*Yearbook of Pharmacy*, 1877, p. 469), who find that the yield of alkaloids from them is much greater than that from *A. Napellus* or *A. ferox*. They obtained a crystalline base, to which they assigned the formula $C^{26}H^{42}NO^9$. As, however, this formula was deduced from the analysis of a very small quantity of substance, and as the base in question formed amorphous salts, Wright is inclined to regard it as identical with pseudaconitine, a view with which Kingzett does not agree.

PSEUDOBUTYLBENZENE ALCOHOL, $C^6H^5.CH^2.CH^2.CH(OH).CH^3$. An alcohol formed by the action of nascent hydrogen on acetocinnamone (p. 1152).

PSEUDOBUTYLENE, $CH^3-CH=CH-CH^3$. See BUTYLENES (p. 361).

PSEUDOCUMENE. Unsymmetrical Trimethylbenzene. See MESITYLENE (p. 1284).

PSEUDO-INDOLE. See INDOLE (p. 1089).

PSEUDOMALACHITE, syn. with Ehlite, $5CuO.P^2O^3.3H^2O$ (p. 705).†

PSEUDOMORPHOSES. A description of the numerous pseudomorphoses of the bed of magnetic iron ore in the Tilly-Foster mine, Putnam County, New York, is given by J. D. Dana (*Sill. Am. J.* [3], viii. 371 and 447; *Jahresb. f. Chem.* 1873, 1284-1292). Pseudomorphs of tin-stone, after orthoclase, from Huel Coates, St. Agnes, Cornwall, are described by J. A. Phillips (*Chem. Soc. J.* xxviii. 684).

On the Microscopical Structure of Pseudomorphs, see Geinitz (*Jahrb. f. Min.* 1876, 449-504; *Chem. Soc. J.* xxxi. 621-700).

PSEUDONITROLES. See PARAFFINS (NITRO-), p. 149.

PSEUDOPHITE. See PENNINE (p. 1498).

PSEUDOPROPYL- or ISOPROPYL-COMPOUNDS. See PROPYL-COMPOUNDS (pp. 1676-1679).

PSEUDOPURPURIN. See ANTHRAQUINONES, TRIOXY- (p. 111).

PSEUDOROSANILINE. See ROSANILINE.

PSEUDOROSOLIC ACID. See ROSOLIC ACID.

PSEUDOTHIOCYANOGEN. The orange-yellow precipitate (*Persulphocyanogen*, iv. 381) which Liebig obtained by the action of chlorine or nitric acid on aqueous potassium thiocyanate, is generally represented by the formula $C^3N^2S^3H$. According to W. R. Hodgkinson, however (*Chem. News*, xxxix. 80), its true composition is represented by the empirical formula CNSH, and it is actually a polymeride of thiocyanic acid, $C^3N^2S^3H^2$. Hodgkinson recommends the use of this yellow substance as a pigment, as it is not altered by light either in the moist or in the dry state.

PSEUDOTOLUIDINE. See TOLUIDINE.

PSEUDO-URIC ACID, $C^6H^6N^4O^4$. This acid, which Schlieper a. Baeyer obtained (iv. 744) by the action of potassium cyanate on uramil (dialuramide), is also produced as ammonium salt, with elimination of ammonia, when uramil is heated with an equal weight of urea. On passing carbon dioxide through a solution of the

* Wright a. Luff designate this base as *japaconitine*; but if $C^{26}H^{44}NO^{11}$ is to be called *japaconine*, it is more consistent to give the name of japaconitine to the hypothetical base $C^{26}H^{44}NO^{12}$, related to japaconine in the same manner as aconitine to aconine.

† CuO is there misprinted CaO.

resulting ammonium-salt in caustic soda, sodium pseudourate separates out, and from this salt the acid may be obtained by precipitation with hydrochloric acid. Its *barium salt*, $(C^4H^3N^3O^4)^2Ba + 5H^2O$, gives off all its water at 150° . The acid is not attacked by phosphorus oxychloride. Sulphuric acid decomposes it at 150° into carbon dioxide, ammonium sulphate, and xanthinine, $C^4H^3N^3O^2$ (*q.v.*):

Pseudo-uric acid is uric acid plus the elements of water, but all attempts to resolve it into these constituents have hitherto been unsuccessful (Grimaux, *Bull. Soc. Chim.* [2], xxxi. 535).

PSEUDOTRIACETONALKAMINE. See ACETONAMINES (p. 32).

PSEUDOTRIPHENYLMELAMINE, $C^6H^3(C^6H^5)^3N^6$, isomeric with Hofmann's triphenylmelamine (p. 1271), is formed, together with carbon dioxide, hydrogen cyanide, benzonitril, and dibenzoyl-dicyanamide, by heating tribenzoylmelamine in a current of hydrogen. It is best purified by solution in phenol, and precipitation with alcohol, whereupon it separates in shining yellow prisms which do not melt at 360° . Hofmann's triphenylmelamine melts at 162° – 163° (Gerlich, *J. pr. Chem.* [2], xiii. 270).

PSILOMELANES. See MANGANESE-ORES (p. 1263).

PSITTACINITE. A hydrated vanadate of lead from mines in the Silver Star District, Montana. See VANADIUM MINERALS.

PUCHERITE. Small brown crystals, $OP \cdot \infty P$, identical in form and composition with native pucherite (vii. 1026), are obtained by evaporating a mixture of bismuth nitrate and vanadium chloride in the exsiccator over sulphuric acid (Frenzel, *Jahrb. f. Min.* 1875, 680).

PURPLE OF THE ANCIENTS (Schunck, *Chem. Soc. J.* xxxv. 589). This colour, which was extracted by the ancients from various kinds of shell-fish, and applied to the dyeing of linen and woollen fabrics, has from time to time excited a considerable amount of interest. Cole, of Bristol (*Phil. Trans.* 1685), discovered on the coasts of Somersetshire and South Wales a shell-fish which yielded a purple dye. A similar species (*Purpura Lapillus*) was discovered by Réaumur in 1710; Duhamel in 1736, and Bancroft in 1803, also worked at the subject. Their results may be summarised as follows:—1. The colour-producing secretion resembles pus, and is contained in a small whitish cyst under the shell close to the head of the animal. This pus-like matter, when applied to white linen and exposed to sunlight, changes from yellow, through light green, dark green, and blue, to purplish-red or crimson, a strong odour resembling garlic or assafetida being at the same time evolved. Day-light is essential; the secretion if kept in the dark remains unchanged for years, and then becomes coloured on exposure to light. The change is not promoted by heat, but proceeds in a vacuum or in hydrogen or nitrogen gas. The colour resists the action of soap, alkalis and most acids; it is destroyed by nitric acid and chlorine. A. and G. de Negri (*Ber.* ix. 84) have recently obtained two colouring matters from a species of murex; one is blue, and presents the characters of indigotin; the other is red, but its nature is not exactly known.

Schunck has made many experiments with *Purpura Lapillus*, which he obtained on rocks at low water near Hastings, live animals alone being used. The pale yellow secretion turns purple when exposed to light, without being applied to linen. Boiling does not hinder the production of the colour. The chromogen can be completely extracted by alcohol and ether from the pounded cysts, a golden-yellow solution being obtained, which becomes purple on exposure to light, and a purple powder being ultimately precipitated, which is granular and crystalline. Hydrochloric acid produces a decomposition somewhat similar to that effected by sunlight, a purple colour being formed. The cysts or veins from 400 animals, yielded on exposure to sunlight 7 mgs. of the purplish powder. It was insoluble in water, alcohol, and ether; slightly soluble in boiling benzene and boiling glacial acetic acid; easily soluble in boiling aniline, the solution giving a broad absorption-band between C and D. Heated between watch-glasses, it yielded a sublimate of crystals with metallic lustre showing at their edges a deep indigo-blue colour. The colouring matter dissolves in strong sulphuric acid to a purplish solution, showing a band between D and E. From these reactions it is inferred that the colouring matter belongs to an unknown member of the indigo-blue group. Schunck proposes to call it *Punicin*. The liquid from which the action of sunlight had precipitated the purple powder did not contain glucose.

PURPUREO-COBALT COMPOUNDS. See COBALT-AMMONIA COMPOUNDS (p. 546).

PURPURIN. See ANTHRAQUINONES (TRIOXY-) (p. 109).

PURPUROGALLIN. A substance produced, according to H. Struve, by the slow oxidation of pyrogallol in contact with lead peroxide, gum-arabic, malt-extract, grape-juice, blood-pigment, or saliva (vii. 1029, 1030).

PURPUROXANTHIN. See ANTHRAQUINONES (DIOXY-) (p. 104).

PYRAMARIC ACID, $C^1H^{16}O^2$. An acid formed, together with benzoic acid, by the action of heat on amaric acid, $C^{16}H^{42}O^6$, in presence of free alkali (p. 1128).

PYRENE, $C^{16}H^{10}$ (vii. 1027). This hydrocarbon crystallises in monoclinic prisms, melts at 148° – 149° , and forms a picric acid compound which melts at 122° . *Mononitropyrene* melts at 149.5° – 150.5° (Fittig, *Ber.* x. 2143).

PYRETHRUM. On the insect-powders prepared from various species of *Pyrethrum*, see p. 1091. J. de Bellesme obtained from *Pyrethrum carneum*, which is an ingredient of most of these powders, a volatile non-poisonous oil, and a crystalline body which exhibits the poisonous properties of the plant, and is probably an alkaloid (*Pharm. J. Trans.* [3], vii. 172). R. Buchheim, by evaporating to dryness the alcoholic extract of *Radix pyrethri*, and exhausting the residue with ether, obtained a crystalline substance, *pyrethrin*, which melted at the heat of the body, and was resolved by alcoholic potash into pyrethic acid and piperidine. Pyrethrin occurs also in *Herba spilanthis* (*N. Rep. Pharm.* xxv. 335).

PYRIDINE-BASES, $C^5H^{2n-5}N$. The following bases of this series are known :

	B. p.		B. p.
Pyridine, C^5H^5N	117°	Parvoline, $C^9H^{13}N$	188°
Picoline, C^6H^7N	133	Coridine, $C^{10}H^{15}N$	211
Lutidine, C^7H^9N	154	Rubidine, $C^{11}H^{17}N$	230
Collidine, $C^8H^{11}N$	179	Viridine, $C^{12}H^{19}N$	251

Pyridine, the lowest member of the series, may be regarded as benzene having one of its CH-groups replaced by nitrogen, and represented by the formula

The other members, derived from it by substitution of CH^3 , C^2H^5 , &c., for one or more of the hydrogen-atoms, admit of isomeric modifications depending on the orientation of the substituted radicles. Picoline or methyl-pyridine, $C^5H^4(CH^3)N$, admits of three such modifications, which are actually known; the higher members, however, are at present known in one modification only, or perhaps as mixtures of several.

The Heats of Formation of some of these bases have been determined by Ramsay (*Chem. Soc. J.* xxxv. 696) with the following results :

	Gram-degrees		Gram-degrees
Pyridine	7117	Lutidine	7184
Picoline	5753	Dipicoline	8084

On their volumes at the respective boiling points, see Ramsay (*ibid.* 472).

Physiological action.—Pyridine, picoline, lutidine, and their salts, exert a soporific action on the animal organism; their methiodides strongly excite the brain and paralyse the extremities. A similar but more energetic action is exerted by their ethyl and allyl derivatives; also by dipyridine and dipicoline. The iodalkyl-compounds (methiodides, ethochlorides, &c.) of the last two bases are strong poisons. Methylic pyridine-carboxylate scarcely acts on the organism; the corresponding ammonium salt gives rise to symptoms resembling epileptic fits (Ramsay, *Phil. Mag.* [5], iv. 241). According to Kendrick a. Dewar (*Proc. Roy. Soc.* xxii. 432, xxiii. 290), the several members of the pyridine series differ from one another in their physiological action, not in kind, but only in degree, but the members of the quinoline series, $C^8H^{2n-11}N$ (quinoline, C^8H^7N ; lepidine, C^8H^9N , &c.), exhibit differences in kind, as well as in degree, in their physiological action.

Pyridine, C^5H^5N , is formed by distilling a salt of pyridine-carboxylic (nicotinic) acid with lime, $C^5H^4N(CO^2H) = CO^2 + C^5H^5N$ (Weidel, *Liebigs Annalen*, clxv. 238; Laiblin, *Ber.* x. 2136); also by distilling the calcium salt of pyridine-dicarboxylic acid (cinchomeronic acid, p. 484), $C^5H^2N(CO^2H)^2 = 2CO^2 + C^5H^5N$.

Dibromopyridine, $C^5H^3Br^2N$, is formed on heating to 200° a mixture of pyridine hydrochloride and bromine, or the orange-coloured precipitate formed on adding bromine to a solution of pyridine hydrochloride, and separates in needle-shaped crystals soluble in ether and in strong hydrochloric acid, precipitated from the acid solution by

water. It melts at 109° , and begins to sublime at 100° . It is not acted upon by baryta-water, ammonia, alcoholic potash, nitric acid, sulphuric acid, or potassium permanganate. *Monobromopyridine* (b. p. 170°) appears to be formed simultaneously with the dibromopyridine (A. W. Hofmann, *Ber.* xii. 984).

covered by Anderson (vi. 977), is obtained, together with other products, by the action of sodium on pyridine. He found its vapour-density to be 5.92; Ramsay (*Phil. Mag.* [5], iv. 241), working with Victor Meyer's apparatus, finds it to be 5.86; the formula $\text{C}^{10}\text{H}^{10}\text{N}^2$ requires 5.46.

Isodipyridine, $\text{C}^{10}\text{H}^{10}\text{N}^2$, obtained by fractionation from the mother-liquors of the crystalline dipyridine, is a yellow oil, which does not solidify in a mixture of snow and salt, even on addition of crystals of dipyridine. Sp. gr. 1.03. Vapour-density by two determinations, 5.70 and 5.79. It is sparingly soluble in water, but mixes in all proportions with alcohol and ether. Its *hydrochloride* forms hard white crystals; the *platinochloride* is a yellow crystalline precipitate. The *methiodide* is a brilliant scarlet powder, insoluble in absolute alcohol and ether, slightly soluble in aqueous alcohol, freely in water, forming a nearly colourless solution. The *methochloride* is a syrupy liquid, giving with platinic chloride a precipitate of the double salt $\text{C}^{10}\text{H}^{10}\text{N}^2, 2\text{CH}^3\text{Cl}, \text{PtCl}^2$ (Ramsay, *Chem. Soc. J.* xxxvi. 264).

Picoline, $\text{C}^6\text{H}^7\text{N} = \text{C}^6\text{H}^7(\text{CH}^3)\text{N}$. This base, as already observed, admits of three isomeric modifications, according as the CH^3 -group is placed in the ortho-, meta-, or para-position with regard to the nitrogen-atom of the pyridine-molecule. The basic oil hitherto known as picoline, extracted from coal-tar naphtha, bone-oil, &c., is a mixture of two of these modifications (α and β), and a third modification (γ) is formed by the distillation of acrolein-ammonia and by heating allyl tribromide with ammonia (Baeyer, vi. 944; vii. 981).

The two modifications obtained by the dry distillation of vegetable and animal substances cannot be separated by fractional distillation, but their separation may be effected by means of the different solubilities of their platinochlorides. The following description of their properties is given by Weidel (*Ber.* xii. 2008).

α -Picoline, obtained from the less soluble of the two platinum salts, is optically inactive, boils at 134° (uncorr.), and is converted by oxidation into picolinic acid. Its platinochloride, $(\text{C}^6\text{H}^7\text{N}, \text{HCl})^2\text{PtCl}^4$, separates from a moderately concentrated slightly acid solution in large, yellow, faintly lustrous monoclinic tablets containing 1 mol. H^2O . Ratio of secondary axes $a : b = 1.0548$. Angle $ac = 102^{\circ} 6'$. Observed faces, 0P , ∞P . From a solution strongly acidulated with hydrochloric acid, on the other hand, the salt separates in large highly lustrous roseate anhydrous prisms also monoclinic, $a : b : c = 0.9185 : 1 : 0.9279$; $ac = 116^{\circ} 10'$. Observed faces ∞P , 0P , 4P^2 .

β -Picoline, obtained from the more soluble of the two platinum salts, is slightly laevogyrate, boils at 140° , and is converted by oxidation into nicotinic acid (p. 1703). It is less soluble in water than α -picoline. Its platinochloride separates from a moderately concentrated solution by slow evaporation in large highly lustrous crystalline grains having the colour of potassium dichromate; by rapid crystallisation from strong solutions it is obtained in needles. The crystals contain 1 mol. H^2O , and belong to the orthorhombic system; $a : b : c = 0.9560 : 1 : 0.6226$. Observed faces P , ∞P , ∞P^{∞} .

γ -Picoline also yields a platinochloride which crystallises with 1 mol. water. The crystals, according to Groth's measurements (*Liebig's Annalen*, clv. 281), are monoclinic, having the axial ratio $a : b : c = 0.9089 : 1 : 0.6641$, and the axial angle $ac = 81^{\circ} 7'$.

A considerable number of salts prepared from the mixture of α - and β -picoline, hitherto known as 'picoline,' and so designated, for simplicity, in the following descriptions, have been examined by W. Ramsay (*Phil. Mag.* [5], ii. 269; iv. 241; vi. 19). The *hydrochloride*, when purified by distillation, is a white deliquescent salt melting at 160° . It appears to absorb chlorine, but is not attacked thereby even at high temperatures. The *hydrobromide*, on the other hand, in aqueous solution, unites readily with a molecule of bromine, forming the compound $\text{C}^6\text{H}^7\text{N}, \text{Br}^2, \text{HBr}$, which is still more readily formed by heating a concentrated solution of the hydrobromide with bromine for an hour at 190° . It crystallises from water in yellow needles which melt and give off bromine at about 85° . This dibromide is resolved by boiling with water into bromine and picoline hydrobromide, and the same decomposition is produced by alkalis, but, on acidulating the alkaline solution, the dibromide appears to be reproduced. Bromine does not exert a substituting action on picoline hydro-

bromide, even when heated with it for a week at 180°. When a mixture of picoline and very strong *hydriodic acid* is first evaporated down and then distilled, a sudden rise of temperature takes place, the mass turns brown and viscid, and the compound $C^6H^7N.I^2.HI$ separates in brown needles which melt at 79°, dissolve with decomposition in ether and in alcohol, and, in contact with water, are converted into a dark brown liquid. This compound is not soluble in carbon disulphide.

Picoline dibromide, $C^6H^7N.Br^2$, is formed by treating picoline dissolved in chloroform with bromine, and is obtained in small needles on evaporating the chloroform in a vacuum. A *chloriodide*, $C^6H^7N.ClI$, prepared in like manner with picoline and iodine monochloride, forms long yellow needles. These two compounds are resolved by alkalis into picoline and the respective halogens; the dibromide, when heated, decomposes and is converted into a resin.

The compound of picoline with *mercuric chloride*, $C^6H^7N.HgCl^2$, crystallises from water in needles, from alcohol in plates; it is not attacked by chlorine.

Picoline platinumchloride, heated with water in a sealed tube for some days at 170°, yields two compounds which can be separated from one another by their different degrees of solubility. They are formed by the following reactions:

The compound $(C^6H^7N)^2PtCl^4$ is a bright yellow powder moderately soluble in water; $C^6H^7N.PtCl^4$ is an insoluble substance of a dirty yellowish-green colour. Neither of these bodies evolves picoline when boiled with caustic alkalis.

Picoline platinocyanide, $(C^6H^7N.HCN)^2Pt(CN)^2 + 4H^2O$, forms yellow transparent crystals; from a hot solution it separates in needles containing 5 mols. water. It dissolves in 83 pts. water at 10°. When picoline is left in contact with *hydroferrocyanic acid*, a blue precipitate is formed, together with crystals, probably consisting of *picoline ferrocyanide*. Picoline hydrochloride and *silver cyanate* react at ordinary temperatures with formation of silver chloride; and the liquid, when left to evaporate over sulphuric acid, deposits crystals which are resolved by water into picoline and a gas, and when heated alone split up into picoline, ammonia, and cyamelide.

Picoline methiodide, $C^6H^7N.CH^3I$, prepared by direct combination of methyl iodide with picoline, is a slightly deliquescent salt which crystallises from alcohol in long white needles, melting at 226.5°–227°. It unites with *iodine*, forming the compound $C^6H^7N.I^2.CH^3I$, which crystallises in bluish-black feathery plates melting at 129°, soluble in alcohol and in ether, insoluble in carbon sulphide and in water. The *methochloride*, prepared by the action of silver chloride on the methiodide, is deliquescent, and crystallises from alcohol in needles. Its platinum salt, $(C^6H^7N.CH^3Cl)^2PtCl^4$, crystallises in small cubes. The *methonitrate*, $C^6H^7N.CH^3NO^3$, obtained from the methiodide with silver nitrate, forms transparent prisms sometimes an inch long. The *methydroxide*, prepared by adding silver oxide to the methiodide, decomposes when evaporated to dryness, leaving a red residue having a putrid odour. The *ethylenobromide*, $(C^6H^7N)^2C^2H^4Br^2$, crystallises with difficulty in small prisms melting at 276°. The corresponding *chloride* crystallises from alcohol in small needles.

The compounds of picoline with *allyl chloride*, *iodide*, &c. are all syrups, except the *platinochloride*, $(C^6H^7N.C^3H^5Cl)^2PtCl^4$.

Picoline acetochloride, $C^6H^7N.C^2H^3OCl$, is formed on mixing the solutions of picoline and acetyl chloride in chloroform, the liquid turning first green, then red, and finally red-brown, and yielding the compound, on evaporation in a vacuum, in brown, very deliquescent crystals, which are decomposed by water into picoline hydrochloride and acetic acid. The *benzochloride* exhibits similar properties.

Picoline tartrate, $(C^6H^7N)^2C^4H^4O^6$, crystallises in white needles, smelling faintly of picoline. The *citrate* is a syrup. The *phosphate* is a crystalline mass which rapidly absorbs water. The *chlorate* forms thin diamond-shaped crystals. Picoline does not combine with acetic, formic, or chromic acid.

Dipicolina, $C^{12}H^{14}N^2$, is formed by the action of sodium on picoline, and may be separated from the product by fractional distillation in a vacuum, under which circumstances it boils at 165°–175°. It is a heavy oil, having a peculiar basic odour, a density of 1.12, boiling under ordinary pressure at 310°–320°, and slightly volatile with vapour of water. Most of its salts show but little tendency to crystallise, but the *platinochloride*, $C^{12}H^{14}N^2.2HCl.PtCl^4$, is a yellow crystalline powder. The *methiodide*, $C^{12}H^{14}N^2.2CH^3I$, is a bright yellow powder, almost insoluble in alcohol and ether, but readily soluble in water, giving a colourless solution. The *metho-*

chloride is a white crystalline salt. The *methylplatinochloride*, $C^{12}H^{14}N^2 \cdot 2CH^3Cl \cdot PtCl^4$, is deposited from water in yellow crystals. Iodine combines with the methiodide, forming brown scales, insoluble in carbon bisulphide, and having the composition $C^{12}H^{14}N^2 \cdot 2CH^3I \cdot I_2$. With *bromine water*, dipicoline gives a bulky buff-coloured precipitate of the compound $C^{12}H^{12}BrN^2 \cdot 2HBr$. On oxidation with potassium permanganate, dipicoline yields a mixture of acids, which when heated evolve the smell of the polymerised bases; hence it is probable that a polymeride of pyridine-dicarboxylic acid is produced.

On Lutidine, C^7H^8N , see iii. 737; vii. 758. On Collidine, $C^8H^{11}N$, i. 1082, vii. 378; viii. 552.

Parvoline, $C^9H^{13}N$ (b. p. 188°), was discovered by C. Greville Williams amongst the volatile bases obtained by the dry distillation of the bituminous shale of Dorsetshire (*Chem. Soc. J.* vii. 97). It occurs also, together with the other bases of the series, in tobacco-smoke (Vohl a. Eulenberg, *Arch. Pharm.* [2], cxlvii. 130).

Coridine, $C^9H^{11}N$, was discovered by G. Thenius (*Chem. Centrl.* 1862, 53) among the bases obtained by distillation of coal-tar. It is a colourless transparent liquid, having a faint odour much like that of new leather. It boils at 211°, and has a density of 0.974. It blues reddened litmus-paper, dissolves sparingly in water, mixes in all proportions with alcohol, ether, and essential oils. Its solutions in acids, when evaporated over the water-bath, yield gummy masses which solidify in the crystalline state when left over calcium chloride. The base itself does not solidify at -17°. The hydrochloric acid solution gives, with mercuric chloride, a white precipitate which is deposited from the warm liquid as a heavy oil, solidifying at low temperatures, and becoming liquid again at 28°; from hot water it crystallises on cooling in white needles. The *platinochloride*, $(C^{10}H^{15}N \cdot HCl)^2 \cdot PtCl^4$, is a dark orange-coloured precipitate, sparingly soluble in water, alcohol, and ether; the *aurochloride* is dark yellow. The base precipitates alumina, chromic oxide and ferric oxide, but not baryta or magnesia. With chloride of lime it produces a yellowish-red colour, which disappears on addition of an acid; a deal-shaving moistened with hydrochloric acid is coloured by it in a similar way.

On Rubidine, $C^{11}H^{11}N$ (b. p. 230°), see v. 127. On Viridine, $C^{12}H^{10}N$ (b. p. 251°), see v. 1003; vii. 1161.

PYRIDINE-CARBOXYLIC ACIDS. Acids are known derived from pyridine by the substitution of one, two, and three carboxyl-groups for hydrogen.

Pyridine-monocarboxylic Acids, $C^6H^5NO^2 = C^6H^4N \cdot COOH$. The constitutional formula of pyridine (p. 1699) shows that three of these acids are possible, the nitrogen and carboxyl occupying the relative positions 1 : 2, 1 : 3, and 1 : 4. They are all known, but the orientation of the carboxyl-group in each has not been determined. One of these acids, picolinic acid, is obtained by oxidation of α -picoline; another, nicotinic acid, by oxidation of nicotine and of β -picoline, and the third by the dry distillation of pyridine-tricarboxylic acid.

(1). *Picolinic acid* (H. Weidel, *Ber.* xii. 1994).—This acid is formed, together with nicotinic acid, by the action of potassium permanganate on the mixture of α - and β -picoline (b. p. 133°–139°) obtained by distillation of animal tar (p. 1700):

The two acids are separated by the difference of solubility of their copper salts, the less soluble salt, when decomposed by hydrogen sulphide, yielding picolinic acid, the more soluble yielding nicotinic acid.

Picolinic acid crystallises in white slender apparently prismatic needles, dissolves easily in water and alcohol, but is nearly insoluble in ether, benzene, chloroform, and carbon sulphide. It is scentless and has an acid taste, with bitter after-taste. It volatilises partially below 100°, melts at 134.5°–136°, then sublimes in highly lustrous needles, and decomposes at a higher temperature, emitting a pungent odour. Its aqueous solution is not precipitated either by normal or by basic acetate of lead, but yields a white gummy precipitate with *silver nitrate*. A moderately dilute solution of the acid or of one of its salts yields with *copper salts* a precipitate consisting of shining needles and laminae of a splendid violet-blue colour, a reaction which may be used for the recognition of the acid. Solutions of picolinic acid are coloured faintly yellow by ferrous sulphate.

Potassium picolinate forms small extremely deliquescent needles and scales; its solution when agitated froths like soapy water. The *ammonium salt* is very soluble, and crystallises by spontaneous evaporation in large colourless triclinic plates having a strong vitreous lustre. The *calcium salt*, $(C^6H^4NO^2)_2Ca + 1\frac{1}{2}H^2O$, is obtained by adding calcium carbonate to a boiling dilute solution of the acid, and evaporating the

filtrate, in tufts of white needles having a faint silky lustre,—or by decomposing the ammonium salt with calcium chloride, whereupon it separates in large efflorescent, apparently prismatic crystals. The water of crystallisation is given off at 160°. The *barium salt*, $(C^6H^4NO^2)^2Ba + H^2O$, prepared like the calcium salt, is much less soluble, and separates from the solution on evaporation in microscopic hard sandy prismatic crystals, which give off their water at 160°. By dry distillation it yields a mixture of pyridine and dipyridine. The *magnesium salt*, $(C^6H^4NO^2)^2Mg + 2H^2O$, obtained by saturation, crystallises on evaporation in hard shining monoclinic prisms, $a : b : c = 1.1368 : 1 : 0.8590$; angle $ac = 73^\circ 52'$. Observed faces, $0P, \infty P\infty, R\infty, \infty P$. The water of crystallisation is given off at 140°. The *cadmium salt*, $(C^6H^4NO^2)^2Cd$ (at 120°), obtained in like manner, forms an aggregate of small shining crystalline plates, having a saccharine taste. The *copper salt*, $(C^6H^4NO^2)^2Ca$, is obtained either by decomposing a soluble picolinate with cupric acetate, or by saturating a boiling hot solution of the acid with cupric carbonate, and is deposited on cooling in needles having a blue-violet colour and metallic lustre.

Picolinic acid likewise unites with strong mineral acids, and with the chlorides of gold and platinum. The *hydrochloride*, $C^6H^5NO^2.HCl$, separates on evaporation over sulphuric acid in large colourless highly lustrous orthorhombic prisms. The *platinohydrochloride*, $(C^6H^5NO^2.HCl)_2.PtCl^4 + 2H^2O$, crystallises in monoclinic prisms.

Calcium picolinate, distilled with quick-lime, yields a mixture of pyridine and dipyridine, the former passing over between 115° and 116°, the latter between 165° and 185°: $C^6H^5NO^2 = CO^2 + C^5H^5N$. Picolinic acid is also resolved into pyridine and carbon dioxide by heating with strong alcoholic potash in a sealed tube at 240° for several hours.

When a solution of sodium picolinate is heated with *sodium-amalgam*, ammonia is given off, and a non-azotised acid is formed, having the composition of hydroxysorbic acid, $C^6H^5O^3$:

This acid crystallises in colourless needles which are extremely deliquescent, very soluble in water, almost insoluble in alcohol, and melt at about 85°. It reduces an alkaline cupric solution. Its barium, calcium, and cadmium salts are amorphous.

(2). *Nicotinic acid*, produced, as above mentioned, by oxidation of the mixture of α - and β -picoline with permanganate, is also formed by oxidation of nicotine. Huber obtained it by oxidising nicotine with chromic acid mixture (vi. 866); Laiblin, by the action of potassium permanganate on the same alkaloid (p. 1392). Weidel in 1872 (*Liebig's Annalen*, clxv. 328), by oxidising nicotine with nitric acid, obtained an acid to which he assigned the formula $C^{10}H^5N^2O^3$; but his more recent experiments have shown that its true formula is $C^6H^5NO^2$, according to which its formation from nicotine may perhaps be represented by the equation:

For the description of its salts see p. 1392.

Like picolinic acid, it unites with acids as well as with bases. The *hydrochloride*, $C^6H^5NO^2.HCl$, crystallises in monoclinic prisms, in which $a : b = 1.0619$, and the angle $ac = 80^\circ 37'$. Observed faces, $0P, \infty P\infty, \infty R\infty, \infty P$. They are very permanent, whereas the crystals of picolinic acid hydrochloride quickly become turbid and opaque.

Nicotinic acid, like picolinic acid, is resolved, by the dry distillation of its calcium salt, into carbon dioxide and pyridine, and when subjected to the action of sodium-amalgam yields an acid apparently identical with the hydroxysorbic acid obtained from picolinic acid.

The points of difference between the two acids may be more plainly seen in the following table (p. 1704).

3. A third pyridine-monocarboxylic acid is obtained by the action of heat on pyridine-tricarboxylic acid: $C^6H^2N(COOH)^3 = 2CO^2 + C^6H^5NO^2$. When this latter acid is cautiously heated to the melting point, carbon dioxide escapes, together with small quantities of other gases, and the fused mass contains a mixture of acids, from which, by repeated crystallisation from water, a pyridine-monocarboxylic acid may be isolated in well-defined granular crystals, while a mixture of mono- and dicarboxylic acids remains in solution.

This pyridine-monocarboxylic acid melts at 305° in closed tubes, volatilises completely under ordinary pressure without previous fusion, and sublimes in fine tabular crystals. Mixed in aqueous solution with cupric acetate and warmed, it yields a green copper salt (Skraup, *Ber.* xii. 2331).

The same acid is also produced, according to Hoogewerff a. van Dorp, who name it *pyrocinchomeronic acid*, by the action of heat on the pyridine-dicarboxylic acid pro-

duced by oxidation of coal-tar quinoline. On heating this dicarboxylic acid in small retorts as long as carbon dioxide continued to escape, and then distilling, a solid distillate was obtained which, when recrystallised from a large quantity of water, yielded the monocarboxylic acid in nodular crystals which did not fuse at 275°. The pyridine-monocarboxylic acid thus obtained dissolves sparingly in water, very sparingly in ether and in benzene; its aqueous solution gives no reaction with ferrous sulphate. Its *hydrochloride*, $C^5H^5NO^2.HCl$, forms large shining crystals. The *platinochloride*, $(C^5H^5NO^2.HCl).PtCl^4 + 2H^2O$, forms fine red crystals which are very much like those of the corresponding salt of nicotinic acid, and give off their water at 110°–115°. The mother-liquor of this acid appeared to contain nicotinic acid.

Characters of Pyridine-monocarboxylic acids.

	Picolinic acid	Nicotinic acid
Crystalline form.	Slender, shining anhydrous needles.	Dull anhydrous needles.
Melting point.	134.6°–136°	228°
Reaction with { Water. Lead acetate. Ammoniacal lead acetate. Copper acetate.	Easily soluble in water, cold or hot. No precipitate. No precipitate. Throws down from a solution of the acid or its salts, after a short time, violet, metallically lustrous laminae, soluble in water on boiling.	Sparingly in cold, easily in warm water. No precipitate. White crystalline precipitate. Light blue-green precipitate, not soluble even in large quantities of water.
„ with Silver nitrate.	White gummy precipitate.	White precipitate.
Crystalline form of ammonium salt.	Triclinic: $a : b : c = 0.9556 : 1 : 0.987$. Always crystallises in large fine tablets.	Obtained only in small lustreless needles, not admitting of measurement.
Crystalline form of calcium salt.	Small shining, unmeasurable needles, or larger prismatic crystals, which soon become turbid.	Monoclinic.
Crystalline form of magnesium salt.	Monoclinic: $a : b : c = 1.1368 : 1 : 0.859$.	Prismatic needles, not admitting of measurement.
Crystalline form of hydrochloride.	Orthorhombic: $a : b : c = 1 : 0.8993 : 0.5635$. The crystals become turbid in a few minutes after removal from the liquid.	Monoclinic: $a : b : c = 1.0619 : 1$. Crystals quite unalterable.
Crystalline form of platinochloride.	Monoclinic: $a : b : c = 1.4468 : 1 : 2.0404$.	Monoclinic: $a : b : c = 1.6233 : 1 : 1.8251$.
Sp. gr. of platinochloride.	2.0672	2.1987

Pyridine-dicarboxylic Acid, $C^5H^5NO^4 = C^5H^5N(COOH)^2$. *Dicarbopyridemic acid*.—Six modifications of this acid are possible, having the two carboxyl-groups in the following positions [N in 1]:

2 : 3 2 : 4 2 : 5 2 : 6
3 : 4 3 : 5

Five of these acids are known, but the relative positions of the two CO^2H -groups in them have not been determined. Dewar in 1871 (*Chem. News*, xxiii. 18), by oxidising picoline (most probably containing lutidine) with potassium permanganate, obtained an acid of this composition, which crystallised in colourless laminae resembling naphthalene, melted at 210°, and was resolved, at a higher temperature, or by distillation with soda-lime, into CO^2 and pyridine; and two other modifications have been discovered by Ramsay (*Phil. Mag.* [5], iv. 241; vi. 19), who obtained them in a similar manner by the oxidation of lutidine. These two modifications are distinguished as β and γ , Dewar's acid as α .

The general method of preparing these acids is as follows: 25 grams of the base are boiled in a tinned iron vessel connected with an inverted condenser, with 250 grams

of potassium permanganate, and 4 litres of water. When the permanganate has lost its colour, the liquid is distilled, to recover unoxidised base, and the distillate is used instead of water in the next preparation. The potassium salts are then evaporated to dryness, and exhausted with absolute alcohol in an apparatus by which the same alcohol is used over and over again. The salts soluble in alcohol are then dissolved in water, and fractionally precipitated with lead nitrate; the lead salt is decomposed by sulphuretted hydrogen, the lead sulphide removed by filtration, and the filtrate evaporated.

The α -acid, obtained in this way from picoline, separated first in long hair-like needles; on recrystallisation from hot water, it was deposited in plates resembling crystals of naphthalene, and these, on standing in their mother-liquor for some time, changed to short thick prisms. It has a sweet taste but no smell, is more soluble in alcohol than in water, and dissolves also in ether.

The β - and γ -acids were obtained in a similar manner, together with the α -acid, by oxidation of lutidine, and were separated by fractional crystallisation, the β -acid, which is but slightly soluble, separating out first from aqueous solution, as a white crystalline powder, while the γ -acid remained in the mother-liquor.

The table on p. 1706 exhibits a comparative view of the properties of these three acids and of their salts.

A fourth pyridine-dicarboxylic acid is cinchomeronic acid, which Weidel obtained by oxidising cinchonine with nitric acid, and to which he originally assigned the formula $C^9H^5N^2O^6$ (p. 483). Later experiments by Weidel a. Schmidt (*Ber.* xii. 1146), have shown, however, that it has the composition $C^9H^5NO^4$, and is resolved by distillation into pyridine and CO_2 , and is therefore a pyridine-dicarboxylic acid.

Cinchonine and cinchonidine, when oxidised by nitric acid, yield cinchoninic acid, $C^{10}H^7NO^2$, and quinolic acid, $C^9H^5N^2O^6$, as well as cinchomeronic acid, but quinine, when oxidised in the same manner, yields cinchomeronic acid as sole product.

Cinchomeronic acid crystallises in white prismatic needles, which melt at 250° , with partial decomposition, and dissolve but very sparingly in boiling water. It is a bibasic acid, and forms two classes of salts. *Sodium-hydrogen cinchomerionate*, $C^9H^4NaNO^4$, forms almost colourless prismatic needles, which soon become opaque on exposure to the air, dissolve easily in water, but only sparingly in alcohol. *Sodium cinchomerionate*, $C^9H^3Na^2NO^4$, forms small, brilliant needles, which are easily soluble in water and in alcohol, and contain 2 mols. of water of crystallisation, which they lose at 110° . *Calcium cinchomerionate* has the composition $C^9H^3CaNO^4 + 3H^2O$ (Hoogewerff a. van Dorp).

The fifth known modification of the acid $C^9H^3N(COOH)^2$ is obtained by oxidation of quinoline (from coal-tar) with potassium permanganate. It crystallises in short shining prisms slightly soluble in cold, more easily in hot water and alcohol, insoluble in ether and in benzene; they blacken when heated, and melt at 222° – 225° , which is nearly the melting point of nicotinic acid (p. 1392); a circumstance which, together with the previous blackening, renders it probable that the dicarboxylic acid is converted by heating into a monocarboxylic acid. The *barium salt* of this pyridine-dicarboxylic acid, $C^9H^2NO^4Ba$, and the *silver salt*, $C^9H^2NO^4Ag^2$, are gelatinous precipitates which become crystalline when heated for some time in a water-bath. The *calcium salt* when heated gives off an odour of Dippel's oil (Hoogewerff a. van Dorp, *Ber.* xii. 747; xiii. 61).

Cinchonine-quinoline, oxidised by potassium permanganate, also yields a pyridine-dicarboxylic acid, which appears to be identical with that just described. It is sparingly soluble in cold water, and the aqueous solution gives with ferrous sulphate a reddish-yellow coloration, with copper acetate a pale blue precipitate, and with silver nitrate a precipitate soluble in hot water (W. Koenigs, *Ber.* xii. 983).

Pyridine-tricarboxylic Acid, $C^9H^3NO^6 = C^9H^2N(COOH)^3$. An acid of this composition is obtained by oxidation of quinine, quinidine, and cinchonidine. When quinine sulphate is oxidised at boiling heat by potassium permanganate in alkaline solution (8.5–9.5 g. $KMnO_4$ to 16 g. dry quinine sulphate), from 22 to 26 per cent. of its carbon is obtained as oxalic acid, and from 41.2 to 43.4 per cent. of its nitrogen as ammonia; and the resulting liquid contains, besides other nitrogenous bodies, a quantity of the acid $C^9H^3NO^6$, amounting to about 15 per cent. of the quinine sulphate. This acid retains, $1\frac{1}{2}$ mol. crystallisation-water at 100° , which it gives off at 120° . It blackens at 190° , and melts at 244° . It is sparingly soluble in cold water, easily in hot water and alcohol, almost insoluble in ether and in benzene. Heated with lime in excess, it gives off the odour of the bases from Dippel's oil. Its *barium salt*, $(C^9H^2NO^6)_2Ba$, is nearly insoluble in water, and is obtained on adding barium acetate to a cold aqueous solution of the acid, as an amorphous precipitate, which is converted into a mass of small needles when heated in the liquid. The *calcium salt*,

Pyridine-dicarboxylic Acids.

<i>a</i>	<i>β</i>	<i>γ</i>
----------	----------	----------

Crystalline Forms :

Hair-like needles, changing in the mother-liquor to plates resembling naphthalene, and then to short prisms.	Granular microscopic octohedrons.	Spear-shaped crystals.
--	-----------------------------------	------------------------

Solubility :

Moderately soluble in water. More soluble in alcohol. Easily soluble in ether.	Soluble with difficulty in water. More soluble in alcohol. Sparingly soluble in ether. 244°-245°.	Moderately soluble in water. Easily soluble in alcohol and ether. 241°-245°.
Decomposing point, 237-5°.		

Salts :

<i>Ammonium Salt</i> .—Small soluble plates.	Moderately soluble needles.	Soluble needles.
<i>Calcium Salt</i> .—Contains no water. Sparingly soluble. Small needles.	Contains 2H ² O. Microscopic needles. Sparingly soluble.	Contains 2H ² O. Small plates. Sparingly soluble.
<i>Barium Salts</i> .—Neutral salt. Contains H ² O, and resembles the calcium salt.	Slightly soluble.	Soluble.
<i>Acid Salt</i> .—Very sparingly soluble.	—	—
<i>Potassium Salts</i> .—Neutral salt. Very soluble. Contains 1½H ² O.	Soluble.	Soluble.
<i>Acid Salt</i> .—Globular masses, consisting of tufts of needles radiating from a common centre.	—	—
<i>Lead Salt</i> .—Short prisms. Sparingly soluble.	White crystalline precipitate.	White crystalline precipitate.
<i>Copper Salts</i> .—(1). Light blue needles. (2). Dark blue prisms.	Light blue precipitate.	Whitish-blue precipitate.
<i>Silver Salts</i> .—(1). Neutral Salt:—Bulky, white, insoluble, gelatinous precipitate. (2). Acid Salt.—Ditto.	Very sparingly soluble crystalline precipitate.	Very sparingly soluble crystalline precipitate.
With <i>Ferric Chloride</i> .—No change of colour; a precipitate, even after addition of ammonia.	—	—
White flocculent precipitate, turning like ferric hydrate on addition of ammonia.	White flocculent precipitate, turning like ferric hydrate on addition of ammonia.	White flocculent precipitate, changed to ferric hydrate by ammonia.
<i>Copper Sulphate</i> .—No precipitate.	Whitish-blue precipitate.	Whitish-blue precipitate.
<i>Methyl Ether</i> .—Thick isolated crystals.	Deliquescent needles.	—
<i>Chloride</i> .—Crystalline mass. Melting point, 60.5°-61°. Boiling point, 284°.	Crystalline mass. Melting point, 49°. Boiling point, 269°-270°.	Crystalline mass. Melting point, 88°-89°. Boiling point, 265°.

($\text{C}^6\text{H}^2\text{NO}^6$) $^2\text{Ca}^2$, is sparingly soluble in water, and crystallises in concentric groups of small needles. The *normal silver salt*, $\text{C}^6\text{H}^2\text{NO}^6\text{Ag}^2$, precipitated from a solution of the acid neutralised with ammonia, appears to be amorphous. An *acid silver salt*, $\text{C}^6\text{H}^2\text{NO}^6\text{Ag}^2$, is thrown down from the aqueous solution of the acid as an amorphous precipitate, which afterwards becomes crystalline. The *normal potassium salt*, $\text{C}^6\text{H}^2\text{NO}^6\text{K}^2$, crystallises in white lustrous laminae. The solution of the acid gives with *cupric acetate* a light blue amorphous precipitate; with *basic and normal lead acetate* white precipitates (Hoogewerff a. van Dorp, *Ber.* xii. 158).

Berberonic acid, obtained by oxidising berberine with nitric acid, has also the composition of pyridine-tricarboxylic acid. To prepare it, berberine is heated with eight to ten times its weight of nitric acid, and the resulting solution is concentrated, a crystalline mass then separating out on cooling. The acid is further purified by crystallisation from hot water and conversion into the calcium salt, which separates from the hot aqueous solution as a crystalline precipitate. The filtrate from the calcium salt has a yellow colour, and contains the salt of an acid which forms an insoluble silver salt, and may be separated therefrom in woolly needles; it has not been further investigated, as it occurs in very small quantities only (Weidel, *Ber.* xii. 410).

Berberonic acid, obtained by decomposing the calcium salt with an acid and crystallisation from hot water, forms groups of shining, transparent, prismatic crystals, which become opaque on exposure to the air. It is sparingly soluble in cold, easily in hot water; alcohol dissolves it but sparingly, and it is insoluble in ether, benzene, and chloroform. It has an acid taste, decomposes carbonates, and is decomposed by heat. When crystallised from dilute aqueous solutions, it forms triclinic prisms, which have the composition $\text{C}^6\text{H}^2\text{NO}^6 + 2\text{H}^2\text{O}$, and on exposure to air lose 1 mol. of water and become opaque. The aqueous solution of berberonic acid, like those of oxyinchomeronic acid (p. 484) and pyridine-dicarboxylic acid, gives, with ferrous sulphate, in the absence of a stronger acid, a deep red coloration.

Calcium berberonate, ($\text{C}^6\text{H}^2\text{NO}^6$) $^2\text{Ca}^2 + 4\text{H}^2\text{O}$, prepared by treating the ammoniacal solution of the acid with calcium chloride, separates out in white shining needles, which after one crystallisation are insoluble in water. The *cadmium salt*, ($\text{C}^6\text{H}^2\text{NO}^6$) $^2\text{Cd}^2 + 2\text{H}^2\text{O}$, crystallises in shining branching needles, and is sparingly soluble in water. The *silver salt*, $\text{C}^6\text{H}^2\text{NO}^6\text{Ag}^2$, is obtained as a white crystalline precipitate. The calcium salt, distilled with lime, yields pyridine, together with other products: $\text{C}^6\text{H}^2\text{NO}^6 = 3\text{CO}^2 + \text{C}^6\text{H}^2\text{N}$. When the acid is fused with potash, ammonia and hydrogen are evolved, and potassium cyanide and acetate are formed.

Berberonic acid closely approximates in percentage composition to the so-called oxyinchomeronic acid, which, as already observed, it also resembles in its reaction with ferrous salts. The following table gives a comparative view of the observed properties of these two acids:

	Oxyinchomeronic	Berberonic
Crystalline form.	Orthorhombic.	Triclinic.
Water of crystallisation	10.84 per cent.; does not effloresce.	14.57 per cent.; effloresces quickly.
Calcium salt	Cauliflower-like crusts; 25.3 per cent. water.	Fine, flexible needles; 21.1 per cent. water.
Cadmium salt	White crystalline powder; 12.2 per cent. water. Precipitated by copper acetate in the cold.	Needles having a satiny lustre; 8.73 per cent. water. Precipitated only when hot, the precipitate redissolving on cooling.

PYROCATECHOL or **CATECHOL**, $\text{C}^6\text{H}^4(\text{OH})^2$ [1 : 2]. *Pyrocatechin* (see *Nomenclature*, p. 1420).—This modification of dihydroxybenzene is formed: α . By the action of melting potash on orthochlorophenol (vii. 906). β . By the dry distillation of protocatechuic acid (Tiemann a. Haarmann, *Ber.* vii. 608):

The resolution of protocatechuic acid into carbon dioxide and catechol takes place also by putrefaction in contact with pancreas. An infusion of the leaves of *Ampelopsis hederacea* left in contact with pancreas also yields catechol. Moreover, when protocatechuic acid is given to animals in their food, part of it is resolved in the organism into CO^2 and catechol, which passes into the urine in the form of a sulphonic acid.

The urine of a rabbit fed on milk diet was free from catechol, but after addition of an infusion of *Ampelopsis hederacea*, catechol was found in the urine.

The following method of preparing catechol from guaiacol (methyl-catechol) is given by Baeyer (*Ber.* viii. 155), the material used being the portion of Rhenish beech-tar creasote which distills at 200°–205°. The guaiacol, under the influence of dry hydrogen iodide at 195°–200°, splits up completely into catechol and methyl iodide. The operation is stopped as soon as red streaks show themselves on the sides of the glass, and the evolution of methyl iodide ceases. The residue is then fractionated, and the portion which distills between 220° and 250° is crystallised. By this process 1 kg. beech-tar creasote yielded 46 g. catechol. The smallness of the product is perhaps due to the presence of liquid phenols in the impure guaiacol employed.

The purification of catechol is best effected by recrystallisation from anhydrous benzene, in which it is much more soluble than resorcinol; the solution on cooling deposits it in perfectly colourless highly lustrous laminæ melting at 104° (*Fittig a. Mager, Ber.* viii. 365).

Nitrocatechol, $C^6H^3(NO^2)(OH)^2$, is formed by the action of nitrous acid in aqueous solution on catechol. 4 g. catechol and 20 g. commercial potassium nitrite are dissolved in 120 g. water; dilute sulphuric acid is added as long as effervescence is thereby produced; the dark brown-red liquid is shaken as rapidly as possible with an equal volume of ether; and the residue left after the expulsion of the ether is purified by recrystallisation from benzene. Nitrocatechol thus obtained forms very small woolly needles easily soluble in water, alcohol, and ether, sparingly in benzene, melting at 157° (uncorr.), and decomposing at a higher temperature. In potash-ley it dissolves with fine purple colour, and the reaction is so delicate that nitrocatechol might be used as an indicator in titration. *Normal barium-nitrocatechol*, $C^6H^3(NO^2)O^2Ba, 3H^2O$, forms dark-red metallicallly lustrous laminæ, very sparingly soluble in water even at the boiling heat. At 130° they give off their water of crystallisation and assume a dark green colour, but do not lose their metallic lustre. The *acid barium salt* is much more soluble, and has not been obtained in the crystalline form.

Nitric acid completely decomposes nitrocatechol, with violent evolution of gas. By tin and hydrochloric acid it is converted into amidocatechol, the hydrochloride of which crystallises from dilute hydrochloric acid in long needles; the free base separated from this salt by alkalis oxidises immediately on exposure to the air, and dissolves with dark violet colour. By the action of nitrous acid on catechol in ethereal solution, another nitro-derivative is formed, which dissolves but sparingly in water, volatilises with water-vapour, and separates in yellow drops which soon solidify.

Dibromodimethylcatechol, or *Dibromoveratrol*, $C^6H^4Br^2O^2$, is contained in the red resin which is formed by the action of bromine on veratric acid. When crystallised from dilute alcohol, it forms hard shining prisms which melt at 83°–84°, are insoluble in water, but dissolve readily in alcohol and ether.

Nitrodimethyl-catechols. See VERATROLS (NITRO-).

Catecholsulphonic acids.—Two of these acids, $C^6H^4(OH).O.SO^3H$ and $C^6H^4(O.SO^3H)^2$, are obtained as potassium salts by the action of potassium pyrosulphate on a solution of catechol in potash-ley:

and

To prepare these salts, 20 pts. of catechol are added to a solution of 20 pts. potassium hydroxide in 25 pts. water, and the cooled mixture is agitated for several hours with 45 pts. potassium pyrosulphate, then heated on a water-bath, and exhausted with not more than an equal volume of absolute alcohol, whereby the catecholdisulphonate is separated, while the monosulphonate remains in the mother-liquor. *Potassium catecholdisulphonate* is a crystalline powder, insoluble in absolute alcohol; its aqueous solution gives no colour-reaction with ferric chloride. The *monosulphate* crystallises on evaporation of its ethereal solution in shining laminæ easily soluble in water; its aqueous solution gives a violet coloration with ferric chloride (*E. Baumann, Ber.* xi. 1907).

PYROCHLORE. On a variety of pyrochlore from the limestones of the Kaiserstuhl-range. see KOPPE (p. 1158).

PYROCHROÏTE, MnH^2O^2 . This mineral occurs, together with manganosite, in a porous limestone rock in the Mossgrube, Wermland, Sweden (*Sjögren, Jahrb. f. Min.* 1877, 538).

PYROCINCHONIC ACID, $C^{10}H^8O^3$. Weidel obtained this acid by the dry distillation of cinchonic acid (p. 485), and assigned to it the formula $C^{10}H^{10}O^3$. Subsequent experiments have, however, shown that the formulæ originally assigned to this acid, and to cinchonic and cinchomeronic acids, were incorrect, and that the true reactions between these acids are represented by the formulæ:

Pyrocinchonic acid crystallises in pearly rhombic plates, has a sweet taste and alkaline reaction, melts at 90° , boils at 214° (uncorr.) Its vapour-density by experiment is 4.16; by calculation for $C^8H^6O^3$, 4.35 (Weidel a. von Schmidt, *Ber.* xii. 1146).

PYROCITRIC ACID. See CITRIC ACID (pp. 511–518).

PYROGALLOL, $C^6H^3(OH)^3$. *Pyrogallic acid. Oxidation.*—When a solution of pyrogallol, mixed with sodium phosphate, is exposed to the air, carbon dioxide is evolved, and pyrogalloquinone, $C^6H^4O^3$, is formed, identical with that which Wichelhaus obtained by dissolving quinone in pyrogallol (vii. 1030). This compound may be separated by ether from two other bodies formed in the reaction, one of these (an acid) being taken up by ether only after the mixture has been acidulated, and the other being nearly insoluble therein. An action similar to that of the phosphate, but less energetic, is exerted by the alkali-salts of weak acids, such as acetic and boric acids. Sodium thiosulphate effects rapid oxidation, but only as a carrier of oxygen; ammonium sulphate, magnesium sulphate, and potassium iodide exert but a feeble action; the chlorides, nitrates, and sulphates of potassium and sodium none at all.

On the oxidation of pyrogallol by *ozone*, see vii. 1029, 1030.

Pyrogallol absorbs *nitrogen dioxide* and *cyanogen*, forming with the latter the compound $C^6H^3O^3.CN$, which decomposes gradually at ordinary temperatures, and more quickly at 100° , yielding a brown-red resinous residue, soluble in alcohol, and sublimable in needles probably consisting of pyrogallol.

Reaction with Alkalis and Alkaloids.—Water containing an alkaline carbonate or an acid carbonate of calcium or magnesium gives in a few minutes, after addition of pyrogallol, a copious black precipitate. Alkaloids form with pyrogallol more or less brown solutions which give a black precipitate with *mercuric chloride*. A solution of mercuric chloride and pyrogallol in alcohol may therefore be used as a test for distinguishing plant-bases from glucosides, bitter principles, &c., more or less resembling them. A solution of 0.5 grm. pyrogallol in 5 c.c. water and 5 c.c. alcohol, mixed with 0.0001 grm. *ferric chloride*, colours crystals of organic bases blue, whereas glucosides are not altered by it. Similar results are obtained with a solution of pyrogallol and *cupric chloride* (Schlagdenhauffen, *Pharm. J. Trans.* [3], iv. 772).

On the reaction of Pyrogallol with *Iron salts*, see vii. 1029.

Reaction with Picric Acid and Potassium Cyanide.—On mixing very strong solutions of pyrogallol (5 grms.), picric acid (10 g.), and potassium cyanide (20 g.), a salt is formed very much like potassium isopurpurate, but apparently less disposed to crystallise. Acids throw down from this solution a purple precipitate; copper, calcium, and barium salts a purple red or leather-coloured precipitate. Stannic chloride produces a light crimson coloration. Ferrous sulphate forms with the solution of this salt a red liquid which, on exposure to the air, deposits a dirty-green precipitate. The solution of the salt decomposes slowly on standing, more quickly at the boiling heat, with separation of a purple precipitate nearly insoluble in water and in cold alcohol. Potassium ferricyanide, added to the solution of the salt, throws down green flocks which dissolve, with apparent decomposition, when washed with water, and dissolve with green colour in alcohol (*J. Walz, Amer. Chem.* 1874, iv. 214).

Reaction with Nitrogen Dioxide.—According to Russell a. Lapraik (*Chem. Soc. J.* xxxii. 35), a solution of potassium-pyrogallol absorbs 58 to 59 vol. p. c. of nitrogen dioxide when left in contact with it for twelve to fifteen hours. A solution of the same salt, saturated with oxygen, absorbs 76 per cent. Solution of potassium hydroxide absorbs 75 to 77 per cent. of the dioxide. Pyrogallol produces no alteration either in dioxide or monoxide of nitrogen. Potassium-pyrogallol does not act on the monoxide.

On the action of Bromine in presence of Water on Tribromopyrogallol, see vii. 1031; also XANTHOGALLOL in this volume.

Pyrogallic Ethers.

Dimethyl Pyrogallate, $C^6H^3(OH)(OCH^3)^2$ (A. W. Hofmann, *Ber.* xi. 333). This ether occurs in beech-tar oil, and is the constituent from which cedrret or cœrulignone (i. 818; vii. 376; viii. 548) is produced. To isolate it, the portion of beech-tar oil which boils at 250° – 270° was treated with benzoyl chloride, and the crystalline product (m. p. 107° – 110°) thereby obtained was decomposed by an alkali. The oil thus obtained, boiling between 250° and 265° , yielded on cooling splendid white prisms of dimethyl pyrogallate, melting at 51° – 52° , boiling constantly at 253° , and resolved by heating with hydrochloric acid into methyl chloride and pyrogallol. The ether may be prepared by heating for four or five hours at 150° – 160° , a mixture of 1 mol. pyrogallol, 2 mols. potassium hydroxide, and 2 mols. methyl iodide dissolved in methyl alcohol.

The conversion of the dimethyl pyrogallate into cedrret may be effected by various oxidising agents, viz. chlorine, bromine, iodine, nitric acid, ferric chloride, potassium ferricyanide, but not by atmospheric oxygen or ozone, and it succeeds best with potassium dichromate in glacial acetic acid, or by adding hydrochloric acid to a hot solution of the ether in soda-ley mixed with potassium dichromate. It appears most probable that an intermediate product, not yet isolated, is formed in the first instance, and then converted by further oxidation into cedrret or cœrulignone,

Ethyl Pyrogallates and the Cedrret of the Ethyl Series (Benedikt, *Ber.* ix. 125; Hofmann, *Ber.* xi. 797). Benedikt finds that pyrogallol cannot be ethylised by means of ethyl iodide, even when an alcoholic solution of the two bodies is heated in a sealed tube at 120° . The mono- and di-ethyl ethers may, however, be prepared, both from pyrogallol and from tannin, by the method adopted by Gorup-Besanez for the preparation of guaiacol (ii. 653). For this purpose the requisite quantities of potassium hydroxide and potassium ethylsulphate are introduced into a champagne or soda-water bottle, and 30 grams of pyrogallol and about 300 c.c. of absolute alcohol are added. The bottle is then tightly closed, and heated for twenty-four hours in a water-bath. When the action is over, the product is supersaturated with sulphuric acid, and shaken with ether; the ether is then removed by distillation; the thick oil which remains is washed with water and distilled; and the distillate, which is a mixture of the solid mono- and the liquid di-ethyl ether, is separated into its two constituents by pipetting. Hofmann, by proceeding in a similar manner, using 1 mol. pyrogallol, 3 mols. potassium hydroxide, and 3 mols. potassium ethylsulphate, has obtained all the three ethylic ethers of pyrogallol. To separate them from the crude product, the alkaline liquid is saturated with hydrochloric acid, the alcohol then removed by distillation in the water-bath, and the dry strongly coloured residue well shaken with ether, which, on evaporation, leaves a dark brown oil having a strong odour of beech-tar. This oil may be freed from unaltered pyrogallol by washing with an equal volume of water, and then treated with soda-ley, whereupon the mono- and di-ethyl ethers dissolve, while the triethyl ether remains undissolved. If the mixture of the three ethers be treated with an insufficient quantity of soda-ley, only the monethyl ether passes into solution.

Monethyl Pyrogallate, $C^6H^3(OH)(OC^2H^5)$, forms crystals melting at 95° , very easily soluble in alcohol and ether, sparingly soluble in cold, more freely in hot water. It crystallises from alcohol in hard needles, from water in small slender needles; volatilises with vapour of water (Benedikt).

Diethyl Pyrogallate, $C^6H^3(OH)(OC^2H^5)^2$, was described by Benedikt as a liquid which did not solidify at -10° , volatilised with vapour of water, and resembled the monethyl ether in its relations to solvents. According to Hofmann, however, it separates from very dilute alcohol in crystals which melt at 79° . When dissolved in glacial acetic acid, and treated with potassium dichromate, it is converted into ethylcedrret, or rather the cedrret of the ethyl-series:

This compound is insoluble in water and in ether, soluble in alcohol, and crystallises in long thin crimson needles, which have a bluish-green shimmer like that of cantharides, become light red when dried or pulverised, and dissolve with cornflower-blue colour in strong sulphuric acid. *Hydroethylcedrret* or *Tetretoxy-dihydroxydiphenyl*,

(OH)(OC²H⁵)²C⁶H²—C⁶H²(OC²H⁵)²(OH), formed by the action of sulphurous acid on ethyl-cedriret, melts with decomposition at 176°, is insoluble in water, easily soluble in ether, and is converted by oxidising agents into cedriret.

Triethyl Pyrogallate, C⁶H²(OC²H⁵)³, crystallises in long needles melting at 39°, resembles the two preceding in most of its physical characters, but is not dissolved by soda-ley (Hofmann).

Ethylene Pyrogallate, C⁸H⁸O³ = C⁶H²(OH) < O > C⁶H⁴ (Magatti, *Ber.* xii. 1860),

is prepared by heating 2 mols. pyrogallol, 3 mols. ethylene bromide, and 6 mols. potash with ethyl alcohol at 100° for fifteen to twenty hours; and may be separated from the product by acidifying with hydrochloric acid and extracting with ether. The ethereal extract yielding it on rectification as a colourless, heavy, strongly refractive liquid having a burning taste, and the odour of beech-wood tar; it boils at 267°. It resembles the phenols in its properties, forming crystalline compounds with alkalis, benzoic chloride, and bromine. The *benzoyl compound*, C⁹H⁷O⁴(OC⁷H⁵O), is a white crystalline substance, easily soluble in boiling alcohol and ether, melting at 109°. The bromo-compound crystallises from glacial acetic acid in transparent tables melting at 67°.

Monethylene pyrogallate is easily oxidised by ferric chloride and potassium dichromate; but the oxidation-product is apparently not uniform in composition. It is not dissolved but blackened by sulphuric acid, and therefore differs from the class of compounds to which cedriret belongs.

Simultaneously with the ethylene pyrogallate there is formed a compound which is insoluble in alkalis, soluble in alcohol and ether, separates from the former in ill-defined crystals melting at 83°, and apparently having the composition C¹⁰H¹¹O³Br.

Methyl-pyrogallol, C⁷H⁵O³ = C⁶H²(OH²)(OH)². The dimethylic ether of this phenol is obtained, together with those of pyrogallol and propyl-pyrogallol, by treating the crude mixture of pyrogallic ether extracted from beech-wood tar (p. 1710) with benzoic chloride. The resulting benzoyl-compounds are separated by fractional crystallisation; that of methyl-pyrogallol melts at 118°–119°, and is resolved by potash into benzoic acid and *dimethylic methylpyrogallate*, C⁸H²(CH³)(OH)(OCH³)², which melts at 36° and boils at 265°. This ether, heated at 150°–160° with strong hydrochloric acid, yields methyl chloride and methyl-pyrogallol, which is soluble in water, melts at 129°, and volatilises unchanged. It bears a strong resemblance to pyrogallol, its alkaline solution turning brown on exposure to the air (Hofmann, *Ber.* xii. 1371).

Propyl-pyrogallol, C⁹H¹²O³ = C⁶H²(C³H⁷)(OH)². The dimethylic ether of this compound, C¹¹H¹⁴O³ = C⁶H²(C³H⁷)(OH)(OCH³)², constitutes the portion of beech-tar oil which boils at 285°. Treated with acetic anhydride, it yields an acetyl-derivative, C¹¹H¹²(C²H³O)², which melts at 87°, is insoluble in water, crystallises from alcohol in white prisms, forms with bromine a dibromo-derivative, C¹¹H¹⁰Br²(C²H³O)², melting at 101·5°–102·5°, and with benzoyl chloride a benzoyl-derivative melting at 91°.

By heating the oil or its acetyl-derivative with strong hydrochloric acid at 130° in a sealed tube, methyl chloride is produced, together with propyl-pyrogallol, which dissolves easily in water, alcohol, and ether, and crystallises in prisms melting at 79°–80° (Hofmann, *Ber.* xi. 329).

Colouring Matters from Pyrogallic Ethers. The formation of cedriret from dimethylic pyrogallate has already been mentioned, and further experiments have shown that pittacal, the blue colouring matter which Reichenbach obtained from the high-boiling portions of wood-tar, belongs to the same class of bodies. The process by which Reichenbach prepared this body is not known, but Grätzel, in Hanover, by subjecting the higher-boiling portions of wood-tar to a peculiar process of oxidation (not yet published), has obtained a brown earthy substance which gives with baryta the blue reaction described by Reichenbach. This brown substance has been examined by Liebermann (*Ber.* ix. 334), who finds that the colouring matter, which is present in small quantity only, may be isolated by digesting the brown substance with hot acetic acid, mixing the filtered solution with excess of neutral lead acetate, treating the resulting precipitate with hydrogen sulphide, and exhausting the washed lead sulphide with warm alcohol, which dissolves the colouring matter, and leaves it on evaporation as an orange-red crystalline powder.

The colouring matter is soluble in alcohol and acetic acid, forming brown solutions. Alkalis dissolve it with purple, ammonia with blue colour, forming solutions from which carbon dioxide throws down blue salts soluble in pure water. In the alkaline solutions calcium, magnesium, barium, and tin salts produce blue precipitates, often

having a beautiful golden lustre. The calcium and magnesium precipitates are soluble in pure water. Hydrochloric and strong sulphuric acids dissolve the substance with red colour: the latter solution turns pure blue on warming. The pure orange-coloured substance acquires a deep golden lustre when moistened with strong mineral acids. In acid solution it dyes animal fibres orange; in ammoniacal solution, especially with tin mordant, blue-violet. The substance is free from nitrogen, and contains, as shown by three concordant analyses, 63.6 per cent. carbon, and 5.6 per cent. hydrogen. Liebermann calls it eupittone, and regards it at least closely allied to Reichenbach's pittacal.
